Additionally, vertical antennas occupy a relatively small amount of space, making them ideal for city-lot property and apartment buildings. The principal limitation in performance is the omnidirectional pattern. This means that QRM can't be nulled out from the directions that are not of interest at a given period. The exception is, of course, when arrays of vertical elements are used. Despite the limitation of a single vertical element with a ground screen or radial system, cost versus performance is an incentive that inspires many antenna builders.

For use on the lower frequency amateur bands — notably 160 and 80 meters — it is not always practical to erect a full-size vertical. In such instances it is satisfactory to accept a shorter radiating element and employ some form of loading to obtain an electrical length of one's choice. Most constructors design a system that contains a  $\frac{1}{4}$ -wavelength driven element. However, good results and lower radiation angles are sometimes realized when using a  $\frac{3}{8}$ - or  $\frac{1}{2}$ -wavelength vertical. At the lower amateur frequencies the larger verticals become prohibitive, especially in urban areas where zoning ordinances may exist, and where limited acreage may rule out the installation of guy-wire systems.

Fig. 25 provides curves for the physical height of verticals in wavelength versus radiation resistance and reactance. The plots are based on perfectly conducting ground, a condition seldom realized in practical installations. It can be seen that the shorter the radiator, the lower the radiation resistance — with 6 ohms being typical for a 0.1-wavelength antenna. The lower the radiation resistance, the more the antenna efficiency depends on ground conductivity. Also, the bandwidth decreases markedly as the length is reduced toward the left of the scale in Fig. 25. Difficulty is also experienced in developing a suitable matching network when the radiation resistance is very low.

Illustrations of various vertical-antenna radiation patterns are given in Fig. 26. The

example at A is for a quarter-wavelength radiator over a theoretically ideal ground. The dashed lines show the current distribution, including the image portion below ground. The image can be equated to one half of a dipole antenna, with the vertical radiator representing the remaining dipole half.

The illustration at B characterizes the pattern of a half-wavelength vertical. It can be seen that the radiation angle is somewhat lower than that of the quarter-wavelength version at A. The lower angles enhance the DX capability of the antenna. Two half wavelengths in phase are shown in Fig. 26 at C and D. From a practical point of view, few amateurs could erect such an antenna unless it was built for use on the higher HF bands, such as 20, 15 or 10 meters. The very low radiation angle is excellent for DXing, however.

### Full-Size Vertical Antennas

When it is practical to erect a full-size vertical antenna, the forms shown in Fig. 27 are worthy of consideration. The example at A is the well-known vertical ground plane. The ground system consists of four or more above-ground radial wires against which the driven element is worked. The length of the radials and the driven element is derived from the standard equation

$$L \text{ (feet)} = \frac{234}{f \text{ (MHz)}}$$

It has been established generally that with four equidistant radial wires drooped at approximately  $45^\circ$  (Fig. 27A) the feed-point impedance is roughly 50 ohms. When the radials are at right angles to the radiator (Fig. 27B) the impedance approaches 36 ohms. The major advantage in this type of vertical antenna over a ground-mounted type is that the system can be elevated well above nearby conductive objects (power lines, trees, buildings, etc.). When drooping radials are utilized they can be used as guy wires for the mast that supports the antenna. The coaxial cable shield braid is connected to the radials, and the center conductor is common to the driven element.

The Marconi antenna shown in Fig. 27C is the classic form taken by a ground-mounted vertical. It can be grounded at the base and shunt fed, or it can be isolated from ground, as shown, and series fed. This antenna depends on an effective ground system for efficient performance. The subject of ground screens is treated later in this chapter. If a perfect ground were located below the antenna, the feed impedance would be near 36 ohms. In a practical case, owing to imperfect ground, the impedance is more apt to be in the vicinity of 50 to 75 ohms.

A gamma feed system for a grounded  $\frac{1}{4}$ -wavelength vertical is presented in Fig. 27D. Some rules of thumb for arriving at workable gamma-arm and capacitor di-

Fig. 26 — Elevation plane responses for a quarter-wavelength vertical antenna (A), a  $\frac{1}{2}$ -wavelength type (B) and two half waves in phase (C and D). It can be seen that the examples at B and D provide more radiated power at low radiation angles than the version at A.

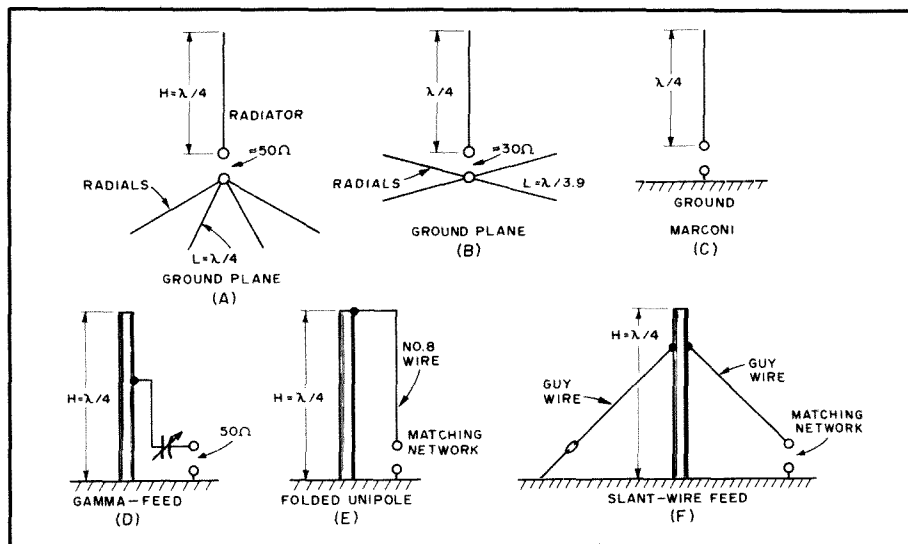

Fig. 27 — Various types of vertical antennas.

mensions are to make the rod length 0.04 to 0.05 wavelength, its diameter  $\frac{1}{3}$  to  $\frac{1}{2}$  that of the driven element and the center-to-center spacing between the gamma arm and the driven element roughly 0.007 wavelength. The capacitance of C1 at a 50-ohm matched condition will be some 7 pF per meter. The absolute value at C1 will depend on whether the vertical is resonant and on the precise value of the radiation resistance. Generally, best results can be had when the radiator is approximately three percent shorter than the resonant length.

Amateur antenna towers lend themselves well to use as shunt-fed verticals, even though an HF band beam antenna may be mounted on the tower. The overall system should be close to resonance at the desired

operating frequency if gamma feed is to be used. The HF-band beam will contribute somewhat to top loading of the tower. The natural resonance of such a system can be checked by dropping a no. 12 or 14 wire down from the top of the tower (making it common to the tower top) to form a folded unipole (Fig. 27E). A four- or five-turn link can be inserted between the lower end of the drop wire and the ground system, then a dip meter inserted in the link to observe the resonant frequency. If the tower is equipped with guy wires, they should be broken up with strain insulators to prevent unwanted loading of the vertical. In such cases where the tower and beam antennas are not able to provide  $\frac{1}{4}$ -wavelength resonance, portions of the top guy wires can be used as top-loading capaci-

Fig. 28 — Vertical antennas that are less than one quarter wavelength in height.

tance. It will be necessary to experiment with the guy-wire lengths (using the dip-meter technique) while determining the proper dimensions.

A folded-unipole type of vertical is depicted at E of Fig. 27. This system has the advantage of increased feed-point impedance. Furthermore, a Transmatch can be connected between the bottom of the drop wire and the ground system to permit operation on more than one band. For example, if the tower is resonant on 80 meters, it can be used as shown on 160 and 40 meters with reasonable results, even though it is not electrically long enough on 160. The drop wire need not be a specific distance from the tower, but spacings between 12 and 30 inches are suggested.

The method of feed shown at Fig. 27F is commonly referred to as "slant-wire feed." The guy wires and the tower combine to provide quarter-wave resonance. A matching network is placed between the lower end of one guy wire and ground and adjusted for an SWR of 1. It does not matter at which level on the tower the guy wires are connected, assuming that

Fig. 29 — At A are the details for the tubing section of the loading assembly. Illustration B shows the top hat and its spokes. The longer the spokes, the better.

the Transmatch is capable of effecting a match to 50 ohms.

### Physically Short Verticals

A group of short vertical radiators is presented in Fig. 28. Illustrations A and B are for top and center loading. A capacitance hat is shown in each example. The hat should be as large as practical to increase the radiation resistance of the antenna and improve the bandwidth. The wire in the loading coil is chosen for the largest gauge consistent with ease of winding and coil-form size. The larger wire diameters will reduce the  $I^2R$  losses in the system. The coil-form material should be of the medium or high dielectric type. Phenolic or fiberglass tubing is entirely adequate.

A base-loaded vertical is shown at C of Fig. 28. Since this is the least effective method of loading in terms of antenna performance, it should be used only as a last choice. The primary limitation is that the current portion of the vertical exists in the coil rather than the driven element. With center loading the portion of the antenna below the coil carries current, and with the top loading version the entire vertical element carries current. Since the current part of the antenna is responsible for most of the radiating, base loading is the least effective of the three methods. The radiation resistance of the coil-loaded antennas shown is usually less than 16 ohms.

A method for using guy wires to top load a short vertical is illustrated in Fig. 28 at D. This system works well with gamma feed. The loading wires are trimmed to provide an electrical quarter wavelength for the overall system. This method of loading will result in a higher radiation resistance and greater bandwidth than the systems shown at A through C of Fig. 28. If any HF band or VHF array is atop the tower, it will simply contribute to the top loading.

A tri-wire unipole is shown at E of Fig.

28. Two no. 8 drop wires are connected to the top of the tower and brought to ground level. The wires can be spaced any convenient distance from the tower — normally 12 to 30 inches from one side. C1 is adjusted for an SWR of 1. This type of vertical has a fairly narrow bandwidth, but because C1 can be motor driven and controlled from the operating position, QSY-ing is accomplished easily. This technique will not be suitable for matching to 50-ohm line unless the tower is less than an electrical quarter wavelength high.

A different method for top loading is shown at F of Fig. 28. W9UCW described this system in "The Minooka Special," December 1974 *QST*. An extension is used at the top of the tower to effect an electrical quarter-wavelength vertical. L1 is a loading coil with sufficient inductance to provide antenna resonance. This type of antenna lends itself nicely to operation on 160 meters.

A method for effecting the top-loading shown in Fig. 28F is illustrated in the drawing of Fig. 29. Pipe section D is mated with the mast above the HF-beam antenna. A loading coil is wound on solid Plexiglas rod or phenolic rod (item C), then clamped inside the collet (B). An aluminum slug (part A) is clamped inside item B. The top part of A is bored and threaded for a 3/8 inch x 24 thread stud. This will permit a standard 8-foot stainless-steel mobile whip to be threaded into item A above the loading coil. The capacitance hat (Fig. 29B) can be made from a 1/4-inch-thick brass or aluminum plate. It may be round or square. Lengths of 1/8-inch brazing rod can be threaded for a 6-32 format to permit the rods to be screwed into the edge of the aluminum plate. The plate contains a row of holes along its perimeter, each having been tapped for a 6-32 thread. The capacitance hat is affixed to item A by means of the 8-foot whip antenna. The

whip will increase the effective height of the vertical antenna.

### Cables and Control Wires on Towers

Most vertical antennas of the type shown in Fig. 28 consist of towers and HF or VHF beam antennas. The rotator control wires and the coaxial feeders to the top of the tower will not affect antenna performance adversely. In fact, they become a part of the composite antenna. To prevent unwanted rf currents from following the wires into the shack, simply dress them close to the tower legs and bring them to ground level. This decouples the wires at RF. The wires should then be routed along the earth surface (or buried underground) to the operating position. It is not necessary to use bypass capacitors or RF chokes in the rotator control leads if this is done, even when maximum legal power is employed.

### Variations in Verticals

A number of configurations qualify for use as vertical antennas even though the radiators are fashioned from lengths of wire. Fig. 30A shows a flat-top T vertical. Dimension H should be as tall as possible for best results. The horizontal section, L, is adjusted to a length which provides resonance. Maximum radiation is polarized vertically despite the horizontal top-loading wire. A variation of the T antenna is depicted at B of Fig. 30. This antenna is commonly referred to as an inverted L. Vertical member H should be as long as possible. L is added to provide an electrical quarter wavelength overall. Some amateurs believe that a 3/8-wavelength version of this antenna is more effective, since the current portion of the wire is elevated higher above ground than is the case with a quarter-wavelength wire.

### Half-Sloper Antenna

A basic-half sloper antenna is shown at C of Fig. 30. The wire portion represents one half of a dipole. The feed point is between the tower leg and the upper end of the slope wire, with the coax shield braid being connected to the tower. The feed-point impedance is generally between 30 and 60 ohms, depending on the length of the wire, the tower height and the enclosed angle between the slope wire and the tower. The tower constitutes a portion of this antenna, and will have a voltage maximum somewhere between the feed point and ground. The half sloper has been found useful for close-in work as well as for DXing. A VSWR as low as 1.5:1 can be obtained (using 50-ohm coax feed line) with the system of Fig. 30C by experimenting with the slope-wire length and the enclosed angle. This assumes there are no guy wires that are common to the tower. If guys are used they should be insulated from the tower and broken into nonresonant lengths for the band of operation.

Many amateurs are likely to have towers that support HF-band Yagis or quad

beams. The conductors situated above the sloper feed point have a marked effect on the tuning of the sloper system. The beam antenna becomes a portion of the overall tower/sloper system. Although the presence of the beam seems to have no appreciable effect on the radiation pattern of the sloper, it does greatly affect the VSWR. If a low VSWR can't be obtained for a given amateur antenna installation, the system illustrated in Fig. 30D can be applied.

The sloper is erected in the usual manner, but a second wire (L2) is added. It is connected to the tower at the antenna feed point, but insulated at the low end. L2 plus the tower constitutes the missing half of the dipole. This half is effectively a fanned element (similar to a conical element) and tends to increase the bandwidth of the sloper system over that which can be obtained with the version at C. The "compensating wire" (L2) is spaced approximately 90° from L1, and is roughly 30° away from the side of the tower. The VSWR can be brought to a low value (usually 1:1) by varying the L2/tower and L1/L2 enclosed angles. The degree of these angles will depend on the tower height, the beam atop the tower and the ground condition below the system.

Tests indicate the sloper to be effective on its harmonics for DX and local work. If harmonic operation is planned, the 50-ohm coaxial feeder should be replaced with open-wire line, which is coupled to the transmitter by means of a Transmatch. With open-wire feed, the L2 compensating wire of Fig. 30D will not be necessary.

Best performance will be had when the base of the tower is well grounded. Buried radials are highly recommended as part of the ground system. Operation on 160 meters can be had by feeding the low end of L2. The bandwidth of the system in Fig. 30 will be approximately 50 kHz on 160 meters, 100 kHz on 80 meters, 200 kHz on 40 meters, and so on, between 2:1 VSWR points.

### Ground Systems

The importance of an effective ground system for vertical antennas cannot be emphasized too strongly. However, it is not always possible to install a radial network that approaches the ideal. A poor ground is better than no ground at all, and therefore the amateur should experiment with whatever is physically possible rather than ruling out vertical antennas. It is often possible to obtain excellent DX results with practically no ground system at all.

Although the matter of less-than-optimum ground systems could be debated almost endlessly, some practical rules of thumb are in order for those wishing to erect vertical antennas. Generally a large number of shorter radials offers a better ground system than a few longer ones. For example, 8 radials of  $1/8 \lambda$  are preferred over 4 radials of  $1/4 \lambda$ . If the physical height

Fig. 30 — Some variations in vertical antennas that offer excellent performance.

of the vertical is an eighth wavelength, the radial wires should be of the same length and dispersed uniformly from the base of the tower.

The conductor size of the radials is not especially significant. Wire gauges from no. 4 to no. 20 have been used successfully by amateurs. Copper wire is preferred, but where soil is low in acid or alkali, aluminum wire can be used. The wires can be bare or insulated, and they can be laid on the earth's surface or buried a few inches below ground. The insulated wires will have greater longevity by virtue of reduced corrosion and dissolution from soil chemicals.

If time and expense are not prime considerations, the amateur should bury as much ground wire as possible. Some operators have literally miles of wire buried radially beneath their vertical antennas.

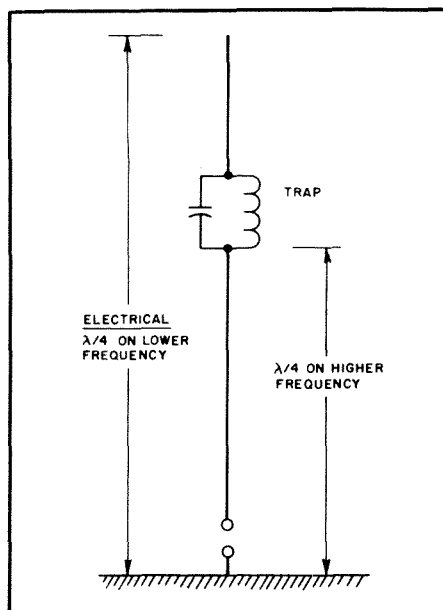

Fig. 31 — A two-band trap vertical antenna. The trap should be resonated as a parallel resonant circuit at the center of the operating range for the higher frequency band; typical component reactances range from 100 to 300 ohms. At the lower frequency the trap will act as a loading inductor, adding electrical length to the total antenna.

When property dimensions do not allow a classic installation of equally spaced radial wires, they can be placed in the ground wherever space will permit. They may run away from the antenna in only one or two compass directions. Results will still exceed those of when no ground system is used.

A single ground rod, or group of them bonded together, is seldom as effective as a collection of random-length radial wires. In some instances a group of short radial wires can be used in combination with ground rods driven into the soil near the base of the antenna. Bear in mind, though, that RF currents at MF and HF seldom penetrate the earth more than several inches. The power company ground can be tied in, and if a metal fence skirts the property it can also be used as part of the ground system. A good rule is to use anything that will serve as a ground when developing a radial ground system.

All radial wires must be connected together at the base of the vertical antenna. The electrical bond needs to be of low resistance. Best results will be obtained when the wires are soldered together at the junction point. When a grounded vertical is used, the ground wires should be affixed securely to the base of the driven element. A lawn edging tool is excellent for cutting slits in the soil when laying radial wires.

#### Trap Verticals

Although a full-size, single-band antenna is more effective than a lumped-constant one, there is justification for using trap

types of multiband antennas. The concept is especially useful to operators who have limited antenna space on their property. Multiband compromise antennas are also appealing to persons who engage in portable operation and are unwilling to transport large amounts of antenna hardware to the field.

The 2-band trap vertical antenna of Fig. 31 operates in much the same manner as a trap dipole or trap-style Yagi. The notable difference is that the vertical is one half of a dipole. The radial system (in-ground or above ground) functions as a ground plane for the antenna, and represents the missing half of the dipole. Therefore, the more effective the ground system, the better the antenna performance.

Trap verticals are adjusted as quarter-wavelength radiators. The portion of the antenna below the trap is adjusted as a quarter-wavelength radiator at the higher proposed operating frequency. That is, a 20/15-meter trap vertical would be a resonant quarter wavelength at 15 meters from the feed point to the bottom of the trap. The trap and that portion of the antenna above the trap (plus the 15-meter section below the trap) constitute the complete antenna during 20-meter operation. But because the trap is in the circuit, the overall physical length of the vertical antenna will be slightly less than that of a single-band, full-size 20-meter vertical.

#### Traps

The trap functions as the name implies: It traps the 15-meter energy and confines it to the part of the antenna below the trap. During 20-meter operation it allows the RF energy to reach all of the antenna. Therefore, the trap in this example should be tuned as a parallel resonant circuit to 21 MHz. At this frequency it divorces the top section of the vertical from the lower section because it presents a high-impedance (barrier) at 21 MHz. Generally, the trap inductor and capacitor have a reactance of 100 to 300 ohms. Within that range it is not critical.

The trap is built and adjusted separately from the antenna. It should be resonated at the center of the portion of the band to be operated. Thus, if one's favorite part of the 15-meter band is between 21,000 and 21,100 kHz, the trap would be tuned to 21,050 kHz.

Resonance is checked by using a dip meter and detecting the dipper signal in a calibrated receiver. Once the trap is adjusted it can be installed in the antenna, and no further adjustment will be required. It is easy, however, to be misled after the system is assembled: Attempts to check the trap with a dip meter will suggest that the trap has moved much lower in frequency (approximately 5 MHz lower in a 20/15-meter vertical). This is because the trap has become absorbed into the overall antenna, and the resultant resonance is that

of the total antenna. Ignore this phenomenon.

Multiband operation for three or four bands is quite practical by using the appropriate number of traps and tubing sections. The construction and adjustment procedure is the same, regardless of the number of bands covered. The highest frequency trap is always closest to the feed end of the antenna, and the next to lowest frequency trap is always the farthest from the feed point. As the operating frequency is progressively lowered, more traps and more tubing sections become a functional part of the antenna.

The trap should be weatherproofed to prevent moisture from detuning it. Several coatings of high dielectric compound, such as Polystyrene Q Dope, are effective. Alternatively, a protective sleeve of heat-shrink tubing can be applied to the coil after completion. The coil form for the trap should be of high dielectric quality and be rugged enough to sustain stress during periods of wind.

The trap capacitor must be capable of withstanding the RF voltage developed across it. The amount of voltage present will depend on the operating power of the transmitter. Fixed-value ceramic transmitting capacitors are suitable for most power levels if they are rated at 5000 to 10,000 volts. A length of RG-58/U or RG-59/U coax cable can be used successfully up to 200 watts. (Check to see how many picofarads per foot your cable is rated at before cutting it for the trap.) RG-8/U or RG-11/U cable is recommended for the trap capacitor at powers in excess of 200 watts. The advantage of using coax cable is that it can be trimmed easily to adjust the trap capacitance.

Large-diameter copper magnet wire is suggested for the trap coil. The heavier the wire gauge the lower the trap losses and the higher the Q. The larger wire sizes will reduce coil heating.

#### YAGI AND QUAD DIRECTIVE ANTENNAS

Most of the antennas described earlier in this chapter have unity gain or just slightly more. For the purpose of obtaining gain and directivity it is convenient to use the Yagi-Uda or cubical quad types of HF-band beam antennas. The former is commonly called a Yagi and the latter is referred to as a quad in the amateur vernacular.

Most operators prefer to erect these antennas for horizontal polarization, but they can be used as vertically polarized arrays as well merely by rotating the elements by 90°. In effect, the beam antenna is turned on its side for vertical polarity. The number of elements employed will depend on the gain desired and the capability of the supporting structure to contain the array safely. Many amateurs obtain satisfactory results with only two elements in a beam antenna, while others have several

Fig. 32 — Elevation-plane response of a three-element Yagi placed  $\frac{1}{2}$  wavelength above a perfect ground (A) and the same antenna spaced one wavelength above ground (B). Pattern calculations courtesy of "Annie." <sup>2</sup>

elements operating for a single amateur band.

Regardless of the number of elements used, the height-above-ground considerations discussed earlier for dipole antennas remain valid with respect to the angle of radiation. This is demonstrated in Fig. 32 at A and B where a comparison of radiation characteristics is given for a three-element Yagi at one-half and one wavelength above a perfectly conducting ground. It can be seen that the higher antennas (Fig. 32B) has a lobe that is more favorable for DX work (roughly  $15^\circ$ ) than the larger lobe of Fig. 32A (approximately  $30^\circ$ ). The pattern at B shows that some useful high-angle radiation exists also, and the higher lobe is suitable for short-skip contacts when propagation conditions dictate the need.

A free-space azimuth pattern for the same antenna is provided in Fig. 33. The back-lobe pattern reveals that most of the power is concentrated in the forward lobe. The power difference dictates the front-to-back ratio in decibels. It is infrequent that two 3-element Yagis with different element spacings will yield the same lobe patterns. The pattern of Fig. 33 is shown only for illustrative purposes.

### Parasitic Excitation

In most of these arrangements the additional elements receive power by induction or radiation from the driven element and reradiate it in the proper phase relationship to give the desired effect. These elements are called parasitic elements, as contrasted to the driven elements, which receive power directly from the transmitter through the transmission line.

The parasitic element is called a director when it reinforces radiation on a line

pointing to it from the driven element, and a reflector when the reverse is the case. Whether the parasitic element is a director or reflector depends on the parasitic-element tuning, which usually is adjusted by changing its length.

### Gain vs. Spacing

The gain of an antenna with parasitic elements varies with the spacing and tuning of the elements. Thus, for any given spacing, there is a tuning condition that will give maximum gain at this spacing. The maximum front-to-back ratio seldom, if ever, occurs at the same condition that gives maximum forward gain. The impedance of the driven element also varies with the tuning and spacing, and thus the antenna system must be tuned to its final condition before the match between the line and the antenna can be completed. The tuning and matching may interact to some extent, however, and it is usually necessary to run through the adjustments several times to ensure that the best possible tuning has been obtained.

### Two-Element Beams

A two-element beam is useful where space or other considerations prevent the use of the larger structure required for a three-element beam. The general practice is to tune the parasitic element as a reflector and space it about 0.15 wavelength from the driven element, although some successful antennas have been built with 0.1-wavelength spacing and director tuning. Gain vs. element spacing for a two-element antenna is given in Fig. 34 for the special case where the parasitic element is resonant. It is indicative of the performance to be expected under maximum-gain tuning conditions.

### Three-Element Beams

A theoretical investigation of the three-element case (director, driven element and reflector) has indicated a maximum gain of slightly more than 7 dB. A number of experimental investigations has shown that the optimum spacing between the driven element and reflector is in the region of 0.15 to 0.25 wavelength, with 0.2 wavelength representing probably the best overall choice. With 0.2-wavelength reflec-

Fig. 33 — Azimuth-plane pattern of a three-element Yagi in free space. Pattern calculation courtesy of "Annie."

Fig. 34 — Gain vs. element spacing for an antenna and one parasitic element. The reference point, 0 dB, is the field strength from a half-wave antenna alone. The greatest gain is in the direction A at spacings of less than 0.14 wavelength, and in direction B at greater spacings. The front-to-back ratio is the difference in decibels between curves A and B. Variation in radiation resistance of the driven element is also shown. These curves are for a self-resonant parasitic element. At most spacings the gain as a reflector can be increased by slight lengthening of the parasitic element; the gain as a director can be increased by shortening. This also improves the front-to-back ratio.

tor spacing, Fig. 35 shows that the gain variation with director spacing is not especially critical. Also, the overall length of the array (boom length in the case of a

Fig. 35 — General relationship of gain of three-element Yagi versus director spacing, the reflector being fixed at 0.2 wavelength.

<sup>2</sup>See footnote 1 earlier in this chapter.

Fig. 36 — Element lengths for a three-element beam. These lengths will hold closely for the tubing elements supported at or near the center.

rotatable antenna) can be anywhere between 0.35 and 0.45 wavelength with no appreciable difference in gain.

Wide spacing of both elements is desirable not only because it results in high gain but also because adjustment of tuning or element length is less critical and the input resistance of the driven element is higher than with close spacing. A higher input resistance improves the efficiency of the antenna and makes a greater bandwidth possible. However, a total antenna length, director to reflector, of more than 0.3

wavelength at frequencies of the order of 14 MHz introduces considerable difficulty from a construction standpoint. Lengths of 0.25 to 0.3 wavelength are therefore used frequently for this band, even though they are less than optimum.

In general, the antenna gain drops off less rapidly when the reflector length is increased beyond the optimum value than it does for a corresponding decrease below the optimum value. The opposite is true of a director. It is therefore advisable to err, if necessary, on the long side for a reflector and on the short side for a director. This also tends to make the antenna performance less dependent on the exact frequency at which it is operated: An increase above the design frequency has the same effect as increasing the length of both parasitic elements, while a decrease in frequency has the same effect as shortening both elements. By making the director slightly short and the reflector slightly long, there will be a greater spread between the upper and lower frequencies at which the gain starts to show a rapid decrease.

When the overall length has been decided on, the element lengths can be found by referring to Fig. 36. The lengths determined by these charts will vary slightly in actual practice with the element diameter and the method of supporting the elements. The tuning of a beam should always be checked after installation. However, the lengths obtained by the use of the charts will be close to correct in practically all cases, and they can be used without checking if the beam is difficult to access.

Table 1 can be used to determine the lengths needed for 4-element Yagis. Both CW and phone lengths are included for the three bands, 20, 15 and 10 meters. The 0.2-wavelength spacing will provide greater bandwidth than the 0.15 spacing. Antenna gain is essentially the same with either spacing. The element lengths given will be the same whether the beam has two, three or four elements. It is recommended that plumbers delight type construction be used, where all the elements are mounted direct-

ly on and grounded to the boom. This puts the entire array at dc ground potential, affording better lightning protection. A gamma section can be used for matching the feed line to the array.

### Tuning Adjustments

The preferable method for checking the beam is by means of a field-strength meter, or the S meter of a communications receiver, used in conjunction with a dipole antenna located at least 10 wavelengths away and as high or higher than the beam that is being checked. A few watts of power fed into the antenna will give a useful signal at the observation point, and the power input to the transmitter should be held constant for all the readings.

Preliminary matching adjustments can be done on the ground. The beam should be set up so the reflector element rests on the earth, with the remaining elements in a vertical configuration. In other words, the beam should be aimed straight up. The matching system is then adjusted for a 1:1 SWR between the feed line and driven element. When the antenna is raised to its operating height, only slight touch-up of the matching network should be required.

A great deal has been printed about the need for tuning elements of a Yagi-type beam. However, experience has shown that for Yagi arrays made from metal tubing, the lengths given in Fig. 36 and Table 1 are close enough to the desired length that no further tuning should be required.

### Simple Systems — The Rotary Beam

Two- and three-element systems are popular for rotary-beam antennas, where the entire antenna system is rotated, to permit its gain and directivity to be utilized for any compass direction. The antennas may be mounted either horizontally (with the plane containing the elements parallel to the earth) or vertically.

A four-element beam will give still more gain than a three-element one, provided the support is sufficient for about 0.2 wavelength spacing between elements. The

tuning for maximum gain involves many variables, and complete gain and tuning data are elusive.

The elements in close-spaced arrays (less than  $\frac{1}{4}$ -wavelength element spacing) preferably should be made of tubing of  $\frac{1}{2}$  to 1 inch diameter. A conductor of large diameter not only has less ohmic resistance but also has lower Q; both these factors are important in close-spaced arrays because the impedance of the driven element usually is quite low compared to that of a simple dipole antenna. With three- and four-element close-spaced arrays the radiation resistance of the driven element may be so low that ohmic losses in the conductor can consume an appreciable fraction of the power.

### Feeding the Rotary Beam

Any of the usual methods of feed (described later under Impedance Matching) can be applied to the driven element of a rotary beam. The popular choices for feeding a beam are the gamma match with series capacitor, the T match with series capacitors, and a half-wavelength phasing section, as shown in Fig. 37. These methods are preferred over any others because they permit adjustment of the matching and the use of coaxial-line feed. The variable capacitors can be housed in small plastic cups for weatherproofing; receiving types with close spacing can be used at powers up to a few hundred watts. Maximum capacitance required is usually 140 pF at 14 MHz and proportionally less at the higher frequencies.

If physically possible, it is better to adjust the matching device after the antenna has been installed at its ultimate height, since a match made with the antenna near the ground may not hold for the same antenna in the air.

### Sharpness of Resonance

Peak performance of a multielement parasitic array depends on proper phasing or tuning of the elements, which can be exact for one frequency only. Close-spaced arrays usually are quite sharp-tuning because of the low radiation resistance. The frequency range over which optimum results can be obtained is only of the order of one or two percent of the resonant frequency, or up to about 500 kHz at 28 MHz. However, the antenna can be made to work satisfactorily over a wider frequency range by adjusting the director or directors to give maximum gain at the highest frequency to be covered, and by adjusting the reflector to give optimum gain at the lowest frequency. This sacrifices some gain at all frequencies but maintains more uniform gain over a wider frequency range.

The use of large-diameter conductors will broaden the response curve of an array, because a larger diameter lowers the Q. This causes the reactances of the elements to change rather slowly with frequency, with the result that the tuning stays near

Fig. 37 — Illustrations of gamma and T matching systems. At A, the gamma rod is adjusted along with C until the lowest SWR is obtained. A T match is shown at B. It is the same as two gamma-match rods. The rods and C1 and C2 are adjusted alternately for a 1:1 SWR. A coaxial 4:1 balun transformer is shown at C. A toroidal balun can be used in place of the coax model shown. The toroidal version has a broader frequency range than the coaxial one. The T match is adjusted for 200 ohms and the balun steps this balanced value down to 50 ohms, unbalanced. Or the T match can be set for 300 ohms, and the balun used to step this down to 75 ohms unbalanced. Dimensions for the gamma and T match rods are not given by formula. Their lengths and spacing will depend on the tubing size used, and the spacing of the parasitic elements of the beam. Capacitors C, C1 and C2 can be 140 pF for 14-MHz beams. Somewhat less capacitance will be needed at 21 and 28 MHz.

optimum over a considerably wider frequency range than with wire conductors.

### Delta Loops and Quad Beams

One of the more effective DX arrays is called the cubical quad, or simply, quad antenna. It consists of two or more square loops of wire, each supported by a bamboo or fiberglass cross-arm assembly. The loops are a quarter wavelength per side (full wavelength overall). One loop is driven and the other serves as a parasitic element — usually a reflector. A variation of the quad is called the delta loop. The electrical properties of both antennas are the same, generally speaking, though some operators report better DX results with the delta loop. Both antennas are shown in Fig. 38. They differ mainly in their physical properties,

Fig. 38 — Information on building a quad or a delta-loop antenna. The antennas are electrically similar, but the delta-loop uses plumber's delight construction.

one being of plumber's delight construction, while the other uses insulating support members. One or more directors can be added to either antenna if additional gain and directivity is desired, though most operators use the two-element arrangement.

It is possible to interlace quads or "deltas" for two or more bands, but if this is done the formulas given in Fig. 38 may have to be changed slightly to compensate for the proximity effect of the second antenna. For quads the length of the full-wave loop can be computed from

$$\text{Full-wave loop (ft)} = \frac{1005}{f(\text{MHz})}$$

If multiple arrays are used, each antenna should be tuned separately for maxi-

mum forward gain, as noted on a field-strength meter. The reflector stub on the quad should be adjusted for this condition. The delta loop gamma match should be adjusted for a 1:1 SWR. No reflector tuning is needed. The delta loop antenna has a broader frequency response than the quad, and holds at an SWR of 1.5:1 or better

across the band for which it is constructed.

The resonance of the quad antenna can be found by checking the frequency at which the lowest SWR occurs. The element length (driven element) can be adjusted for resonance in the most-used portion of the band by lengthening or shortening it.

A two-element quad or delta loop anten-

na compares favorably with a three-element Yagi array in terms of gain (see *QST*, May 1963 and January 1969, for additional information). The quad and delta-loop antennas perform very well at 50 and 144 MHz. A discussion of radiation patterns and gain, quads vs. Yagis, was presented by Lindsay in May 1968 *QST*.

## VHF and UHF Antennas

Improving an antenna system is one of the most productive moves open to the VHF enthusiast. It can increase transmitting range, improve reception, reduce interference problems and bring other practical benefits. The work itself is by no means the least attractive part of the job. Even with high-gain antennas, experimentation is greatly simplified at VHF and UHF because an array is a workable size, and much can be learned about the nature and adjustment of antennas. No large investment in test equipment is necessary.

Whether we buy or build our antennas, we soon find that there is no one "best" design for all purposes. Selecting the antenna best suited to our needs involves much more than scanning gain figures and prices in a manufacturer's catalog. The first step should be to establish priorities.

### Gain

Shaping the pattern of an antenna to concentrate radiated energy, or received-signal pickup, in some directions at the expense of others is the only possible way to develop gain. This is best explained by starting with the hypothetical isotropic antenna, which would radiate equally in all directions. A point source of light illuminating the inside of a globe uniformly, from its center, is a visual analogy. No practical antenna can do this, so all antennas have gain over isotropic (dBi). A half-wave dipole in free space has a gain of 2.1 dBi. If we can plot the radiation pattern of an antenna in all planes, we can compute its gain, so quoting it with respect to isotropic is a logical base for agreement and understanding. It is rarely possible to erect a half-wave antenna that has anything approaching a free-space pattern; this fact is responsible for much of the confusion about true antenna gain.

Radiation patterns can be controlled in various ways. One is to use two or more driven elements, fed in phase. Such collinear arrays provide gain without markedly sharpening the frequency response, compared to that of a single element. More gain per element, but with a sacrifice in frequency coverage, is obtained by placing parasitic elements, longer and shorter than the driven one, in the plane of the first element, but not driven from the feed line. The

reflector and directors of a Yagi array are highly frequency sensitive and such an antenna is at its best over frequency changes of less than one percent of the operating frequency.

### Frequency Response

Ability to work over an entire VHF band may be important in some type of work. The response of an antenna element can be broadened somewhat by increasing the conductor diameter, and by tapering it to something approximating a cigar shape, but this is done mainly with simple antennas. More practically, wide frequency coverage may be a reason to select a collinear array, rather than a Yagi. On the other hand, the growing tendency to channelize operations in small segments of our bands tends to place broad frequency coverage low on the priority list of most VHF stations.

### Radiation Pattern

Antenna radiation can be made omnidirectional, bidirectional, practically unidirectional, or anything between these conditions. A VHF net operator may find an omnidirectional system almost a necessity, but it may be a poor choice otherwise. Noise pickup and other interference problems tend to be greater with such antennas, and those having some gain are especially bad in these respects. Maximum gain and low radiation angle are usually prime interests of the weak-signal DX aspirant. A clean pattern, with lowest possible pickup and radiation off the sides and back, may be important in high-activity areas, or where the noise level is high.

### Height Gain

In general, the higher an antenna is installed, the better in VHF antenna installations. If raising the antenna clears its view over nearby obstructions, it may make dramatic improvements in coverage. Within reason, greater height is almost always worth its cost, but height gain must be balanced against increased transmission-line loss. Line losses are considerable at VHF, and they increase with frequency. The best available line may be none too good, if the run is long in terms of wavelength. Give line-loss information,

shown in table form in Chapter 16, close scrutiny in any antenna planning.

### Physical Size

A given antenna design for 432 MHz will have the same gain as one for 144 MHz, but being only one-third the size it will intercept only one-third as much energy in receiving. Thus, to be equal in communication effectiveness, the 432-MHz array should be at least equal in size to the 144-MHz one, which will require roughly three times as many elements. With all the extra difficulties involved in going higher in frequency, it is well to be on the big side in building an antenna for the higher bands.

### DESIGN FACTORS

Having sorted out objectives in a general way, we face decisions on specifics, such as polarization, type of transmission line, matching methods and mechanical design.

### Polarization

Whether to position the antenna elements vertically or horizontally has been a moot point since early VHF pioneering. Tests show little evidence on which to set up a uniform polarization policy. On long paths there is no consistent advantage, either way. Shorter paths tend to yield higher signal levels with horizontal in some kinds of terrain. Man-made noise, especially ignition interference, tends to be lower with horizontal. Verticals are markedly simpler to use in omnidirectional systems and in mobile work.

Early VHF communication was largely vertical, but horizontal gained favor when directional arrays became widely used. The major trend to FM and repeaters, particularly in the 144-MHz band, has tipped the balance in favor of verticals in mobile work and for repeaters. Horizontal predominates in other communication on 50 MHz and higher frequencies. It is well to check in advance in any new area in which you expect to operate, however, as some localities still use vertical almost exclusively. A circuit loss of 20 dB or more can be expected with cross-polarization.

### Transmission Lines

There are two main categories of

transmission lines, balanced and unbalanced. Balanced lines include open-wire lines separated by insulating spreaders, and twin-lead, in which the wires are embedded in solid or foamed insulation. Line losses result from ohmic resistance, radiation from the line and deficiencies in the insulation. Large conductors, closely spaced in terms of wavelength, and using a minimum of insulation, make the best balanced lines. Impedances are mainly 300 to 500 ohms. Balanced lines are best in straight runs. If bends are unavoidable, the angles should be as obtuse as possible. Care should be taken to prevent one wire from coming closer to metal objects than the other. Wire spacing should be less than  $1/20$  wavelength.

Properly built open-wire line can operate with very low loss in VHF and even UHF installations. A total line loss under 2 dB per hundred feet at 432 MHz is readily obtained. A line made of no. 12 wire, spaced  $3/4$  inch or less with Teflon spreaders, and running essentially straight from antenna to station, can be better than anything but the most expensive coax, at a fraction of the cost. This assumes the use of baluns to match into and out of the line, with a short length of quality coax for the moving section from the top of the tower to the antenna. A similar 144-MHz setup could have a line loss under 1 dB.

Small coax such as RG-58/U or -59/U should never be used in VHF work if the run is more than a few feet. Half-inch lines (RG-8/U or -11/U) work fairly well at 50 MHz, and are acceptable for 144-MHz runs of 50 feet or less. If these lines have foam rather than solid insulation they are about 30 percent better. Aluminum-jacket lines with large inner conductors and foam insulation are well worth their cost. They are readily waterproofed, and can last almost indefinitely. Beware of any "bargains" in coax. Lost transmitter power can be made up to some extent by increasing power, but once lost, a weak signal can never be recovered in the receiver.

Effects of weather should not be ignored. A well-constructed open-wire line works well in nearly any weather, and it stands up well. Twin-lead is almost useless in heavy rain, wet snow or icing. The best grades of coax are impervious to weather. They can be run underground, fastened to metal towers without insulation, or bent into any convenient position, with no adverse effects on performance.

### Impedance Matching

Theory and practice in impedance matching are given in detail in earlier chapters, and theory, at least, is the same for frequencies above 50 MHz. Practice may be similar, but physical size can be a major modifying factor in choice of methods.

#### Universal Stub

As its name implies, the double-

Fig. 39 — Matching methods commonly used in VHF antennas. The universal stub, A, combines tuning and matching. The adjustable short on the stub and the points of connection of the transmission line are adjusted for minimum reflected power in the line. In the delta match, B and C, the line is fanned out to tap on the dipole at the point of best impedance match. Impedances need not be known in A, B and C. The gamma match, D, is for direct connection of coax. C1 tunes out inductance in the arm. Folded dipole of uniform conductor size, E, steps up antenna impedance by a factor of four. Using a larger conductor in the unbroken portion of the folded dipole, E, gives higher orders of impedance transformation.

adjustment stub of Fig. 39A is useful for many matching purposes. The stub length is varied to resonate the system, and the transmission line and stub impedances are equal. In practice this involves moving both the sliding short and the point of line connection for zero reflected power, as indicated on an SWR indicator connected in the line.

The universal stub allows for tuning out any small reactance present in the driven part of the system. It permits matching the antenna to the line without knowledge of the actual impedances involved. The position of the short yielding the best match gives some indication of how much reactance is present. With little or no reactive component to be tuned out, the stub will be approximately a half wavelength from load to short.

The stub should be stiff bare wire or rod, spaced no more than  $1/20$  wavelength. Preferably it should be mounted rigidly, on insulators. Once the position of the short is determined, the center of the short can be grounded, if desired, and the portion of

the stub no longer needed can be removed.

It is not necessary that the stub be connected directly to the driven element. It can be made part of an open-wire line, as a device to match into or out of the line with coax. It can be connected to the lower end of a delta match, or placed at the feed point of a phased array. Examples of these uses are given later.

#### Delta Match

Probably the first impedance match was made when the ends of an open line were fanned out and tapped onto a half-wave antenna at the point of most efficient power transfer, as in Fig. 39B. Both the side length and the points of connection either side of the center of the element must be adjusted for minimum reflected power in the line, but as with the universal stub, the impedances need not be known. The delta makes no provision for tuning out reactance, so the universal stub is often used as a termination for it, to this end.

Once thought to be inferior for VHF applications because of its tendency to radiate

if adjusted improperly, the delta has come back to favor now that we have good methods for measuring the effects of matching. It is very handy for phasing multiple-bay arrays with open lines, and its dimensions in this use are not particularly critical. It should be checked out carefully in applications like that of Fig. 39C which have no tuning device.

#### Gamma Match

The gamma match is shown in Fig. 39D. There being no RF voltage at the center of a half-wave dipole, the outer conductor of the coax is connected to the element at this point, which may also be the junction with a metallic or wooden boom. The inner conductor, carrying the RF current, is tapped out on the element at the matching point. Inductance of the arm is canceled by means of C1, resulting in electrical balance. Both the point of contact with the element and the setting of the capacitor are adjusted for zero reflected power, with a bridge connected in the coaxial line.

The capacitor can be made variable temporarily, then replaced with a suitable fixed unit when the required capacitance value is found, or C1 can be mounted in a waterproof box. Maximum capacitance should be about 100 pF for 50 MHz and 35 to 50 pF for 144. The capacitor and arm can be combined with the arm connecting to the driven element by means of a sliding clamp, and the inner end of the arm sliding inside a sleeve connected to the inner conductor of the coax. One can be constructed from concentric pieces of tubing, insulated by plastic sleeving. RF voltage across the capacitor is low, once the match is adjusted properly, so with a good dielectric, insulation presents no great problem, if the initial adjustment is made with low power. A clean, permanent, high-conductivity bond between arm and element is important, as the RF current is high at this point.

#### Folded Dipole

The impedance of a half-wave antenna broken at its center is 72 ohms. If a single conductor of uniform size is folded to make a half-wave dipole, as shown in Fig. 39E, the impedance is stepped up four times. Such a folded dipole can thus be fed directly with 300-ohm line with no appreciable mismatch. Coaxial line of 70 to 75 ohms impedance may also be used if a 4:1 balun is added. (See balun information in Chapter 16.) Higher impedance step-up can be obtained if the unbroken portion is made larger in cross-section than the fed portion, as in Fig. 39F. For design information see Chapter 16.

#### Baluns and Transmatches

Conversion from balanced loads to unbalanced lines, or vice versa, can be performed with electrical circuits, or their equivalents made of coaxial line. A balun made from flexible coax is shown in Fig. 40A. The looped portion is an electrical

Fig. 40 — Conversion from unbalanced coax to a balanced load can be done with a half-wave coaxial balun, A. Electrical length of the looped section should be checked with a dip meter, with ends shorted, B. The half-wave balun gives a 4:1 impedance step up.

Fig. 41 — The balun conversion function, with no impedance change, is accomplished with quarter-wave lines, open at the top and connected to the coax outer conductor at the bottom. The coaxial sleeve, A, is preferred.

half-wavelength. The physical length depends on the propagation factor of the line used, so it is well to check its resonant frequency, as shown at B. The two ends are shorted, and the loop at one end is coupled to a dip-meter coil. This type of balun gives an impedance step-up of 4:1 in impedance, 50 to 200 ohms, or 75 to 300 ohms typically.

Coaxial baluns giving a 1:1 impedance transfer are shown in Fig. 41. The coaxial sleeve, open at the top and connected to the outer conductor of the line at the lower end (A) is the preferred type. A conductor of approximately the same size as the line is used with the outer conductor to form a quarter-wave stub, in B. Another piece of coax, using only the outer conductor, will serve this purpose. Both baluns are intended to present an infinite impedance to any RF current that might otherwise tend to flow on the outer conductor of the coax.

The functions of the balun and the impedance transformer can be handled by various tuned circuits. Such a device, commonly called an antenna coupler or Transmatch, can provide a wide range of impedance transformations. Additional

selectivity inherent to the Transmatch can reduce RFI problems.

#### Stacking Yagis

Where suitable provision can be made for supporting them, two Yagis mounted one above the other and fed in phase may be preferable to one long Yagi having the same theoretical or measured gain. The pair will require a much smaller turning space for the same gain, and their lower radiation angle can provide interesting results. On long ionospheric paths a stacked pair occasionally may show an apparent gain much greater than the 2 to 3 dB that can be measured locally as the gain from stacking.

Optimum spacing for Yagis of five elements or more is one wavelength, but this may be too much for many builders of 50-MHz antennas to handle. Worthwhile results can be obtained with as little as one-half wavelength (10 feet), but 5/8 wavelength (12 feet) is markedly better. The difference between 12 and 20 feet may not be worth the added structural problems involved in the wider spacing, at 50 MHz at least. The closer spacings give lowered

Fig. 42 — A method for feeding a stacked Yagi array.

measured gain, but the antenna patterns are cleaner (less power in the high-angle lobes) than will be obtained with one-wavelength spacing. The extra gain with wider spacings is usually the objective on 144 MHz and higher bands, where the structural problems are not severe.

One method for feeding two 50-ohm antennas, as might be used in a stacked Yagi array, is shown in Fig. 42. The transmission lines from each antenna to the common feed point must be equal in length and an odd multiple of a quarter wavelength. This line acts as an impedance transformer and raises the feed impedance of each antenna to 100 ohms. When the two antennas are connected in parallel at the coaxial T fitting, the resulting impedance is close to 50 ohms.

## COLLINEAR ANTENNAS

Information given thus far is mainly on parasitic arrays, but the collinear antenna has much to recommend it. Inherently broad in frequency response, it is a logical choice where coverage of an entire band is wanted. This tolerance also makes a collinear array easy to build and adjust for any VHF application. The use of many driven elements is popular in very large phased arrays, such as may be required for moon-bounce (EME) communication.

### Large Collinear Arrays

Bidirectional curtain of arrays of four, six and eight half-waves in phase are shown in Fig. 43. Usually reflector elements are added, normally at about 0.2 wavelength in back of each driven element, for more gain and a unidirectional pattern. Such

Fig. 43 — Element arrangements for 8, 12 and 16-element collinear arrays. Parasitic reflectors, omitted here for clarity, are five percent longer and 0.2 wavelength in back of the driven elements. Feed points are indicated by black dots. Open circles are recommended support points. The elements can run through wood or metal booms, without insulation, if supported at their centers in this way. Insulators at the element ends (points of high RF voltage) tend to detune and unbalance the system.

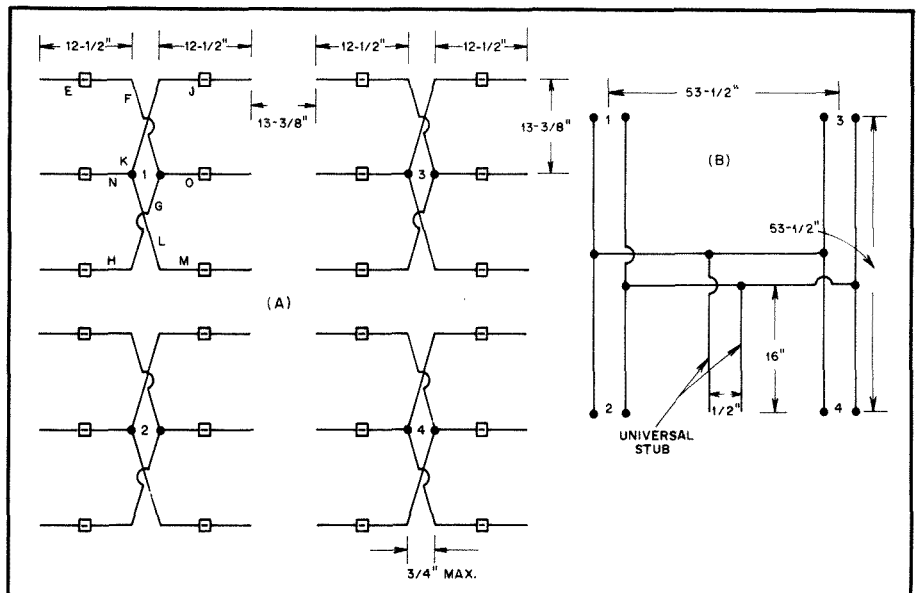

Fig. 44 — Large collinear arrays should be fed as sets of no more than eight driven elements each, interconnected by phasing lines. This 48-element array for 432 MHz (A) is treated as if it were four 12-element collinear arrays. Reflector elements are omitted for clarity. Phasing harness is shown at B.

parasitic elements are omitted from the sketch in the interest of clarity.

When parasitic elements are added, the feed impedance is low enough for direct connection to open line or twin-lead, connected at the points indicated by black dots. With coaxial line and a balun, it is suggested that the universal stub match, Fig. 39A, be used at the feedpoint. All elements should be mounted at their electrical centers, as indicated by open circles in Fig. 43. The framework can be metal or insulating material, with equally good results. The metal supporting structure is entirely in back of the plane of the reflector

elements. Sheet-metal clamps can be cut from scraps of aluminum to make this kind of assembly, which is very light in weight and rugged as well. Collinear elements should always be mounted at their centers, where RF voltage is zero — never at their ends, where the voltage is high and insulation losses and detuning can be very harmful.

Collinear arrays of 32, 48, 64 and even 128 elements can be made to give outstanding performance. Any collinear should be fed at the center of the system, for balanced current distribution. This is very important in large arrays, which are

treated as sets of six or eight driven elements each. The sets are fed through a balanced harness, each section of which is a resonant length, usually of open-wire line. A 48-element collinear array for 432 MHz, Fig. 44, illustrates this principle.

A reflecting plane, which may be sheet metal, wire mesh, or even closely spaced elements of tubing or wire, can be used in place of parasitic reflectors. To be effective, the plane reflector must extend on all sides to at least a quarter wavelength beyond the area occupied by the driven elements. The plane reflector provides high front-to-back ratio, a clean pattern, and somewhat more gain than parasitic elements, but large physical size rules it out for amateur use below 420 MHz. An interesting space-saving possibility lies in

using a single plane reflector with elements for two different bands mounted on opposite sides. Reflector spacing from the driven element is not critical. About 0.2 wavelength is common.

### **Circular Polarization**

Polarization is described as "horizontal" or "vertical," but these terms have no meaning once the reference of the earth's surface is lost. Many propagation factors can cause polarization change — reflection or refraction and passage through magnetic fields (Faraday rotation), for example. Polarization of VHF waves is often random, so an antenna capable of accepting any polarization is useful. Circular polarization, generated with helical antennas or with crossed elements fed 90 degrees

out of phase, will respond to any linear polarization.

The circularly polarized wave, in effect, threads its way through space, and it can be left- or right-hand polarized. These polarization senses are mutually exclusive, but either will respond to any plane polarization. A wave generated with right-hand polarization, when reflected from the moon, comes back with left-hand, a fact to be borne in mind in setting up EME circuits. Stations communicating on direct paths should have the same polarization sense.

Both senses can be generated with crossed dipoles, with the aid of a switchable phasing harness. With helical arrays, both senses are provided with two antennas, wound in opposite directions.

# Voice Communications

The history of radiotelephony is indeed interesting. Way back in 1878, Bell and Tainter devised a system to voice-modulate a light beam! Called the photophone, it relied on a silvered plane mirror mounted so that it could be vibrated by sound waves. Detection was by a light-sensitive selenium cell in the receiver. By using a focusing lens and a parabolic mirror, this method spanned 250 yards.

Radio voice communications owe credit to Fessenden. In 1902, he developed a system to modulate continuous waves with the human voice. Before this time, most voice transmissions were attempts at

modulating spark transmitters, with generally poor results.

Frequency modulation (FM) was first technically addressed by John R. Carson in *Proceedings of the IRE*, in February 1922. By mathematical analysis, he "proved" FM inferior to AM on two counts: bandwidth requirements and distortion.

The Carson analysis held until May 1936, when another paper on FM appeared in the same journal. In this work, Major Edwin H. Armstrong set the stage for viable FM communications. Some of his ideas are still in use today!

Eleven years later, single-sideband suppressed-carrier (SSB) came on the amateur scene. On September 21, 1947, Oswald G. Villard, W6QYT, operating W6YX, worked Winfield G. Wagener, W6VQD on the 75-meter band. The SSB era had begun.

Recently, a new single-sideband technique, Amplitude Companded Single Sideband (ACSSB) has been introduced. This mode, basically designed for the Land Mobile Service, combines the advantages of FM and SSB. ACSSB may very well find a future in the crowded amateur repeater subbands, and for satellite work.

## Single Sideband

On the high-frequency amateur bands, single sideband is the most widely used radiotelephony mode. Since SSB is a sophisticated (or simplified, depending on one's point of view) form of amplitude modulation, it is worthwhile to take a brief look at some AM fundamentals. Modulation is a mixing process. When RF and AF signals are combined in a standard AM transmitter (such as one used for commercial broadcasting) four output signals are generated: the original carrier or RF signal, the original AF signal, and two sidebands, whose frequencies are the sum and difference of the original RF and AF signals, and whose amplitudes are proportional to that of the original AF signal. The sum component is called the upper sideband. It is erect, in that increasing the frequency of the modulating audio signal causes a corresponding increase in the frequency of the RF output signal. The difference component is called the lower sideband, and is inverted, meaning an increase in the modulating frequency results in a decrease in the output frequency. The amplitude and frequency of the carrier are unchanged by the modulation process, and the original AF signal is rejected by the RF output network. The RF envelope (sum of sidebands and carrier), as viewed on an oscilloscope, has the shape of the modulating waveform.

Fig. 1B shows the envelope of an RF

(A)

(B)

Fig. 1 — Electronic displays of AM signals in the frequency and time domains. (A) Unmodulated carrier or single-tone SSB signal. (B) Full-carrier AM signal with single-tone sinusoidal modulation.

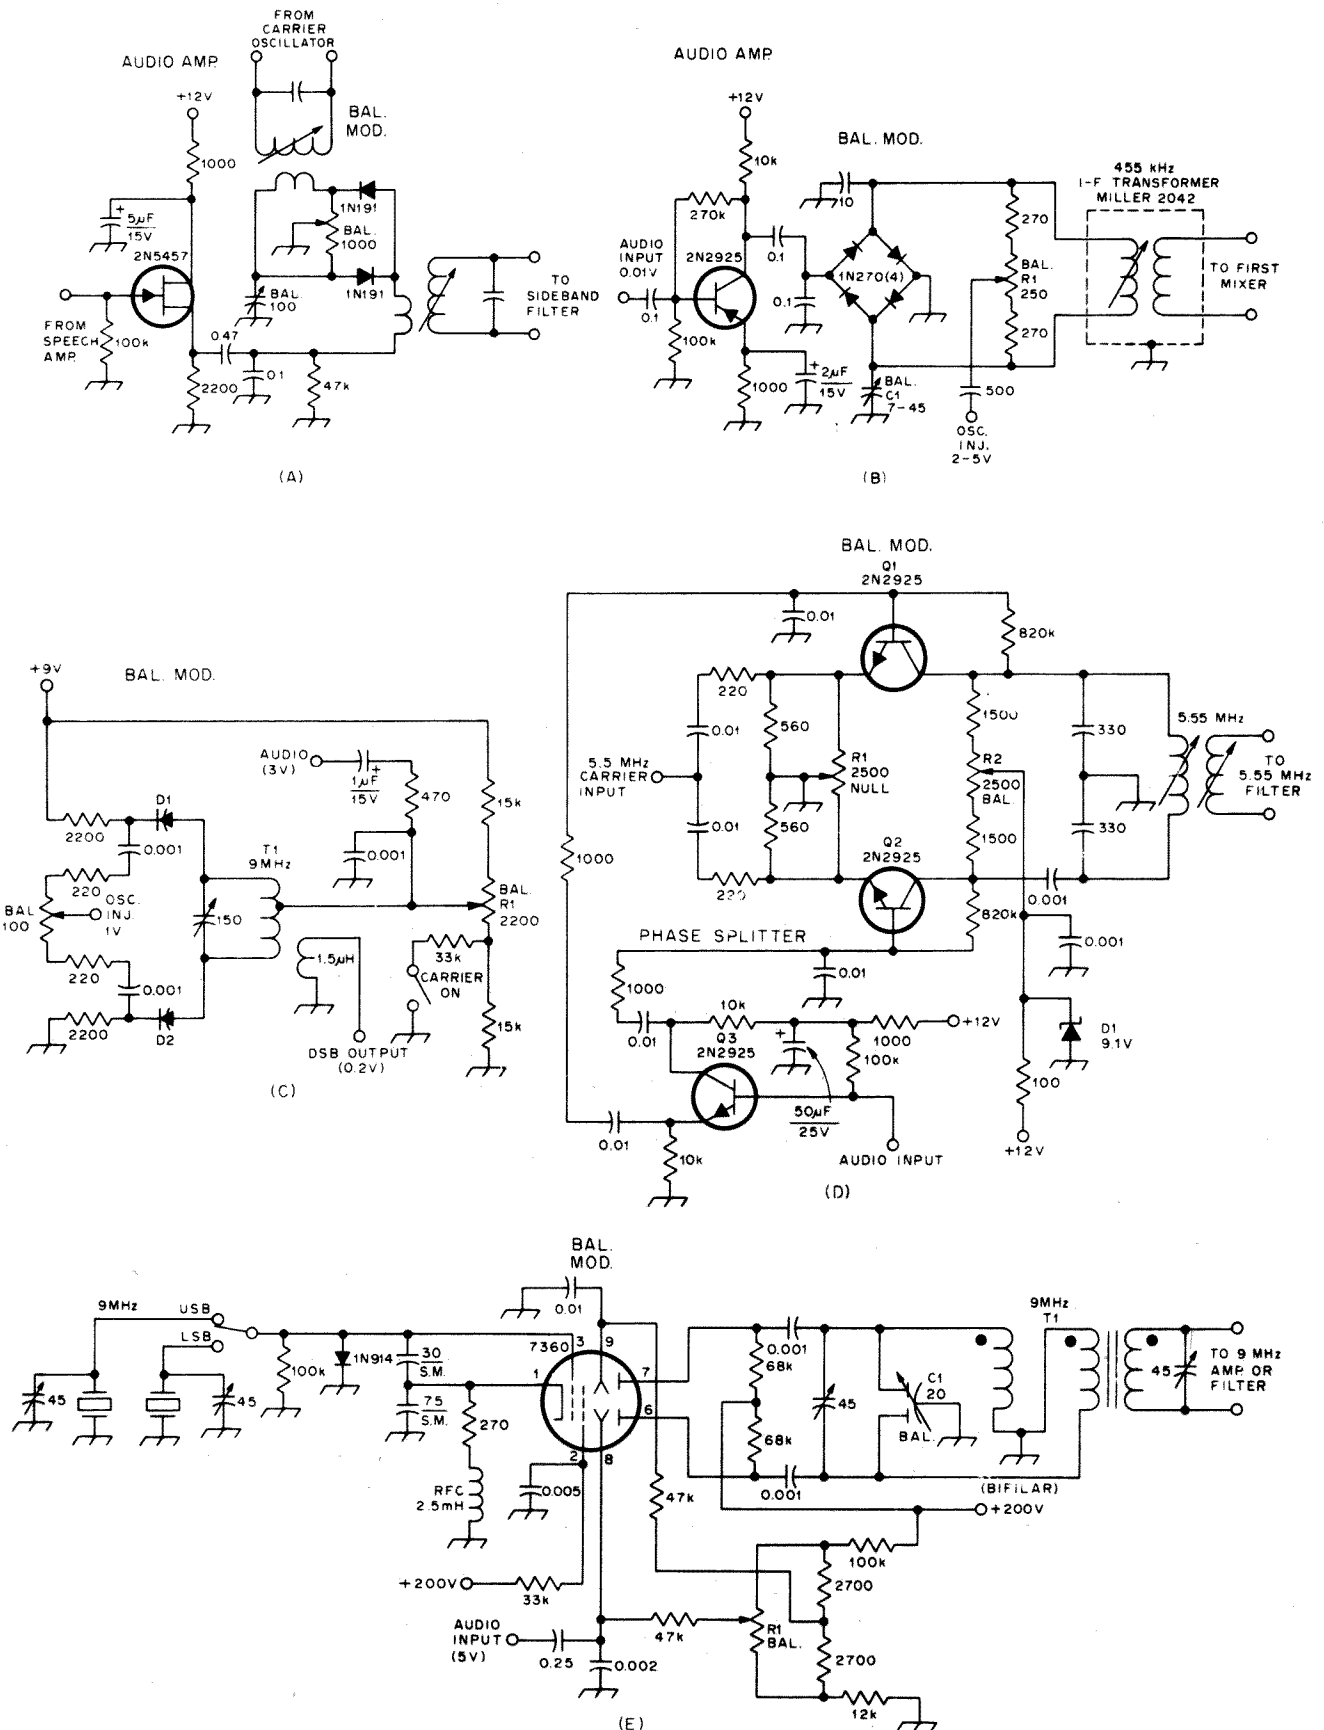

Fig. 2 — Typical balanced modulator circuits. The representative parts values should serve as a basis for designing one's own equipment.

signal that is modulated 20 percent by an AF sine wave. The envelope varies in amplitude because it is the vector sum of the carrier and the sidebands. A spectrum analyzer or selective receiver will show the carrier to be constant. The spectral photograph also shows that the bandwidth of an AM signal is twice the highest frequency component of the modulating wave.

An amplitude-modulated signal cannot be frequency multiplied without special processing because the phase/frequency relationship of the components of the modulating waveform would be severely distorted. For this reason, once an AM signal has been generated, it can be moved in frequency only by heterodyning.

All of the intelligence is contained in the sidebands, but two-thirds of the RF power is in the carrier. The carrier serves only to demodulate the signal in the receiver. If this carrier is suppressed in the transmitter and reinserted in the proper phase in the receiver, several significant communications advantages accrue. If the reinserted carrier is strong compared to the incoming double-sideband signal, exalted carrier reception is achieved in which distortion caused by frequency-selective fading is reduced greatly. A refinement of this technique, called synchronous detection, uses a phase-locked loop to enhance the rejection of interference. Also, the lack of a transmitted carrier eliminates the heterodyne interference common to adjacent AM signals. Perhaps the most important advantage of eliminating the carrier is that the overall efficiency of the transmitter is increased. The power consumed by the carrier can be put to better use in the sidebands. The power in the carrier is continuous, and an AM transmitter requires a heavy-duty power supply. An SSB transmitter having the same power output as an AM transmitter can use a much lighter power supply because the duty cycle of voice operation is low.

### Balanced Modulators

The carrier can be suppressed or nearly eliminated by using a balanced modulator or an extremely sharp filter. In SSB transmitters it is common practice to use both devices. The basic principle of any balanced modulator is to introduce the carrier in such a way that only the sidebands will appear in the output. The type of balanced-modulator circuit chosen by the builder will depend on the constructional considerations, cost, and the active devices to be employed.

In any balanced-modulator circuit there will be no output with no audio signal. When audio is applied, the balance is upset, and one branch will conduct more than the other. Since any modulation process is the same as "mixing," sum and difference frequencies (sidebands) will be generated. The modulator is not balanced for the

Table 1

Forward-to-Reverse Resistance Ratio for Different Classes of Solid-State Diodes

Diode Type	Ratio M = 1,000,000	
Point-contact germanium (1N98)	500	
Small-junction germanium (1N270)	0.1	M
Low-conductance silicon (1N457)	48	M
High-conductance silicon (1N645)	480	M
Hot-carrier (HPA-2800)	2000	M

sidebands, and they will appear in the output.

A rectifier-type balanced modulator is shown in Fig. 2, at A and B. If they have equal forward resistances, the diode rectifiers are connected so that no RF can pass from the carrier source to the output circuit by either of the two possible paths. The net effect is that no RF energy appears in the output. When audio is applied, it unbalances the circuit by biasing the diode (or diodes) in one path, depending on the instantaneous polarity of the audio, and hence some RF will appear in the output. The RF energy in the output will appear as a double-sideband suppressed-carrier signal.

For minimum distortion in any diode modulator, the RF voltage should be at least six to eight times the peak audio voltage. The usual operation involves a fraction of a volt of audio and several volts of RF. Desirable diode characteristics for balanced modulator and mixer service include: low noise, low forward resistance, high reverse resistance, good temperature stability and fast switching time (for high-frequency operation).

Table 1 lists the different classes of diodes, giving the ratio of forward-to-reverse resistance of each. This ratio is an important criterion in the selection of

diodes. Also, the individual diodes used should have closely matched forward and reverse resistances; an ohmmeter can be used to select matched pairs or quads.

One of the simplest diode balanced modulators in use is that of Fig. 2A. Its use is usually limited to low-cost portable equipment in which a high degree of carrier suppression is not vital. A ring balanced modulator, shown in Fig. 2B, offers good carrier suppression at low cost. Diodes D1 through D4 should be well matched and can be 1N270s or similar. C1 and R1 are adjusted for best RF balance as evidenced by maximum carrier null. It may be necessary to adjust each control several times alternately to secure optimum carrier suppression.

Varactor diodes are part of the unusual circuit shown in Fig. 2C. This arrangement allows single-ended input of nearly equal levels of audio and carrier. Excellent carrier suppression, 50 dB or more, and a simple method of unbalancing the modulator for CW operation are features of this design. D1 and D2 should be rated at 20 pF for a bias of -4 V. R1 can be adjusted to cancel any mismatch in the diode characteristics, so it isn't necessary that the varactors be well matched. T1 is wound on a small-diameter toroid core. The tap on the primary winding of this transformer is at the center of the winding.

A bipolar-transistor balanced modulator is shown in Fig. 2D. This circuit is similar to one used by Galaxy Electronics and uses closely matched transistors at Q1 and Q2. A phase splitter (inverter), Q3, is used to feed audio to the balanced modulator in push-pull. The carrier is supplied to the circuit in parallel and the output is taken in push-pull. D1 is a Zener diode and is used to stabilize the dc voltage. Controls R1 and R2 are adjusted for best carrier suppression.

The circuit at E offers superior carrier suppression and uses a 7360 beam-deflec-

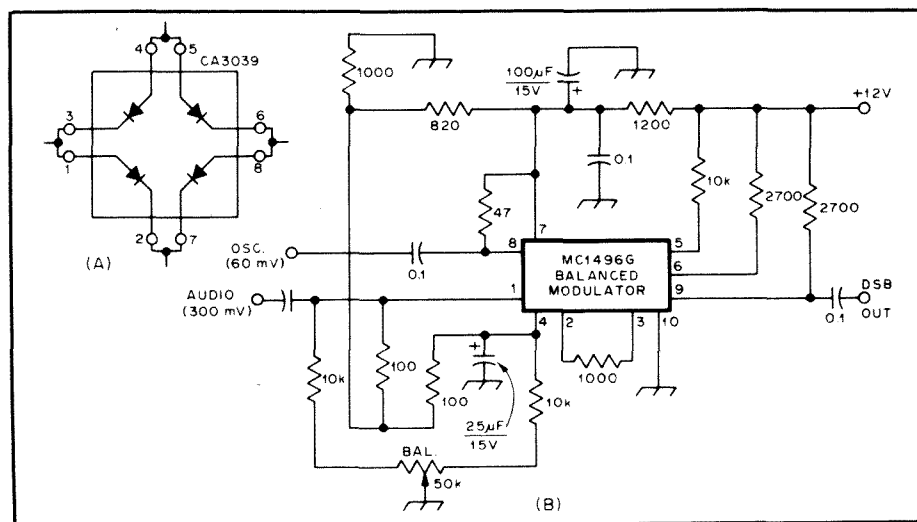

Fig. 3 — Additional balanced-modulator circuits in which integrated circuits are used.

**Table 2**

**Guidelines for Amateur SSB Signal Quality**

Parameter	Suggested Standard
Carrier suppression	At least 40-dB below PEP
Opposite-sideband suppression	At least 40-dB below PEP
Hum and noise	At least 40-dB below PEP
Third-order intermodulation distortion	At least 30-dB below PEP
Higher-order intermodulation distortion	At least 35-dB below PEP
Long-term frequency stability	At most 100-Hz drift per hour
Short-term frequency stability	At most 10-Hz P-P deviation in a 2-kHz bandwidth

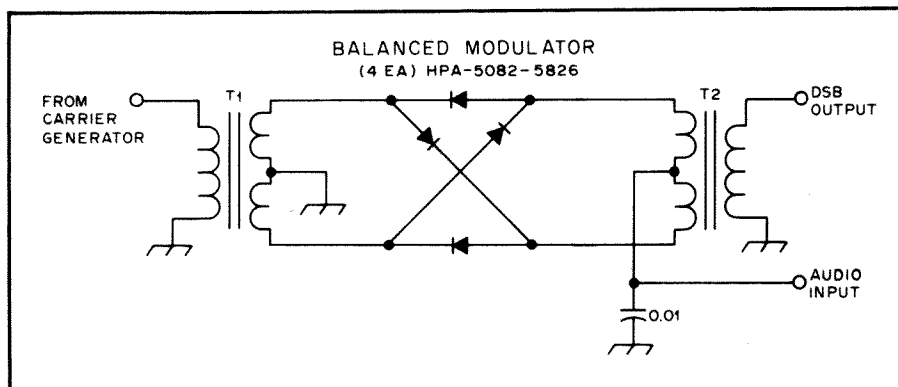

Fig. 4 — Balanced-modulator design using hot-carrier diodes.

tion tube as a balanced modulator. This tube is capable of providing as much as 60 dB of carrier suppression. When it is used with mechanical or crystal-lattice filters, the total carrier suppression can be as great as 80 dB. Most well-designed balanced modulators can provide between 30 and 50 dB of carrier suppression. The primary of transformer T1 should be bifilar wound for best results.

Vacuum-tube balanced modulators can be operated at high power levels and the double-sideband output can be used directly into the antenna. Past issues of *QST* have given construction details on such transmitters.

### IC Balanced Modulators

Integrated circuits (ICs) are presently available for use in balanced-modulator and mixer circuits. A diode array such as the RCA CA3039 is ideally suited for use in circuits such as that of Fig. 3A. Since all diodes are formed on a common silicon chip, their characteristics are extremely well matched. This fact makes the IC ideal in a circuit where good balance is required. The hot-carrier diode also has closely matched characteristics and excellent temperature stability. Using broadband toroidal-wound transformers, it is possible to construct a circuit similar to that of Fig. 4 that will have 40 dB of carrier suppression without the need for balance controls. T1 and T2 consist of trifilar windings, 12 turns of no. 32 enam. wire wound on a ½-inch toroid core. Another device with good inherent balance is the special IC made for modulator/mixer service, such as the Motorola MC1496G or Signetics S5596. A sample circuit using the MC1496 is shown in Fig. 3B. R1 is adjusted for best carrier balance. The amount of energy delivered from the carrier generator affects the level of carrier suppression; 100 mV of injection is about optimum, producing up to 55 dB of carrier suppression.

### SINGLE-SIDEBAND EMISSION

A further improvement in communications effectiveness can be obtained by transmitting only one of the sidebands. When the proper receiver bandwidth is used, a single-sideband signal will show an effective gain of up to 9 dB over an AM signal of the same peak power. Because the redundant information is eliminated, the required bandwidth of an SSB signal is half that of a comparable AM or DSB emission. Unlike DSB, the phase of the local carrier generated in the receiver is unimportant.

#### Generating the SSB Signal: The Filter Method

If the DSB signal from the balanced modulator is applied to a band-pass filter, one of the sidebands can be greatly attenuated. Because a filter cannot have infinitely steep skirts, to obtain adequate suppression of the unwanted sideband the

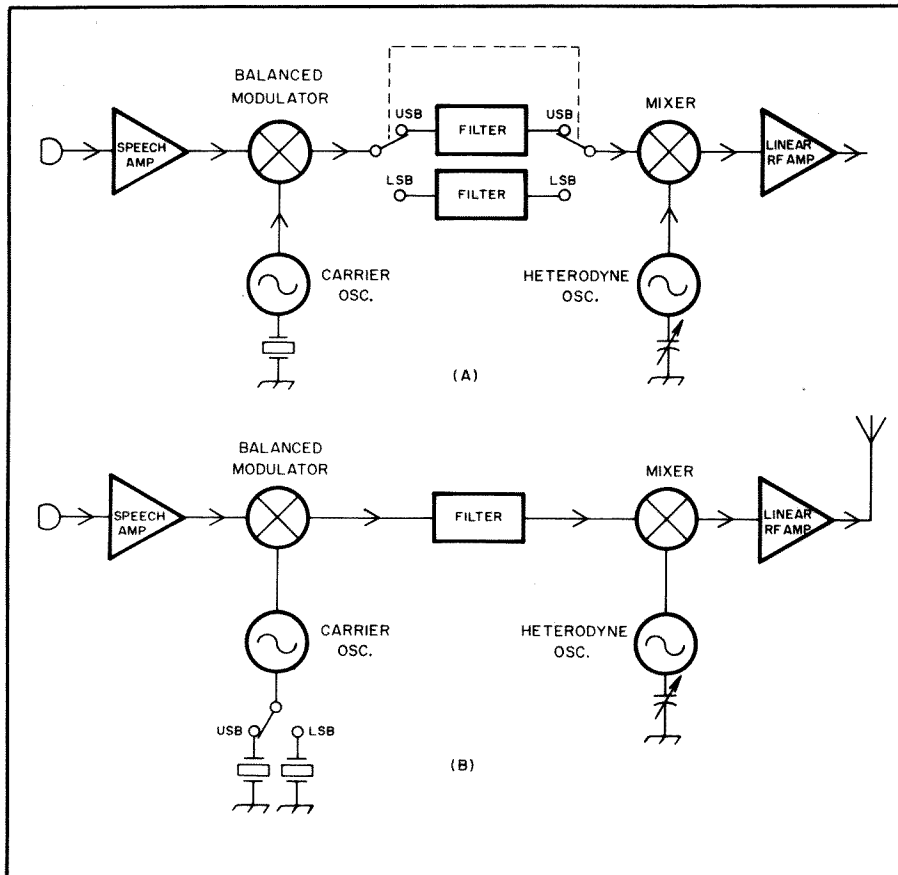

Fig. 5 — The filter method of SSB generation. Two sideband selection schemes are commonly used.

response of the filter must begin to roll off within about 300 Hz of the phantom carrier. This effect limits the ability to transmit bass frequencies, but these frequencies have little communications value. The filter rolloff can be used to obtain an additional 20 dB of carrier suppression. The bandwidth of an SSB filter is selected for the specific application. For voice communications, typical values are 1.8 to 3.0 kHz.

Fig. 5 illustrates two variations of the filter method of SSB generation. The heterodyne oscillator is represented as a simple VFO, but may be a premixing system or synthesizer. The scheme at B is perhaps less expensive than that of A, but the heterodyne-oscillator frequency must be shifted when changing sidebands if the dial calibration is to be maintained. The ultimate sense (erect or inverted) of the final output signal is influenced as much by the relationship of the heterodyne-oscillator frequency to the fixed SSB frequency as by the filter or carrier frequency selection. The heterodyne-oscillator frequency must be chosen to allow the best image rejection. This consideration requires that the heterodyne-oscillator frequency be above the fixed SSB frequency on some bands and below it on others. To reduce circuit complexity, early amateur filter types of SSB transmitters did not include a sideband selection switch. The result was that the output was LSB on 160, 75 and 40 meters, and USB on the higher bands. This convention persists despite the flexibility of most modern amateur SSB equipment.

### Filter Types

For carrier frequencies in the 50- to 100-kHz region, a satisfactory filter can be made up of lumped-constant LC sections. High quality components and careful adjustment are required for good results with this type of filter. An alternate possibility is a "synthesized" filter comprised of high-performance operational amplifiers used as gyrators or "active inductors." A further drawback of SSB generation in this frequency range is that multiple conversion is necessary to reach the desired output frequency with adequate suppression of spurious mixing products.

Mechanical filters are an excellent choice for SSB generation in the 400- to 500-kHz region. These filters are described in some detail in the receiving chapter. For wide-dynamic-range receiving applications, the more modern types using piezoelectric transducers are preferred for lowest intermodulation distortion. In transmitters, where the signal levels can be closely predicted, the types using magnetostrictive transducers are entirely suitable.

Quartz crystal filters are commonly used in systems in which the SSB signal is generated in the high-frequency range. Some successful amateur designs have also employed crystals at 455 kHz. Generally, four or more crystal elements are required to obtain adequate selectivity for SSB

transmission. Crystal-filter design is a sophisticated subject, and the more esoteric aspects are beyond the scope of this *Handbook*. The discussion of piezoelectric crystal theory in Chapter 4 is sufficient background material for the general understanding of the concepts outlined in this section.

A fundamental crystal-filter section is the half-lattice, shown in Fig. 6. The passband of this type of filter is slightly wider than the frequency spacing between the crystals. The antiresonant (parallel resonant) frequency or pole of the low-frequency crystal must be equal to the series-resonant frequency or zero of the high-frequency crystal. Such a filter is useful for casual receiving purposes, but the ultimate stop-band attenuation is poor, and numerous spurious responses will exist just outside the passband. Cascading two of these sections back to back, as in Fig. 7, will greatly suppress these parasitic resonances and steepen the skirts without materially affecting the passband. An important factor in the design of this type of filter is the coefficient

of coupling between the two halves of the transformer. The coupling must approach unity for proper operation. A twisted bifilar winding on a high-permeability ferrite core most nearly approximates this ideal. Some crystal filters have tuned input and output transformers. The flatness of the passband is heavily dependent on the terminating resistances. Lattice filters exhibit fairly symmetrical response curves and can be used for LSB or USB selection by means of placing the carrier frequency on the upper or lower skirt.

An asymmetrical filter is shown in Fig. 8. Using this approach, good unwanted sideband suppression can be obtained with only two crystals. The crystals are ground for the same frequency. The potential bandwidth here is only half that obtained with a half-lattice design. The maximum bandwidth of almost any crystal filter can be increased by using plated crystals intended for overtone operation.

The home construction of crystal filters can be very time consuming, if not expensive. The reason for this is that one must

Fig. 6 — The half-lattice crystal filter. Crystals A and B should be chosen so that the parallel-resonant frequency of one is the same as the series-resonant frequency of the other. Very tight coupling between the two halves of the secondary of T1 is required for optimum results. The theoretical attenuation-vs.-frequency curve of a half-lattice filter shows a flat passband between the lower series-resonant frequency and higher parallel-resonant frequency of the pair of crystals.

Fig. 7 — Half-lattice filters cascaded in a back-to-back arrangement. The theoretical curve of such a filter has increased skirt selectivity and fewer spurious responses, as compared with a simple half lattice, but the same passband as the simple circuit.

Fig. 8 — An asymmetrical filter and theoretical attenuation curve.

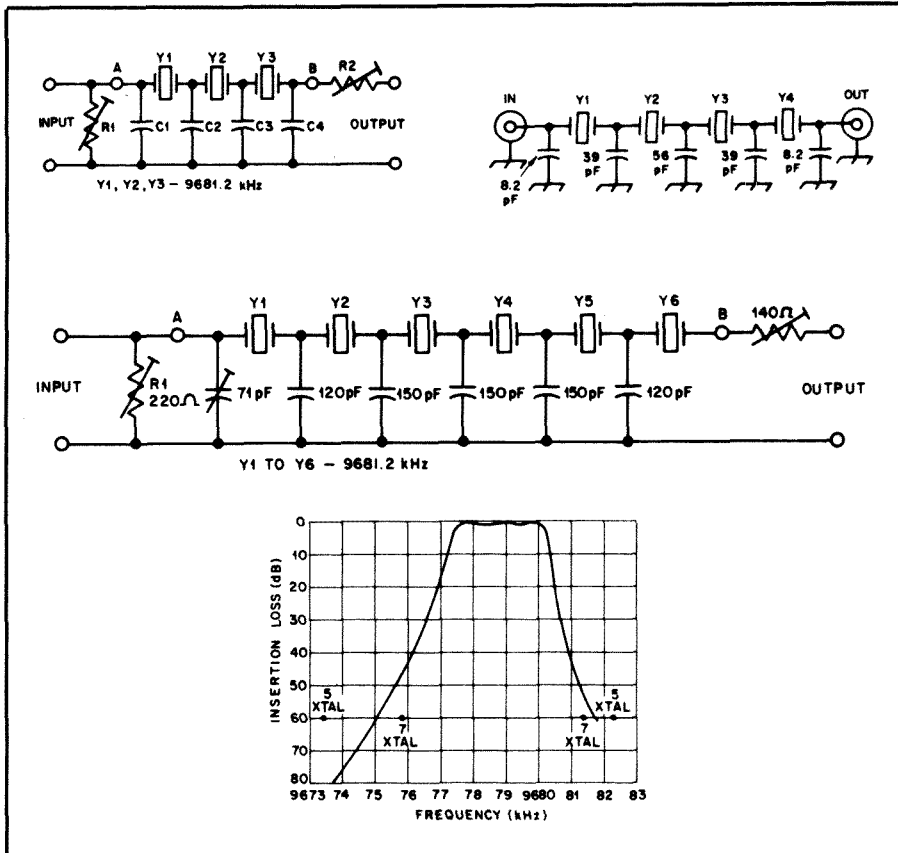

Fig. 9 — Some ladder filters based on CB crystals, with the response that can be expected from the 6-pole unit.

experiment with a large number of crystals to produce a filter with satisfactory performance. Crystal grinding and etching can be a fascinating and highly educational activity, but most home builders would prefer to spend their time on other aspects of equipment design. High-quality filters are available from several manufacturers. Most amateurs who build their own SSB equipment adopt a "systems engineering" approach and design their circuits around filters of known performance. Some filter suppliers are listed in the Component Data chapter. It is still worthwhile to have an appreciation for the basic design ideas, however, for many of the less expensive filters can be improved markedly by the addition of a couple of crystals external to the package. The technique is to steepen the skirts by grouping sharp notches on either side of the passband.

An important exception is the ladder filter. Although this type of filter is treated in textbooks, it has received attention in the amateur literature only recently. The significant feature of ladder filters is that all of the crystals are ground for the same frequency. Low-cost CB crystals are ideally suited to this application. Representative designs by F6BQP and G3JIR are given in Fig. 9. Filter sections of this type can be cascaded for improved shape factor with very little effect on the 3-dB bandwidth.

Ladder filters having six or more elements are suitable for SSB transmitting and receiving service. In general, the bandwidth is inversely proportional to the values of the shunt capacitors and directly proportional to the terminal impedances. Table 3 lists the frequencies of the CB channels. Overtone crystals for CB service have fundamental resonance at approximately one third of the listed frequency.

#### Filter Applications

The important considerations in circuits using band-pass filters are impedance matching and input/output isolation. The requirements for isolation are less severe in transmitting applications than they are for receiving. With proper layout and grounding, the opposite sideband suppression should be determined by the shape factor rather than signal leakage. The filter must be terminated with the proper impedances to ensure a smooth bandpass response.

Fig. 10A shows a typical SSB generator using a KVG crystal filter. The grounded-gate JFET presents a broadband 50-ohm termination to the balanced modulator and transforms the impedance to the 500 ohms required by the filter. The DC return for the source of the JFET is through the output transformer of the modulator. The tank circuit is broadly resonant at 9 MHz

and rejects any spurious signals generated in the modulator that might be propagated through the filter. Crystal filters should be isolated from any dc voltages present in the circuit.

A circuit using a Collins mechanical filter is illustrated in Fig. 10B. The IF transformer prevents spurious responses and

removes dc bias. The output terminating network does double duty as the bias network for the transistor amplifier stage. The filter output transformer is the dc return for the base circuit. This technique is legitimate so long as the current is limited to 2 mA.

#### SSB Generation: The Phasing Method

Fig. 11 shows another method for obtaining a single-sideband signal. The audio and carrier signals are each split into components separated 90° in phase and applied to balanced modulators. When the DSB outputs of the modulators are combined, one sideband is reinforced and the other is cancelled. The figure shows sideband selection by means of transposing the audio leads, but the same result can be had by means of switching the carrier leads.

The phasing method was used in many pre-1960 amateur SSB excitors, but became less popular after the introduction of

relatively inexpensive high-performance band-pass filters. The phase shift and amplitude balance of the two channels must be very accurate if the unwanted sideband is to be adequately attenuated. Table 4 shows the required phase accuracy of one channel (AF or RF) for various levels of opposite sideband suppression. The numbers given assume perfect amplitude balance and phase accuracy in the other channel. It can be seen from the table that a phase accuracy of  $\pm 1^\circ$  must be maintained if the signal quality is to satisfy the criteria tabulated at the beginning of this chapter. It is difficult to achieve this level of overall accuracy over the entire speech band. Note, however, that speech has a complex spectrum with a large gap in the octave from 700 to 1400 Hz. The phase-accuracy tolerance can be loosened to  $\pm 2^\circ$  if the peak deviations can be made to occur within the spectral gap.

The major advantage of the phasing system is that the SSB signal can be generated at the operating frequency without the need for heterodyning. Phasing can be used to good advantage even in fixed-frequency systems. A loose-tolerance ( $\pm 4^\circ$ ) phasing exciter followed by a simple two-pole crystal filter can generate a high-quality signal at very low cost.

#### Audio Phasing Networks

It would be difficult to design a two-port network having a quadrature (90°) phase relationship between input and output with constant-amplitude response over a decade of bandwidth. A practical approach, pioneered by Robert Dome, W2WAM, is to use two networks having a differential phase shift of 90°. This differential can be closely maintained in a simple circuit if precision components are used. The 350/2Q4 audio phase shift network

manufactured by Barker and Williamson is such a circuit. The 2Q4 is a 1950 vintage component but it is still useful. A modern design using this device is given in Fig. 12. The insertion loss of the 2Q4 is 30 dB, and the phase-shift accuracy is  $\pm 1.5^\circ$  over the 300-3000 Hz speech band.

The tolerances of the components can be relaxed considerably if several phase-shift sections are cascaded. A sixth-order network designed by HASWH is shown in Fig. 13. Using common  $\pm 10\%$  tolerance components, this phase shifter provides approximately 60 dB of opposite-sideband attenuation over the range of 300 to 3000 Hz.

Numerous circuits have been developed to synthesize the required 90° phase shift electronically. Active-filter techniques are used in most of these systems, but precision components are needed for good results. An interesting phasing system described in *Electronics* for April 13, 1978, makes use of a tapped analog delay line. These "bucket brigade" devices are becoming available at reasonable prices on the surplus market.

#### RF Phasing Networks

If the SSB signal is to be generated at a fixed frequency, the RF phasing problem is trivial; any method that produces the proper phase shift can be used. If the signal is produced at the operating frequency, problems similar to those in the audio networks must be overcome.

A differential RF phase shifter is shown in Fig. 14. The amplitudes of the quadrature signals won't be equal over an entire phone band, but this is of little consequence as long as the signals are strong enough to saturate the modulators.

Where percentage bandwidths are small, such as in the 144.1- to 145-MHz range, the RF phase shift can be obtained convenient-

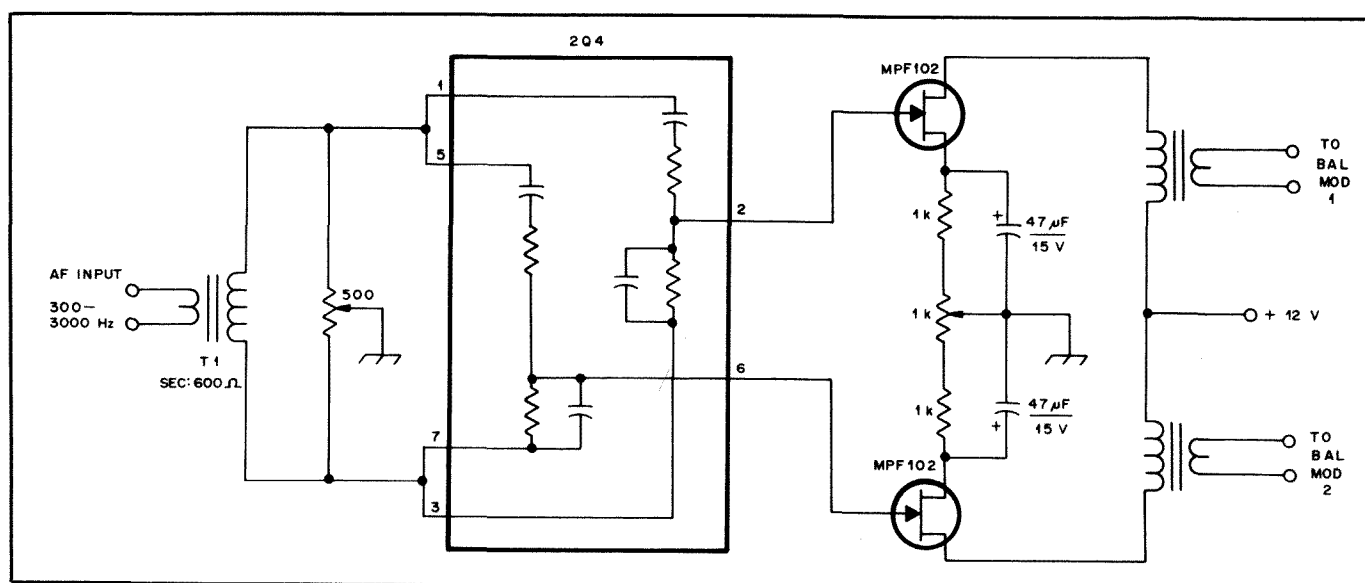

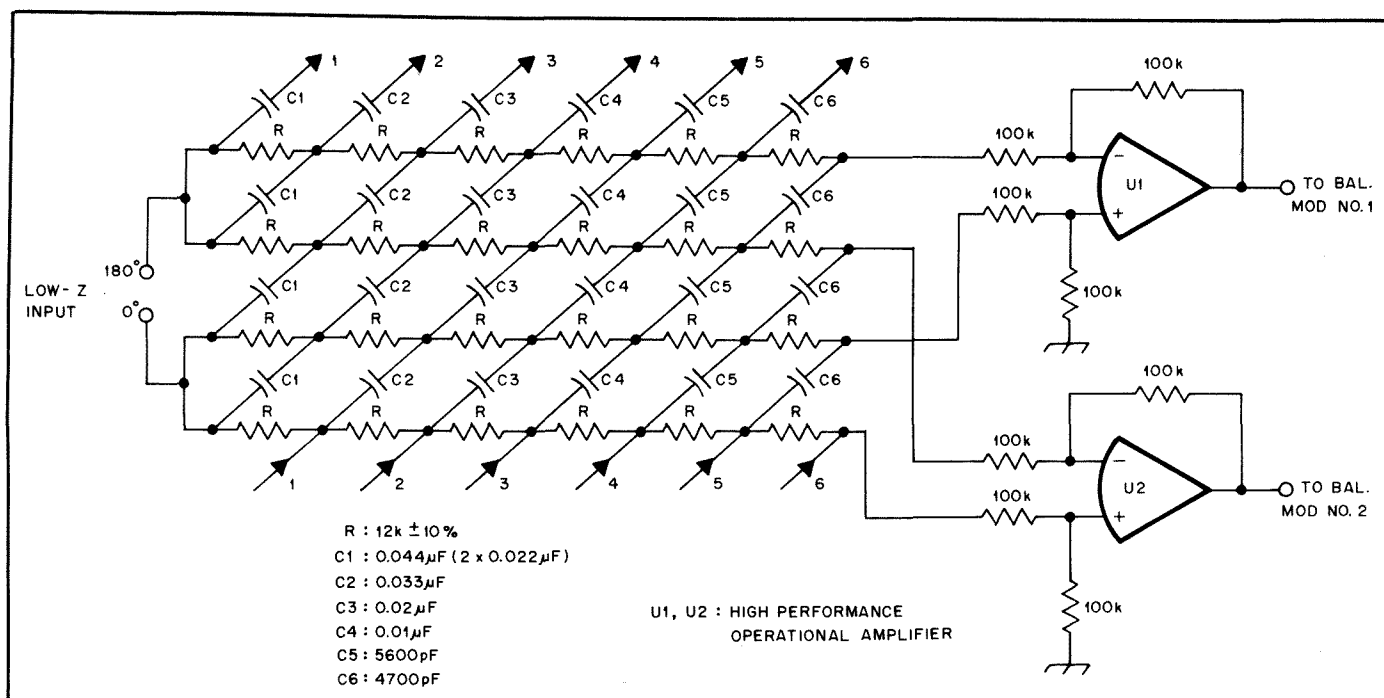

Fig. 12 — A circuit using the B&W 2Q4 audio phase shift network.

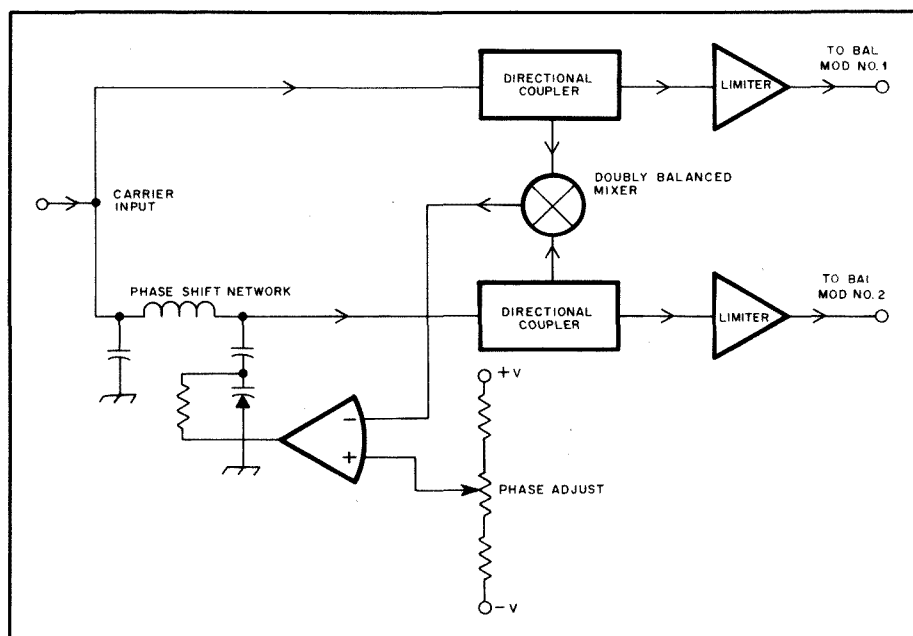

**Fig. 13 — A high-performance audio phase shifter made from ordinary loose-tolerance components.**

**Fig. 14 — A simple RF phase shifter. One of the capacitors can be variable for precise alignment.**

ly by means of transmission-line methods. If one balanced-modulator feed line is made an electrical quarter wavelength longer than the other, the two signals will be 90° out of phase. It is important that the cables be properly terminated.

One method for obtaining a 90° phase shift over a wide bandwidth is to generate the quadrature signals at a fixed frequency and heterodyne them individually to any desired operating frequency. Quadrature hybrids having multioctave bandwidths are manufactured commercially, but they cost hundreds of dollars. Another practical approach is to use two VFOs in a master-slave phase-locked-loop system. Many phase detectors lock the two signals in phase quadrature. A doubly balanced mixer has this property. One usually thinks of a phase-locked loop as having a VCO locked to a reference signal, but a phase dif-

**Fig. 15 — Block diagram of a phase-locked-loop phase-shifting system capable of maintaining quadrature over a wide bandwidth. The doubly balanced mixer is used as a phase detector.**

ferential can be controlled independently of the oscillator. The circuit in Fig. 15 illustrates this principle. Two digital phase shifters are sketched in Fig. 16. If ECL ICs are used, this system can work over the entire HF spectrum.

## DETECTORS

## Diode Detectors

The simplest detector for AM is the

diode. A germanium or silicon crystal is an imperfect form of diode (a small current can usually pass in the reverse direction), but the principle of detection in a semiconductor diode is similar to that in a vacuum-tube diode.

Circuits for both half-wave and full-wave diodes are given in Fig. 17. The simplified half-wave circuit at Fig. 17A includes the RF tuned circuit, L2C1, a coupling coil, L1, from which the RF

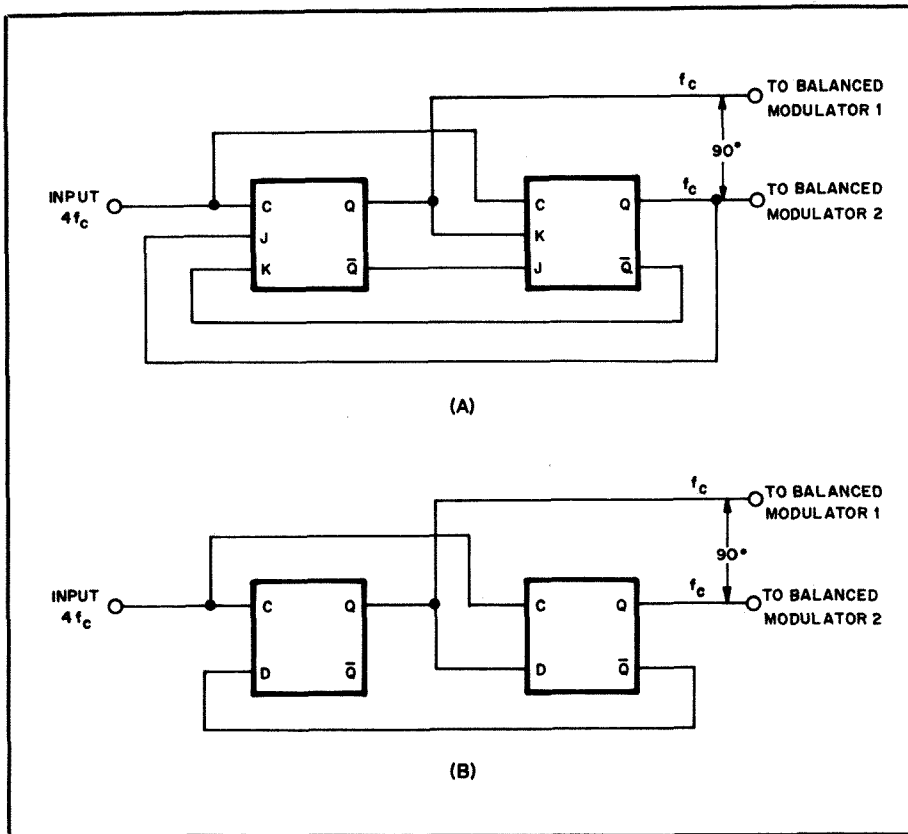

Fig. 16 — Digital RF phase shift networks. The circuit at A uses JK flip flops, and the circuit at B uses D flip flops. In each case the desired carrier frequency must be quadrupled before it is processed by the phase-shift network.

energy is fed to  $L_2C_1$ , and the diode,  $D_1$ , with its load resistance,  $R_1$ , and bypass capacitor,  $C_2$ .

The progress of the signal through the detector or rectifier is shown in Fig. 18. A typical modulated signal as it exists in the tuned circuit is shown at A. When this signal is applied to the rectifier, current will flow only during the part of the RF cycle when the anode is positive with respect to cathode, so that the output of the rectifier consists of half-cycles of RF. These current pulses flow in the load circuit comprised of  $R_1$  and  $C_2$ .  $C_2$  charges to the peak value of the rectified voltage on each pulse and retains enough charge between pulses so that the voltage across  $R_1$  is smoothed out, as shown in C.  $C_2$  thus acts as a filter for the radio-frequency component of the output of the rectifier, leaving a dc component that varies in the same way as the modulation on the original signal. When this varying dc voltage is applied to a following amplifier through a coupling capacitor ( $C_4$  in Fig. 17), only the variations in voltage are transferred, so the final output signal is ac, as shown in D.

In the circuit at 17B,  $R_1$  and  $C_2$  have been divided for the purpose of providing a more effective filter for RF. It is important to prevent the appearance of any RF voltage in the output of the detector, because it may cause overloading of a succeeding amplifier stage. The audio-

frequency variations can be transferred to another circuit through a coupling capacitor,  $C_4$ .  $R_2$  is usually a "potentiometer" so the audio volume can be adjusted to a desired level.

Coupling from the potentiometer (volume control) through a capacitor also avoids any flow of dc through the moving contact of the control. The flow of dc through a high-resistance volume control often tends to make the control noisy (scratchy) after a short while.

The full-wave diode circuit at Fig. 17C differs in operation from the half-wave circuit only in that both halves of the RF cycle are utilized. The full-wave circuit has the advantage that RF filtering is easier than in the half-wave circuit. As a result, less attenuation of the higher audio frequencies will be obtained for any given degree of RF filtering.

The reactance of  $C_2$  must be small compared to the resistance of  $R_1$  at the radio frequency being rectified, but at audio frequencies must be relatively large compared to  $R_1$ . If the capacitance of  $C_2$  is too large, response at the higher audio frequencies will be lowered.

Compared with most other detectors, the gain of the diode is low, normally running around 0.8 in audio work. Since the diode consumes power, the Q of the tuned circuit is reduced, bringing about a reduction in selectivity. The loading effect of the

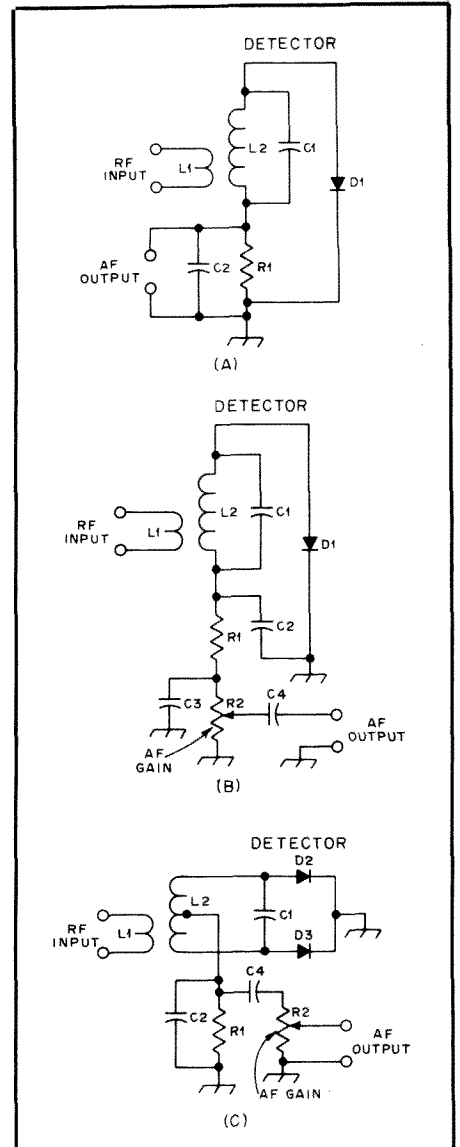

Fig. 17 — Simplified and practical diode detector circuits. A, the elementary half-wave diode detector; B, a practical circuit with RF filtering and audio output coupling; C, full-wave diode detector, with output coupling indicated. The circuit,  $L_2C_1$ , is tuned to the signal frequency; typical values for  $C_2$  and  $R_1$  in A and C are 250 pF and 250 k $\Omega$ , respectively; in B,  $C_2$  and  $C_3$  are 100 pF each;  $R_1$ , 50  $\Omega$ , and  $R_2$  250  $\Omega$ .  $C_4$  is 0.1 pF.

Fig. 18 — Illustrations of the detection process.

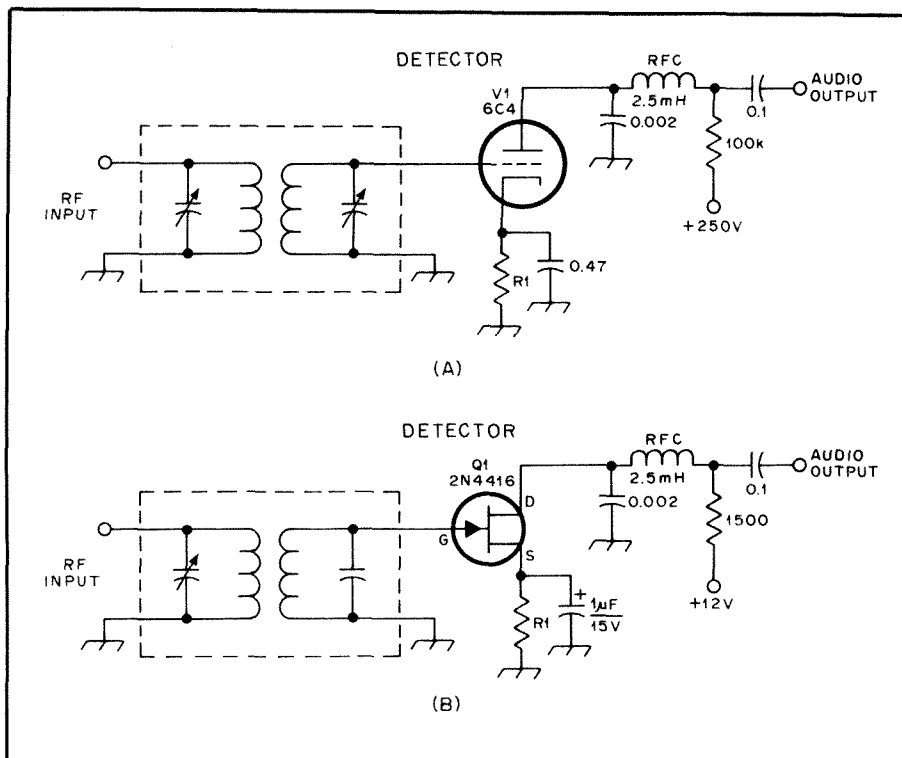

Fig. 19 — Plate-detection circuits. In each example the input circuit is tuned to the signal frequency. Typical  $R_1$  values for the tube circuit at A are 1000 to 5600 ohms. For the FET circuit at B,  $R_1$  is on the order of 100 to 3900 ohms.

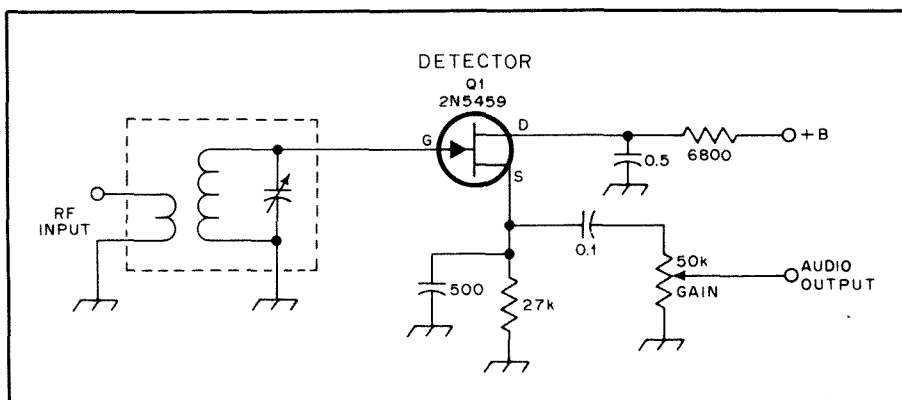

Fig. 20 — An infinite-impedance detector.

diode is close to one half the load resistance. The detector linearity is good, and the signal-handling capability is high.

### Plate Detectors

The plate detector is arranged so that rectification of the RF signal takes place in the plate circuit of the tube or the drain of the FET. Sufficient negative bias is applied to the grid to bring the plate current nearly to the cutoff point, so that application of a signal to the grid circuit causes an increase in average plate current. The average plate current follows the changes in the signal in a fashion similar to the rectified current in a diode detector.

In general, transformer coupling from the plate circuit of a plate detector is not satisfactory, because the plate impedance of any tube is very high when the bias is near the plate-current cutoff point. The same is true of a JFET or MOSFET. Impedance coupling may be used in place of the resistance coupling shown in Fig. 19. Usually 100 henrys or more of inductance is required.

The plate detector is more sensitive than the diode detector because there is some amplifying action in the tube or transistor. It will handle large signals, but is not as tolerant as the diode. Linearity, with the self-biased circuits shown, is good. Up to

the overload point the detector takes no power from the tuned circuit, and so does not affect its Q and selectivity.

### Infinite-Impedance Detector

The circuit of Fig. 20 combines the high signal-handling capabilities of the diode detector with the low distortion and, like the plate detector, does not load the tuned circuit it connects to. The circuit resembles that of the plate detector, except that the load resistance, 27 kΩ, is connected between source and ground and thus is common on both gate and drain circuits, giving negative feedback for the audio frequencies. The source resistor is bypassed for RF but not for audio, while the drain circuit is bypassed to ground for both audio and radio frequencies. An RF filter can be connected between the source and the output coupling capacitor to eliminate any RF that might otherwise appear in the output.

The drain current is very low with no signal but increases with signal as in the case of the plate detector. The voltage drop across the source resistor consequently increases with signal. Because of this and the large initial drop across this resistor, the signal usually cannot drive the gate positive with respect to the source.

### Product Detectors

A product detector is similar in function to a balanced or product modulator. It is also similar to a mixer. In fact, the latter is sometimes called a "first detector" in a receiver circuit. Product detectors are used principally for SSB, CW and RTTY FSK signal detection. Essentially, it is a detector whose output is equal to the product of the beat-frequency oscillator (BFO) and the RF signals applied to it. Output from the product detector is at audio frequency. Some RF filtering is necessary at the detector output to prevent unwanted IF or BFO voltage from reaching the audio amplifier which follows the detector. LC or RC RF decoupling networks are satisfactory, and they need not be elaborate. Fig. 22 illustrates this type of filtering.

### Diode Product Detectors

The product detectors shown in Fig. 21 are called "passive." The term means that the devices used do not require an operating voltage. Active devices (transistors, ICs and tubes) do require an operating voltage. Passive mixers and detectors exhibit a conversion loss, whereas active detectors can provide conversion gain. Passive detectors usually require a substantially greater level of BFO injection voltage than is the case with active detectors. Therefore, the primary drawbacks to the use of diodes in these circuits are the loss in gain and the high injection level required. A typical conversion loss for a two-diode detector (Fig. 21A) is 5 dB. The four-diode detectors have a loss of approximately 8 dB. The BFO injection level for each of the diode detectors shown in Fig. 21 is +13 dBm, or 20 mW.

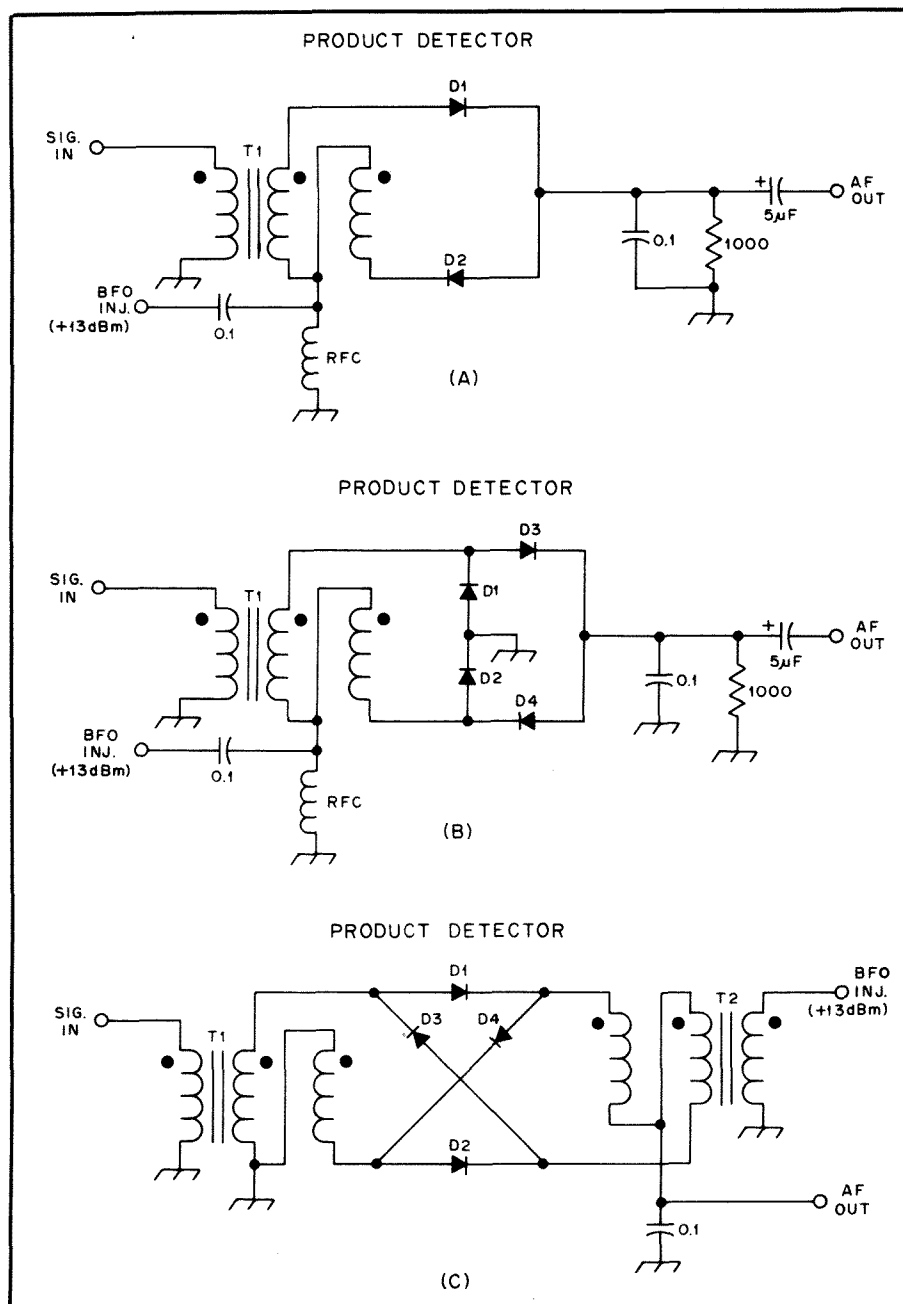

Fig. 21 — Examples of diode product detectors. Singly balanced types are shown at A and B. A doubly balanced version is illustrated at C.

Since the terminal impedance of the detector is roughly 50 ohms, an RMS BFO voltage of 1, or P-P voltage of 2.8, is required.

The advantages to the use of diodes in a product detector are circuit simplicity, low cost, broadband characteristics, low noise figure and good port-to-port signal isolation. This type of detector is excellent at the input of a direct-conversion receiver (to be treated later in the chapter).

The transformers shown in the circuits of Fig. 21 are broadband, toroidally wound types. The black dots near the windings of T1 and T2 indicate the phasing required. The core material is ferrite, and the windings are trifilar. Core permeability can be

950 for most applications, although some designers use cores with less initial permeability. An Amidon FT-50-43 is entirely suitable as a transformer core for the circuits shown. Fifteen trifilar turns are ample for each transformer.

High-speed silicon switching diodes are satisfactory for use in the circuits of Fig. 21. They should be as closely matched as possible for forward and back resistance. Closely matched diodes can be had by using a diode-array IC, such as the RCA CA3019 or 3039. Hot-carrier diodes are excellent for the circuits shown. Matched 1N914s are the choice of many amateur designers.

A singly balanced detector is shown at A in Fig. 21. An improved singly balanced

detector is shown at B. Two diodes have been added to improve the circuit balance while presenting a more symmetrical load to the BFO. The result is better isolation between the BFO and IF input ports.

Two broadband transformers are used to provide the doubly balanced detector of Fig. 21C. The advantage with this configuration is that all three ports are effectively isolated from one another.

### Simple Active Product Detectors

Fig. 22 contains two examples of single-ended active detectors that employ FETs. They are quite acceptable for use in simple receivers that do not require high performance characteristics. The circuit at A uses a JFET which has BFO injection voltage supplied across the source resistor. Because the source is not bypassed, instability can occur if the circuit is used as a mixer which has an IF that is close to the signal frequency. This problem is not apt to become manifest when the output is at audio frequency. Slightly more injection power is needed for circuit A than is necessary for the detector at B. An RMS voltage of roughly 0.8 is typical (6.5 mW).

The detector of Fig. 22B operates in a similar fashion to that of A, but the BFO is injected on control gate no. 2. Approximately 1 volt RMS is needed (0.1 mW). FETs with proper injection levels and moderate signal-input amounts have excellent IMD characteristics. Generally, they are preferred to single-ended, bipolar-transistor detectors. The circuits at A and B contain RF chokes and bypass capacitors in the drain leads to minimize the transfer of BFO energy to the succeeding audio stage. The bypass capacitors are also useful for rolling off the unwanted high-frequency audio components.

### Active Balanced Product Detectors

Examples of active IC product detectors are given in Fig. 23. A singly balanced version is shown at A. It uses an RCA differential-pair IC. Except for its conversion gain, it performs similarly to the singly balanced diode detector of Fig. 21B. Doubly balanced active detectors are seen at B and C of Fig. 23. These ICs contain two sets of differential amplifiers each. The "diffamps" are cross-connected in the examples shown to obtain double balanced circuits. The virtues of these detectors are similar to the equivalent four-diode types, but they exhibit several decibels of conversion gain. The MC1496G is made by Motorola, and the CA3102E is an RCA device.

### Other SSB Modes

An SSB transmitter is simply a frequency translator. Any frequency- or amplitude-varying signal (within the bandwidth capabilities of the transmitter) applied to the input will be translated intact (although frequency inversion takes place in LSB) to the chosen radio frequency. If amplitude-

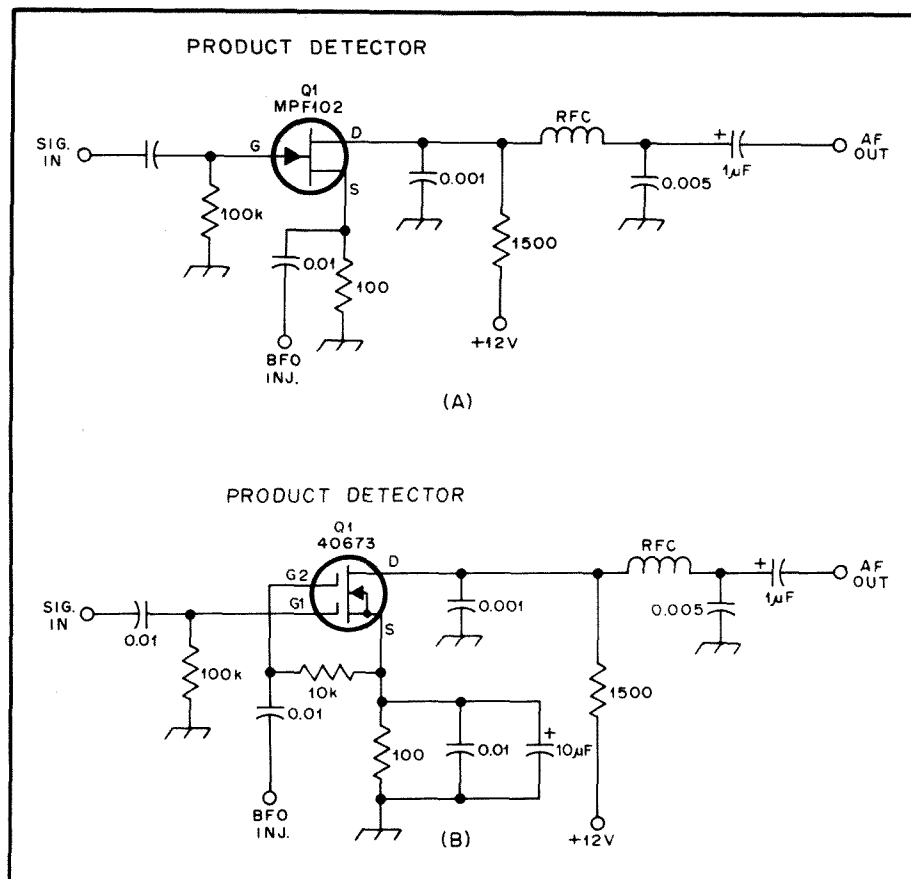

Fig. 22 — Active product detectors. A JFET example is provided at A and a dual-gate MOSFET type is at B.

limited tones corresponding to the video information of a slow-scan television picture are fed into the microphone input, F3F emission will result. Two alternating tones from an AFSK RTTY keyer will cause the transmitter to produce an F1B signal. A keyed audio tone will be translated into an A1A signal. This technique is a perfectly legitimate way to operate CW with an SSB transceiver, and is simpler than the more traditional method of upsetting the balanced modulator for carrier leakage. One can vary the transmitting frequency independently of the receiving frequency by means of changing the audio tone. The strength of the tone determines the transmitter power output. Good engineering practice requires that the tone be frequency-stable and that the total harmonic distortion be less than 1%. Also, the carrier and opposite sideband must be suppressed at least 40 dB. Of course the rise and decay times of the audio envelope must be controlled to avoid key clicks.

#### Independent-Sideband Emission

If two SSB exciters, one USB and the other LSB, share a common carrier oscillator, two channels of information can be transmitted from one antenna. Methods for ISB generation in filter and phasing transmitters are shown in Fig. 24. May 1977 *QST* carried an article on converting the

popular Drake TR-4C to ISB.

Many commercially manufactured SSB transceivers have provisions for controlling the transmit or receive frequency with an external VFO or receiver. With slight modification it should be possible to slave two transceivers to a single VFO for ISB operation. The oscillators in the transceivers must be aligned precisely.

The most obvious amateur application for independent sideband is the transmission of slow-scan television with simultaneous audio commentary. On the VHF bands, other combinations are possible, such as voice and code or SSTV and RTTY.

#### Power Ratings of SSB Transmitters

Fig. 25A is more or less typical of a few voice-frequency cycles of the modulation envelope of a single-sideband signal. Two amplitude values associated with it are of particular interest. One is the maximum peak amplitude, the greatest amplitude reached by the envelope at any time. The other is the average amplitude, which is the average of all the amplitude values contained in the envelope over some significant period of time, such as the time of one syllable of speech.

The power contained in the signal at the maximum peak amplitude is the basic transmitter rating. It is called the peak-

envelope power, abbreviated PEP. The peak-envelope power of a given transmitter is intimately related to the distortion considered tolerable. The lower the signal-to-distortion ratio the lower the attainable peak-envelope power as a general rule. For splatter reduction, an S/D ratio of 25 dB is considered a border-line minimum, and better figures are desirable.

The signal power, *S*, in the classical definition of S/D ratio is the power in one tone of a two-tone test signal. This is 6 dB below the peak-envelope power in the same signal. Manufacturers of amateur SSB equipment usually base their published S/D ratios on PEP, thereby getting an S/D ratio that looks 6 dB better than one based on the classical definition. *QST* product reviews also use the PEP reference. In comparing distortion-product ratings of different transmitters or amplifiers, first make sure the ratios have the same base.

#### Peak vs. Average Power

Envelope peaks occur only sporadically during voice transmission, and have no direct relationship to meter readings. The meters respond to the amplitude (current or voltage) of the signal averaged over several cycles of the modulation envelope. (This is true in practically all cases, even though the transmitter RF output meter may be calibrated in watts. Unfortunately, such a calibration means little in voice transmission since the meter can be calibrated in watts only by using a sine wave — which a voice-modulated signal definitely is not.)

The ratio of peak-to-average amplitude varies widely with voices of different characteristics. In the case shown in Fig. 25 the average amplitude, found graphically, is such that the peak-to-average ratio of amplitudes is almost 3:1. The ratio of peak power to average power is something else again. There is no simple relationship between the meter reading and actual average power, for the reason mentioned earlier. See Chapter 2 for a complete discussion of computing PEP.

#### Testing a Sideband Transmitter

There are three commonly used methods for testing an SSB transmitter. These include the wattmeter, oscilloscope and spectrum-analyzer techniques. In each case, a two-tone test signal is fed into the mic input to simulate a speech signal. From the measurements, information concerning such quantities as PEP and intermodulation-distortion-product (IMD) levels can be obtained. Depending on the technique used, other aspects of transmitter operation (such as hum problems and carrier balance) can also be checked.

As might be expected, each technique has both advantages and disadvantages and the suitability of a particular method will depend on the desired application. The wattmeter method is perhaps the simplest one but it also provides the least amount of in-

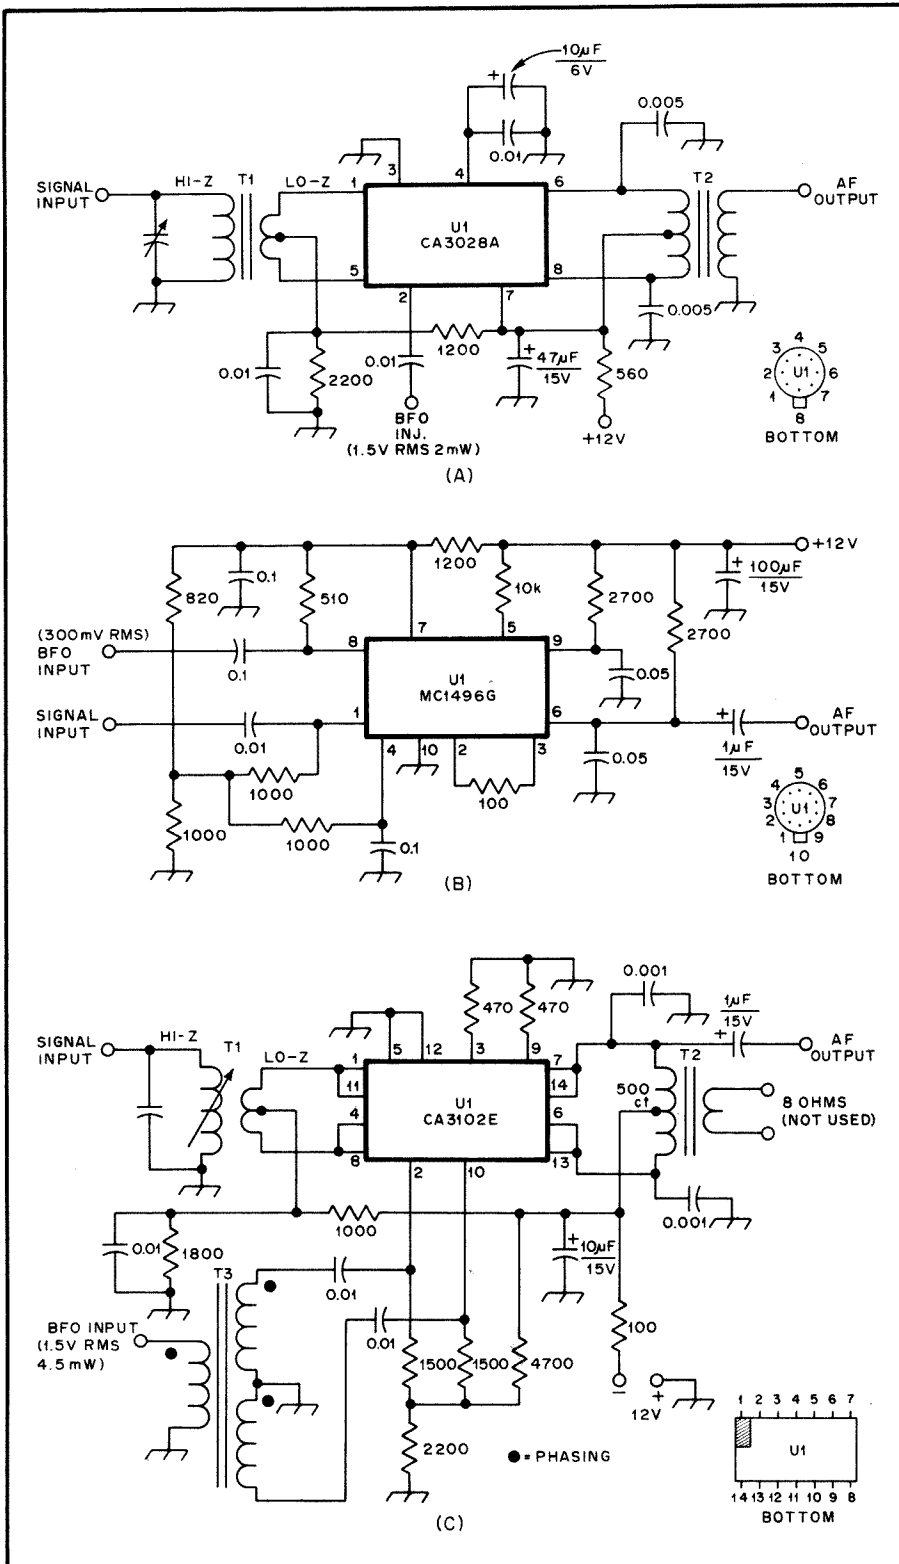

Fig. 23 — Examples of IC product detectors. At A is a singly balanced version, while those at B and C are doubly balanced.

formation. RF wattmeters suitable for single-tone or CW operation may not be accurate with a two-tone test signal. A suitable wattmeter for the latter case must have a reading that is proportional to the actual power consumed by the load. The reading must be independent of signal

waveform. A thermocouple ammeter connected in series with the load would be a typical example of such a system. The output power would be equal to  $I^2R$ , where  $I$  is the current in the ammeter and  $R$  is the load resistance (usually 50 ohms). In order to find the PEP output with the latter

method (using a two-tone test input signal), the power output is multiplied by two.

A spectrum analyzer is capable of giving the most information (of the three methods considered here), but it is also the most costly method and the one with the greatest chance of misinterpretation. Basically, a spectrum analyzer is a receiver with a readout that provides a plot of signal amplitude vs. frequency. The readout could be in the form of a paper chart but usually it is presented as a trace on a CRT. For a spectrum analyzer to provide accurate information about a signal, that signal must be well within the linear dynamic range of the analyzer. For an explanation of the function and application of this instrument see Chapter 25.

### Two-Tone Tests and Scope Patterns

A very practical method for amateur applications is to use a two-tone test signal (usually audio) and sample the transmitter output. The sample is then applied directly to the vertical-deflection plates in an oscilloscope. An alternative method is to use an RF probe and detector to sample the waveform and apply the resulting audio signal to the vertical-deflection amplifier input.

If the amplifier has good linearity, the resulting envelope will approach a perfect sine wave pattern (see Fig. 26A). As a comparison, a spectrum-analyzer display for the same transmitter and under the same conditions is shown in Fig. 26B. In this case, spurious products approximately 30 dB below the amplitude of each of the tones can be seen.

As the distortion increases, so does the level of the spurious products, and the resulting waveform departs from a true sine-wave function. This can be seen in Fig. 26C. One of the disadvantages of the scope and two-tone test method is that a relatively high level of IMD-product voltage is required before the waveform seems distorted to the eye. For instance, the waveform in Fig. 26C doesn't seem too much different from the one in Fig. 26A but the IMD level is only 17 dB below the level of the desired signal (see analyzer display in Fig. 26D). A 17- to 20-dB level corresponds to approximately 10% distortion in the voltage waveform. Consequently, a "good" waveform means the IMD products are at least 30 dB below the desired tones. Any noticeable departure from the waveform in Fig. 26A should be suspect, and the transmitter operation should be checked.

The relation between the level at which distortion begins for the two-tone test signal and an actual voice signal is a rather simple one. The maximum deflection on the scope is noted (for an acceptable two-tone test waveform) and the transmitter is then operated such that voice peaks are kept below this level. If the voice peaks go above this level, a type of distortion called "flattopping" will occur. Results are shown for a two-tone test signal in

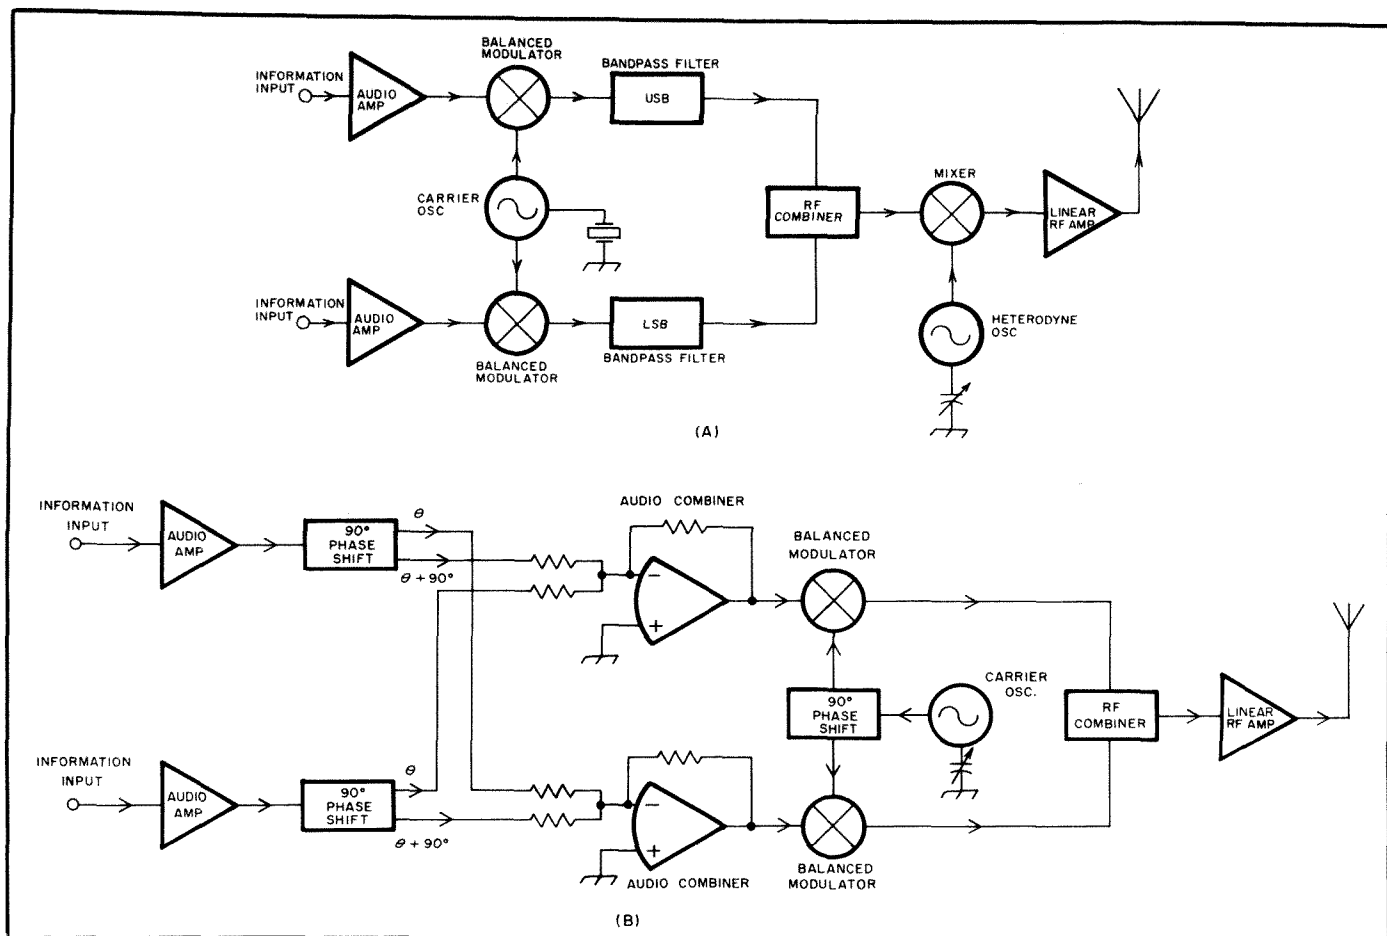

Fig. 24 — Independent-sideband generators. (A) Filter system. (B) Phasing system. The block marked "RF combiner" can be a hybrid combiner or a summing amplifier.

Fig. 25 — (A) Typical SSB voice-modulated signal might have an envelope of the general nature shown, where the RF amplitude (current or voltage) is plotted as a function of time, which increases to the right horizontally. (B) Envelope pattern after speech processing to increase the average level of power output.

Fig. 26E. IMD-product levels rise very rapidly when flattopping occurs. For instance, third-order product levels will increase 30 dB for every 10-dB increase in desired output as the flattopping region is approached, and fifth-order terms will increase by 50 dB.

#### Interpreting Distortion Measurements

Unfortunately, considerable confusion has grown concerning the interpretation and importance of distortion in SSB gear. Distortion is a very serious problem when high spurious-product levels exist at frequencies removed from the passband of the desired channel. In this case, such distortion may cause needless interference to other channels ("splatter"), and should be avoided. This can be seen quite clearly in Fig. 26F, where the flattopping region is approached and the fifth and higher order terms increase dramatically. The situation is less serious if such products fall within the bandwidth of operation.

On the other hand, attempting to suppress in-band products more than necessary is not only difficult to achieve but may not result in any noticeable increase in signal quality. In addition, measures required to

suppress in-band IMD often cause problems at the expense of other qualities such as efficiency. This can lead to serious difficulties such as shortened tube life or transistor heat-dissipation problems.

The two primary causes of distortion can be seen in Fig. 27. While the waveform is for a single-tone input signal, similar effects occur for the two-tone case. As the drive signal is increased, a point is reached at which the output current (or voltage) cannot follow the input, and the amplifier saturates. As mentioned earlier, this condition is often referred to as flattopping. It can be prevented by ensuring that excessive drive doesn't occur; the usual means of accomplishing this is by ALC action. The ALC provides a signal that is used to lower the gain of earlier stages in the transmitter.

The second type of distortion is called "crossover" distortion and occurs at low signal levels. (See Fig. 27.) Increasing the idling plate or collector current is one way of reducing the effect of crossover distortion in regards to producing undesirable components near the operating frequency. Instead, the components occur at frequencies considerably removed from the

(A)

(B)

Fig. 28 — Speech pattern of the word "X" in a properly adjusted SSB transmitter.

(C)

(D)

Fig. 29 — Severe clipping (same transmitter as Fig. 22 but with high drive and ALC disabled).

(E)

(F)

Fig. 26 — Scope patterns for a two-tone test signal and corresponding spectrum-analyzer displays. The pattern in A is for a properly adjusted transmitter and consequently the IMD products are relatively low as can be seen on the analyzer display. At C, the PA bias was set to zero idling current and considerable distortion can be observed. Note how the pattern has changed on the scope and the increase in IMD level. At E, the drive level was increased until the flattopping region was approached. This is the most serious distortion of all since the width of the IMD spectrum increases considerably, causing splatter (F).

Fig. 27 — Waveform of an amplifier with a single-tone input showing flattopping and crossover distortion.

operating frequency and can be eliminated by filtering.

As implied in the earlier discussion, the effect of distortion is to generate frequency components that add or subtract in order to make up the complex waveform. A more familiar example would be the harmonic generation caused by the nonlinearities often encountered in amplifiers. However, a common misconception that should be avoided is that IMD is caused by fundamental-signal components beating with harmonics. Generally speaking, no such simple relation exists. For instance, single-ended stages have relatively poor second-harmonic suppression but with proper biasing to increase the idling current, such stages can have very good IMD-suppression qualities.

However, a definite mathematical relation does exist between the desired com-

ponents in an SSB signal and the "distortion signals." Whenever nonlinearities exist, products between the individual components which make up the desired signal will occur. The mathematical result of such multiplication is to generate other signals of the form  $(2f_1 - f_2)$ ,  $(3f_1)$ ,  $(5f_2 - f_1)$  and so on. Hence the term intermodulation-distortion products. The "order" of such products is equal to the sum of the multipliers in front of each frequency component. For instance, a term such as  $(3f_1 - 2f_2)$  would be called a fifth-order term, since  $3 + 2$  is equal to 5. In general, the third, fifth, seventh and similar "odd-order" terms are the most important ones since some of these fall near the desired transmitter output frequency and can't be eliminated by filtering. As pointed out previously, such terms do not normally result from fundamental components beating with harmonics. An exception would be when the fundamental signal along with its harmonics is applied to another nonlinear stage such as a mixer. Components at frequencies identical to the IMD products will result.

When two equal tones are applied to an amplifier and the result is displayed on a spectrum analyzer, the IMD products appear as "pips" off to the side of the main signal components (Fig. 26). The amplitudes associated with each tone and the IMD products are merely the decibel difference between the particular product and one tone. However, each desired tone is 3 dB down from the average power out-

put and 6 dB down from the PEP output.

Since PEP represents the most important quantity as far as IMD is concerned, relating IMD-product levels to PEP is one logical way of specifying the "quality" of a transmitter or amplifier in regard to low distortion. For instance, IMD levels are referenced to PEP in "Product Review" specifications of commercially made gear in *QST*. PEP output can be found by multiplying the PEP input by the efficiency of the amplifier. The input PEP for a two-tone test signal is given by

$$\text{PEP} = \frac{E_p I_p}{n} \left[ 1.57 - 0.57 \frac{I_o}{I_p} \right]$$

where

$E_p$  = plate voltage

$I_p$  = average plate current

$I_o$  = idling (zero signal) plate current

$n$  = duty cycle of test tones (= 1.0 for steady two-tone test, 0.5 for 50% duty cycle, etc)

The inclusion of a factor for test-tone duty cycle allows calculation of amplifier PEP input with the application of *pulsed* test tones. (Pulsed tones result in lower average power input, and this allows longer test periods if the amplifier under test cannot tolerate continuous operation at maximum PEP input. See Goodman, "Pulsed Signals Through S.S.B. Transmitters," *QST*, Sept 1965, pp 18-19.) If continuous test tones are used,  $n = 1.0$ .

Generally speaking, most actual voice

patterns will look alike (in the presence of distortion) except in the case where severe flattopping occurs. This condition is not too common since most rigs have an ALC system, which prevents overdriving the amplifiers. However, the voice pattern in a properly adjusted transmitter usually has a "Christmas tree" shape when observed on a scope; an example is shown in Fig. 28.

### More Information

Further discussion on measurements, including FCC power measurement procedures, can be found in Chapter 25. For a discussion of voice processing see Chapter 7. Equipment and accessory construction projects are presented in Chapters 27 through 34.

## Amplitude Compandored Single Sideband

There has not been much said about Amplitude Compandored Single Sideband (ACSSB) in Amateur Radio literature. However, amateur experimenters should be aware of ACSSB developments now underway in the land-mobile communications industry.

SSB is the standard mode for HF voice communications. Amateurs have used SSB at VHF and UHF with good success but usually between fixed locations and experienced operators. When SSB was tried in the Land Mobile Service, several problems were noticed. One was that the users (who are not trained operators) couldn't master the control known as CLARIFIER to land-mobile people and receiver incremental tuning or RIT to amateurs. In addition, the users were annoyed by the fading and noise experienced with SSB over the FM they were familiar with. So, to get the spectrum savings of SSB over FM, the land-mobile engineers had to come up with a form of SSB that gave the land-mobile users everything that they were accustomed to with FM, including signaling.

### Pilot Tone

A conventional SSB transmission has a suppressed carrier. In order to demodulate the signal at the receiver, the missing carrier is replaced. At higher frequencies it is unrealistic to expect the original carrier at the transmitter and that reinserted at the receiver to be exactly the same. As mentioned above, adding a knob to compensate for the error is unacceptable for land-mobile service. So manufacturers have added a pilot tone to the audio, sufficiently separated in frequency and filtered so that the two do not interfere with each other. The pilot tone is usually 3.1 kHz. As shown

Fig. 30 — Bandwidth of an ACSSB signal is 3.1 kHz.

in Fig. 30, the pilot power level is about 10 dB below the voice peak power. Thus, the transmitter has an output power of approximately 1/10th of maximum when there is no voice modulation.

At the receiver, the pilot tone is compared with an internal reference oscillator in a phase-locked-loop circuit. The difference voltage thus produced is used to shift the receiver local oscillator until the frequency error is eliminated. The time constant of the phase-locked loop is short enough to be ignored by the user and to be compatible with tone decoders used for signaling purposes.

The pilot tone serves other functions than locking the receiver on frequency. It is used to control squelch and AGC circuits

as well. The pilot tone can also be modulated for signaling or telemetry transmission — a useful feature in logic-controlled systems.

### Amplitude Compandoring

Compression of voice signals is common in Amateur Radio SSB. What is not common in amateur SSB is to employ an expander at the receiving end. The term "compandor" is a fusion of the terms "compressor" and "expandor." The compandor circuitry provides an operator with a sensation similar to the "capture effect" in FM. Thus, when the signal strengths are high, FM and ACSSB give comparable results with noticeably less flutter on ACSSB than on FM. A detailed discussion of compandor operation is included in Chapter 7.

### In Operation

The FCC has made tests of ACSSB in direct comparison with FM under actual operating conditions. Preliminary results indicate that with equal power (PEP and carrier), range and capture effect are about the same. ACSSB is quieter until lock is lost; in the fringe area, noise begins to appear on voice peaks (because of compandoring).

ACSSB is a means of packing about four times more voice transmission in a given band than FM. The pilot tones and compandoring compensate for some inherent SSB shortcomings but with additional complexity. This appears to be an interesting area for Amateur Radio experimentation.

## Frequency Modulation

Methods of radiotelephone communication by frequency modulation were developed in the 1930s by Major Edwin Armstrong in an attempt to reduce the problems of static and noise associated with receiving AM broadcast transmissions. The primary advantage of FM, the ability to produce a high signal-to-noise ratio when receiving a signal of only moderate strength, has made FM the mode chosen for mobile communications services and quality broadcasting. The disadvantages (the wide bandwidth required and the sometimes poor results obtained when an FM signal is propagated via the ionosphere because of phase distortion), have limited the use of frequency modulation to the 10-meter band and the VHF/UHF section of the spectrum.

FM has some impressive advantages for VHF operation, especially when compared to AM. With FM, the modulation process takes place in a low-level stage and remains the same, regardless of transmitter power. The signal may be frequency multiplied after modulation, and the PA stage can be operated Class C for best efficiency, as the "final" need not be linear.

In recent years there has been increasing use of FM by amateurs operating around 29.6 MHz. The VHF spectrum now in

popular use includes 52 to 54 MHz, 146 to 148 MHz, 222 to 225 MHz, and 440 to 450 MHz.

### Frequency and Phase Modulation

It is possible to convey intelligence by modulating any property of a carrier, including its frequency and phase. When the frequency of the carrier is varied in accordance with the variations in a modulating signal, the result is frequency modulation (FM). Similarly, varying the phase of the carrier current is called phase modulation (PM). Frequency and phase modulation are not independent, since the frequency cannot be varied without also varying the phase, and vice versa.

### Frequency Modulation

When a modulating signal is applied to an FM modulator, the carrier frequency is increased during one half cycle of the modulating signal and decreased during the half cycle of opposite polarity. The change in the carrier frequency (frequency deviation) is proportional to the instantaneous amplitude of the modulating signal. Thus, the deviation is small when the instantaneous amplitude of the modulating signal is small, and is greatest when the modulating signal reaches its peak, either positive or negative.

### Phase Modulation

If the phase of the current in a circuit shifts, there is an instantaneous frequency change during the time that the phase is shifting. The amount of frequency change, or deviation, is directly proportional to how rapidly the phase is shifting and the total amount of the phase shift. The rapidity of the phase shift is directly proportional to the frequency of the modulating signal. Further, in a properly operating PM system the amount of phase shift is proportional to the instantaneous amplitude of the modulating signal. This means that the amount of frequency change, or deviation, caused by a phase modulator, is directly proportional to both the instantaneous voltage and the frequency of the modulating signal. This is the outstanding difference between FM and PM, since in

FM the frequency deviation is proportional only to the amplitude of the modulating signal. See Chapter 9 for further discussion of this and related topics.

## FREQUENCY MODULATION METHODS

### Direct FM

A simple, satisfactory device for producing FM in an amateur transmitter is the reactance modulator. This is a vacuum tube or transistor connected to the RF tank circuit of an oscillator in such a way as to act as a variable inductance or capacitance.

Fig. 32A is a representative circuit. Gate 1 of the modulator MOSFET is connected across the oscillator tank circuit, C1/L1, through resistor R1 and blocking capacitor C2. C3 represents the input capacitance of the modulator transistor. The resistance of R1 is large compared to the reactance of C3, so the RF current through R1/C3 will be practically in phase with the RF voltage appearing at the terminals of the tank circuit. However, the voltage across C3 will lag the current by 90 degrees. The RF current in the drain circuit of the modulator will be in phase with the grid voltage, and consequently is 90 degrees behind the current through C3, or 90 degrees behind the RF tank voltage. This lagging current is drawn through the oscillator tank, giving the same effect as though an inductance were connected across the tank. The frequency increases in proportion to the amplitude of the lagging plate current of the modulator. The audio voltage, introduced through a radio-frequency choke, varies the transconductance of the transistor and thereby varies the RF drain current.

The modulated oscillator usually is operated on a relatively low frequency, so a high order of carrier stability can be secured. Frequency multipliers are used to raise the frequency to the final frequency desired.

A reactance modulator can be connected to a crystal oscillator as well as to the self-controlled type as shown in Fig. 32B. However, the resulting signal can be more phase-modulated than it is frequency-

Fig. 31 — Portability and reliability make 2-meter FM hand-held operation a natural for supplying communications during emergencies, particularly when normal lines of communication are disrupted and access to the affected area is limited. (KB4GJH photo)

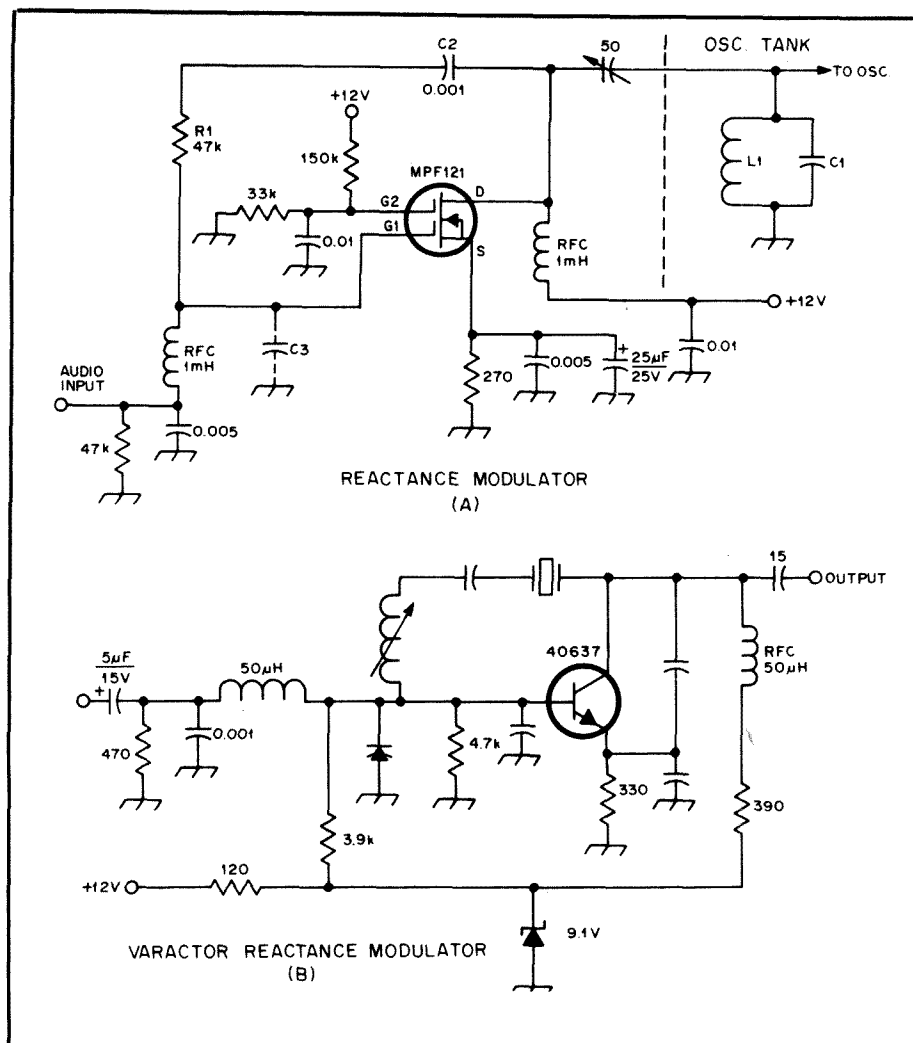

Fig. 32 — Reactance modulators using (A) a high-transconductance MOSFET and (B) a varactor diode.

modulated, because the frequency deviation that can be secured by varying the frequency of a crystal oscillator is quite small.

The sensitivity of the modulator (frequency change per unit change in modulating voltage) depends on the transconductance of the modulator transistor. It increases when R1 is made smaller in comparison with C3. It also increases with an increase in LC ratio in the oscillator tank circuit. However, for highest carrier stability it is desirable to use the largest tank capacitance that will permit the desired deviation to be secured while keeping within the limits of linear operation.

A change in any of the voltages on the modulator transistor will cause a change in RF drain current, and consequently a frequency change. Therefore it is advisable to use a regulated power supply for both modulator and oscillator.

#### Indirect FM

The same type of reactance-tube circuit that is used to vary the tuning of the oscillator tank in FM can be used to vary the tuning of an amplifier tank and thus vary the phase of the tank current for PM.

Hence the modulator circuit of Fig. 32A or 33A can be used for PM if the reactance transistor or tube works on an amplifier tank instead of directly on a self-controlled oscillator. If audio shaping is used in the speech amplifier, as described above, an FM-compatible signal will be generated by the phase modulator.

The phase shift that occurs when a circuit is detuned from resonance depends on the amount of detuning and the Q of the circuit. The higher the Q, the smaller the amount of detuning needed to secure a given number of degrees of phase shift. If the Q is at least 10, the relationship between phase shift and detuning (in kilohertz either side of the resonant frequency) will be substantially linear over a phase-shift range of about 25 degrees.

From the standpoint of modulator sensitivity, the tuned circuit Q on which the modulator operates should be as high as possible. On the other hand, the effective Q of the circuit will not be very high if the amplifier is delivering power to a load since the load resistance reduces the Q. There must therefore be a compromise between modulator sensitivity and RF power out-

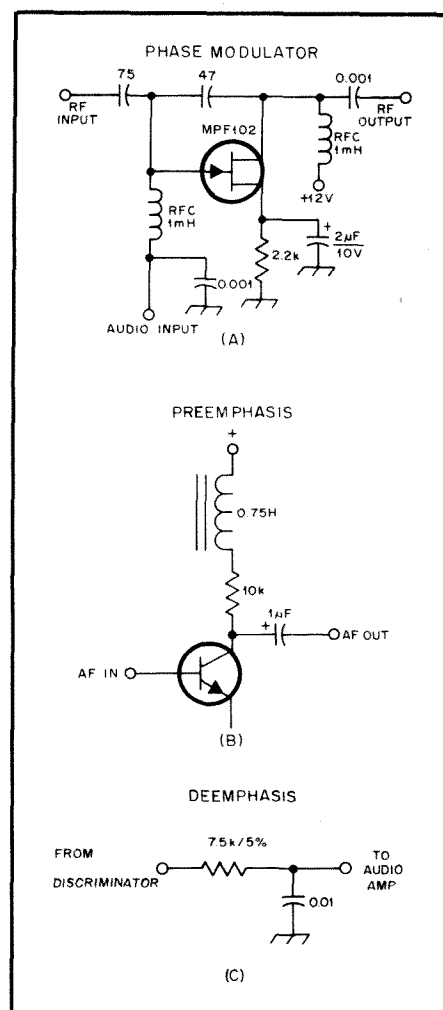

Fig. 33 — (A) The phase-shifter type of phase modulator. (B) preemphasis and (C) deemphasis circuits.

put from the modulated amplifier. An optimum Q figure appears to be about 20; this allows reasonable loading of the modulated amplifier, and the necessary tuning variation can be secured from a reactance modulator without difficulty. It is advisable to modulate at a low power level.

Reactance modulation of an amplifier stage usually results in simultaneous amplitude modulation because the modulated stage is detuned from resonance as the phase is shifted. This must be eliminated by feeding the modulated signal through an amplitude limiter or one or more saturating stages — that is, amplifiers that are operated Class C and driven hard enough so that variations in the amplitude of the input excitation produce no appreciable variations in the output amplitude.

For the same type of reactance modulator, the speech-amplifier gain required is the same for PM as for FM. However, since the actual frequency deviation increases with the modulating audio frequency in PM, it is necessary to cut off the frequencies above about 3000 Hz before modulation takes place. If this is not done,

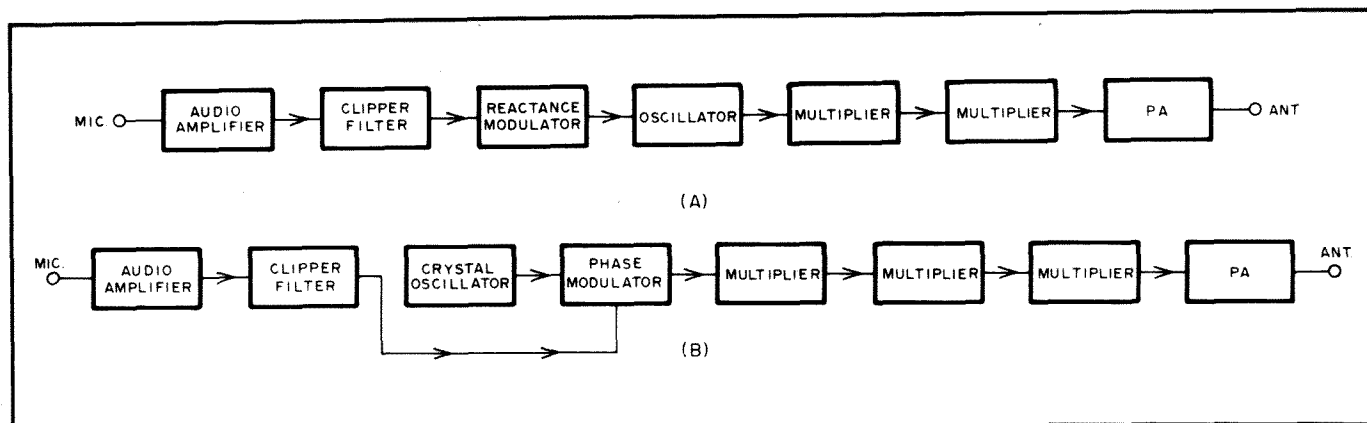

Fig. 34 — Block diagrams of typical FM exciters.

unnecessary sidebands will be generated at frequencies considerably removed from the carrier.

### Speech Processing for FM

The speech amplifier that feeds the modulator is of ordinary design, except that no power is taken from it and the AF voltage required by the modulator input usually is small — only a volt or two for transistors. Because of these modest requirements, only a few speech stages are needed; a two-stage amplifier consisting of two bipolar transistors, both resistance-coupled, will more than suffice for crystal ceramic or Hi-Z dynamic microphones.

Several forms of speech processing produce worthwhile improvements in FM system performance. It is desirable to limit the peak amplitude of the audio signal applied to an FM or PM modulator, so that the deviation of the FM transmitter will not exceed a preset value. This peak limiting is usually accomplished with a simple audio clipper placed between the speech amplifier and modulator.

The clipping process produces high-order harmonics which, if allowed to pass through to the modulator stage, would create unwanted sidebands. Therefore, an audio low-pass filter with a cut-off frequency between 2.5 and 3 kHz is needed at the output of the clipper. Excess clipping can cause severe distortion of the voice signal. An audio processor consisting of a compressor and a clipper has been found to produce audio with a better sound (less distortion) than a clipper alone.

To reduce the amount of noise in some FM communication systems, an audio shaping network called preemphasis is added at the transmitter to proportionally attenuate the lower audio frequencies, giving an even spread to the energy in the audio band. This results in an FM signal of nearly constant energy distribution. Preemphasis applied to an FM transmitter will give the emission the deviation characteristics of PM. The reverse process, called deemphasis, is accomplished at the receiver to restore the audio to its original

relative proportions. See Fig. 33.

### FM Exciters

FM exciters and transmitters take two general forms. One, shown at Fig. 34A, consists of a reactance modulator which shifts the frequency of an oscillator to generate an FM signal directly. Successive multiplier stages provide output on the desired frequency, which is amplified by a PA stage. This system has a disadvantage in that, if the oscillator is free running, it is difficult to achieve sufficient stability for VHF use. If a crystal-controlled oscillator is employed, because the amount that the crystal frequency is changed is kept small, it is difficult to achieve equal amounts of frequency swing.

The indirect method of generating FM shown in Fig. 34B is currently popular. Shaped audio is applied to a phase modulator to generate FM. Since the amount of deviation produced is very small, a large number of multiplier stages is needed to achieve wide-band deviation at the operating frequency. In general, the system shown at A will require a less complex circuit than that at B, but the indirect method (B) often produces superior results.

### Testing an FM Transmitter

Accurate checking of the operation of an FM or PM transmitter requires different methods than the corresponding checks on an AM or SSB set. This is because the common forms of measuring devices either indicate amplitude variations only (a milliammeter, for example), or because their indications are most easily interpreted in terms of amplitude.

The quantities to be checked in an FM transmitter are the linearity and frequency deviation and the output frequency, if the unit uses crystal control. The methods of checking differ in detail.

### Frequency Checking

Channelized FM operation requires that a transmitter be held within a few hundred hertz of the desired channel even in the wide-band system. Having the transmitter

on the proper frequency is particularly important when operating through a repeater. The rigors of mobile and portable operation make a frequency check of a channelized transceiver a good idea at three-month intervals.

Frequency meters generally fall into two categories, the heterodyne type and the digital counter. Today the digital counter is used almost universally; units counting to over 500 MHz are available at relatively low cost in kit form. Even less expensive low-frequency counters can be employed by using a prescaler, a device that divides an input frequency by a preset ratio, usually 10 or 100. Many prescalers may be used at 148 MHz or higher, using a counter with a 2-MHz (or more) upper frequency limit. If the counting system does not have a sufficient upper frequency limit to measure the output of an FM transmitter directly, one of the frequency-multiplier stages can be sampled to provide a signal in the range of the measurement device. Alternatively, a crystal-controlled converter feeding an HF receiver that has accurate frequency readout can be employed, if a secondary standard is available to calibrate the receiving system.

### Deviation and Deviation Linearity

A simple deviation meter can be assembled following the diagram of Fig. 35A. This circuit was designed by K6VKZ. The output of a wide-band receiver discriminator (before any deemphasis) is fed to two amplifier transistors. The output of the amplifier section is transformer coupled to a pair of rectifier diodes to develop a dc voltage for the meter, M1. There will be an indication on the meter with no signal input because of detected noise, so the accuracy of the instrument will be poor on weak signals.

To calibrate the unit, signals of known deviation will be required. If the meter is to be set to read 0-15 kHz, then a 7.5-kHz deviation test signal should be employed. R1 is then adjusted until M1 reads half scale, 50  $\mu$ A. To check the peak deviation of an incoming signal, close both S1 and

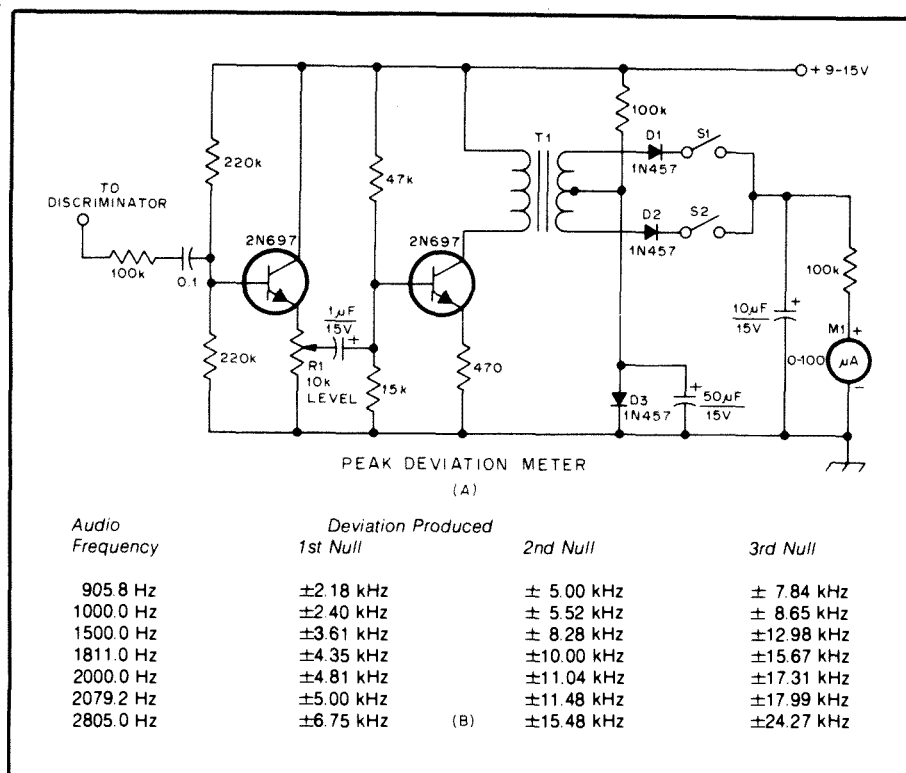

Fig. 35 — (A) Schematic diagram of the deviation meter. Resistors are 1/2-watt composition, and capacitors are ceramic, except those with polarity marked, which are electrolytic. D1-D3, incl., are high-speed silicon switching diodes. R1 is a linear-taper composition control, and S1, S2 are SPST toggle switches. T1 is a miniature audio transformer with 10-kΩ primary and 20-kΩ center-tapped secondary (Triad A31X). (B) Chart of audio frequencies that will produce a carrier null when the deviation of an FM transmitter is set for the values given.

S2. Then, read the meter. Opening first one switch and then the other will indicate the amount of positive and negative deviation of the signal, a check of deviation linearity.

### Measurement of Deviation Using Bessel Functions

Using a mathematical relationship known as the Bessel Function it is possible to predict the points at which, with certain audio-input frequencies and predetermined deviation settings, the carrier output of an FM transmitter will disappear completely. Thus, by monitoring the carrier frequency with a receiver, it will be possible to identify aurally the deviation at which the carrier is nulled. A heterodyne signal at either the input or receiver IF is required so the carrier will produce a beat tone that can be identified easily. Other tones will be produced in the modulation process, so some concentration is required when making the test. With an audio tone selected from the chart (Fig. 35B), advance the deviation control slowly until the first null is heard. If a higher-order null is desired, continue advancing the control further until the second, and then the third, null is heard. Using a carrier null beyond the third is generally not practical.

For example, if a 905.8-Hz tone is used, the transmitter will be set for 5-kHz deviation when the second null is reached. The second null achieved with a 2805-Hz audio

input will set the transmitter deviation at 15.48 kHz. The Bessel-function approach can be used to calibrate a deviation meter, such as the unit shown in Fig. 35A.

### Reception of FM Signals

Receivers for FM signals differ from others principally in two features — there is no need for linearity preceding detection (it is, in fact, advantageous if amplitude variations in signal and background noise can be minimized). Also, the detector must be capable of converting frequency variations of the incoming signal into amplitude variations.

Frequency-modulated signals can be received after a fashion on any ordinary receiver. The receiver is tuned to put the carrier frequency halfway down on one side of the selectivity curve. When the frequency of the signal varies with modulation it swings as indicated in Fig. 36, resulting in an AM output varying between X and Y. This is then rectified as an AM signal.

With receivers having steep-sided selectivity curves, the method is not very satisfactory because the distortion is quite severe unless the frequency deviation is small, since the frequency deviation and output amplitude is linear over only a small part of the selectivity curve.

### The FM Receiver

Block diagrams of an AM/SSB and an

Fig. 36 — FM detector characteristics. Slope detection, using the sloping side of the receiver's selectivity curve to convert FM to AM for subsequent detection.

FM receiver are shown in Fig. 37. Fundamentally, to achieve a sensitivity of less than 1 μV, an FM receiver requires a gain of several million — too much total gain to be accomplished with stability on a single frequency. Thus, the use of the super-heterodyne circuit has become standard practice. Three major differences will be apparent from a comparison of the two block diagrams. The FM receiver employs a wider-bandwidth filter and a different detector, and has a limiter stage added between the IF amplifier and the detector. Otherwise the functions, and often the circuits, of the RF, oscillator, mixer and audio stages will be the same in either receiver.

In operation, the noticeable difference between the two receivers is the effect of noise and interference on an incoming signal. From the time of the first spark transmitters, QRN has been a major problem for amateurs. The limiter and discriminator stages in an FM set can eliminate a good deal of impulse noise, except noise that manages to acquire a frequency-modulation characteristic. Accurate alignment of the receiver IF system and phase tuning of the detector are required to achieve good noise suppression. FM receivers perform in an unusual manner when QRM is present, exhibiting a characteristic known as the capture effect. The loudest signal received, even if it is only two or three times stronger than other stations on the same frequency, will be the only transmission demodulated. By comparison, an S9 AM or CW signal can suffer noticeable interference from an S2 carrier.

### Bandwidth

Most FM sets that use tubes achieve IF selectivity by using a number of over-coupled transformers. The wide bandwidth and phase-response characteristic needed in the IF system dictate careful design and

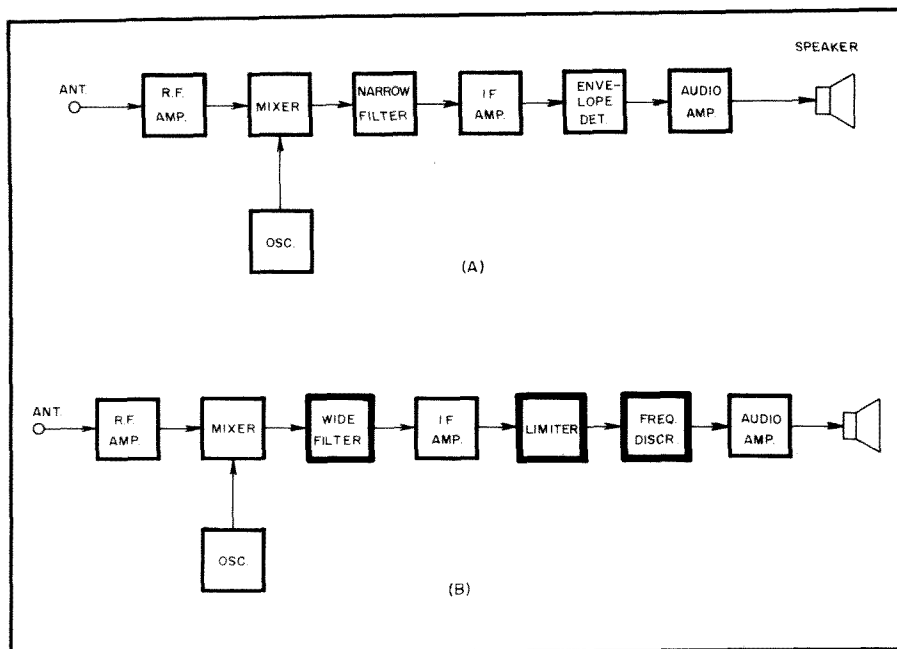

Fig. 37 — Block diagrams of (A) an AM, (B) an FM receiver. Dark borders outline the sections that are different in the FM set.

Fig. 38 — (A) Input wave form to a limiter stage shows AM and noise. (B) The same signal, after passing through two limiter stages, is devoid of AM components.

Fig. 39 — Representation of limiter action. Amplitude variations on the signal are removed by the diode action of the grid- and plate-current saturation.

adjacent-channel interference, especially in congested areas.

### Limiters

When FM was first introduced, the main selling point for the new mode was that noise-free reception was possible. The circuit in the FM receiver that has the task of chopping off noise and amplitude modulation from an incoming signal is the limiter. Most types of FM detectors respond to both frequency and amplitude variations of the signal. Thus, the limiter stages preceding the detector are included so only the desired frequency modulation will be demodulated. This action can be seen in Fig. 38.

Limiter stages can be designed using tubes, transistors or ICs. For an amplifier to act as a limiter, the applied voltages are chosen so the stage will overload easily, even with a small amount of signal input. As shown in Fig. 39, the input signal limits when it is of sufficient amplitude so that diode action of the input voltage and output current saturation clip both sides of the input signal, producing a constant-amplitude output voltage.

Obviously, a signal of considerable strength is required at the input of the limiter to assure full clipping, typically 1 volt for transistors and several hundred microvolts for ICs. Limiting action should start with an RF input of  $0.2 \mu\text{V}$  or less, so a large amount of gain is required between the antenna terminal and the limiter stages. For example, many commercial solid-state receivers use nine transistor stages for sufficient gain before the first limiter. The new ICs offer some simplification of the IF system, as they pack a lot of gain into a single package.

When sufficient signal arrives at the receiver to start limiting action, the set quiets — that is, the background noise disappears. The sensitivity of an FM receiver is rated in terms of the amount of input signal required to produce a given amount of quieting, usually 20 dB. Use of solid-state devices allows receivers to achieve 20 dB quieting with 0.15 to  $0.5 \mu\text{V}$  of input signal.

A single transistor amplifier stage will not provide good limiting over a wide range of input signals. Two stages, with different input time constants, are a minimum requirement. The first stage is set to handle impulse noise satisfactorily while the second is designed to limit the range of signals passed on by the first. At frequencies below 1 MHz it is useful to employ untuned RC-coupled limiters that provide sufficient gain without oscillation.

Fig. 40A shows a two-stage limiter using transistors in two stages biased for limiter service. The base bias on either transistor may be varied to provide limiting at a desired level. The input-signal voltage required to start limiting action is called the limiting knee. This refers to the point at which collector current ceases to rise with

alignment of all interstage transformers.

For the average ham, the use of a high-selectivity filter in a homemade receiver offers some simplification of the alignment task. Following the techniques used in SSB receivers, a crystal or ceramic filter should be placed in the circuit as close as possible to the antenna connector — at the output of the first mixer, in most cases. Table 5 lists a number of suitable filters available to amateurs. Experimenters who wish to build their own can use surplus HF crystals or ceramic resonators.

One item of concern to every amateur FM user is the choice of IF bandwidth for the receiver. Deviation of 5 kHz is now standard on the amateur bands above 29 MHz. A wide-band receiver can receive narrow-band signals, suffering only some loss of audio level in the detection process. Naturally, it also will be subject to

increased input signal. Modern ICs have limiting knees of 100 mV for the circuit shown in Fig. 40C, using the RCA CA3028A or Motorola MC1550G, or 200 mV for the MC1590G of Fig. 40D. Because the high-gain ICs such as the CA3076 and MC1590G contain as many as six or eight active stages that will saturate with sufficient input, one of these devices pro-

vides superior limiter performance compared to a pair of transistors.

#### Detectors

The first type of FM detector to gain popularity was the frequency discriminator. The characteristic of such a detector is shown in Fig. 41. When the FM signal has no modulation, and the carrier is at point

0, the detector has no output. When audio input to the FM transmitter swings the signal higher in frequency, the rectified output increases in the positive direction. When the frequency swings lower, the output amplitude increases in the negative direction. Over a range where the discriminator is linear (shown as the straight portion of the line), the conversion

Fig. 41 — The characteristic of an FM discriminator.

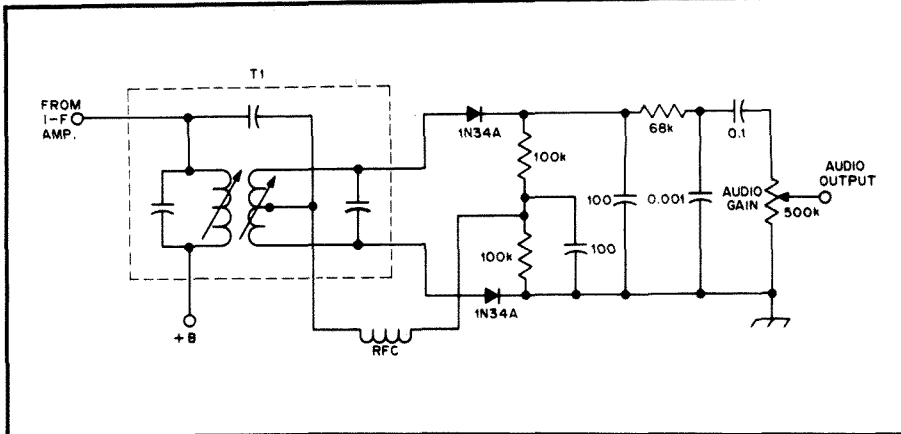

Fig. 42 — Typical frequency-discriminator circuit used for FM detection. T1 is a Miller 12-C45.

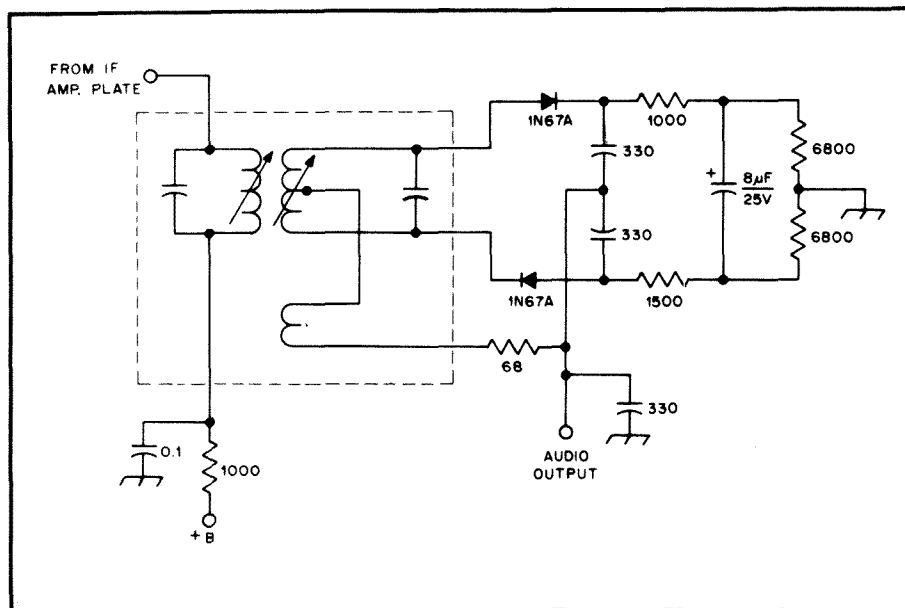

Fig. 43 — A ratio detector of the type often used in entertainment radio and TV sets. T1 is a ratio-detector transformer such as the Miller 1606.

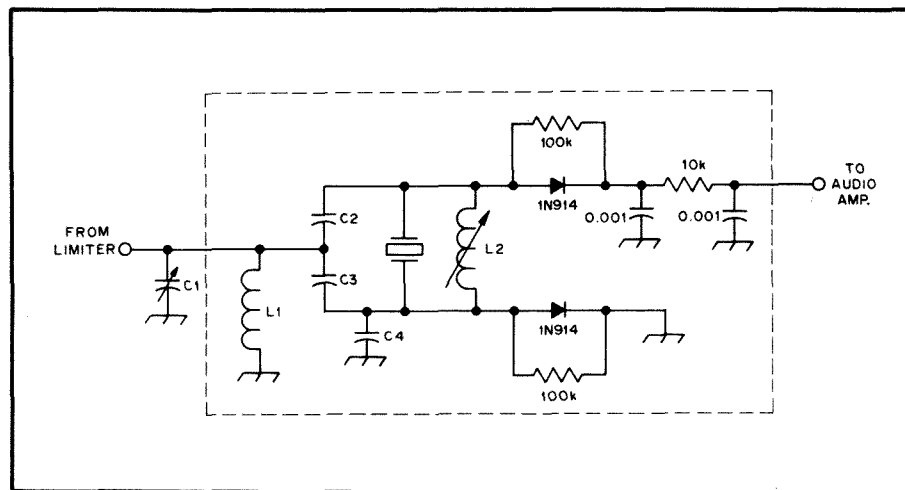

Fig. 44 — Crystal discriminator, C1 and L1 are resonant at the intermediate frequency. C2 is equal in value to C3. C4 corrects any circuit imbalance so equal amounts of signal are fed to the detector diodes.

of FM to AM will also be linear.

A practical discriminator circuit is shown in Fig. 42. The voltage induced in the T1 secondary is 90 degrees out of phase with the current in the primary. The primary signal is introduced through a center tap on the secondary, coupled through a capacitor. The secondary voltages combine on each side of the center tap so that the voltage on one side leads the primary signal while the other side lags by the same amount. When rectified, these two voltages are equal and of opposite polarity, resulting in zero-voltage output. A shift in input frequency causes a shift in the phase of the voltage components that results in an increase of output amplitude on one side of the secondary, and a corresponding decrease on the other side. The differences in the two changing voltages, after rectification, constitute the audio output.

In the search for a simplified FM detector, RCA developed a circuit that became standard in entertainment radios; it eliminated the need for a preceding limiter stage. Known as the ratio detector, this circuit is based on the idea of dividing a dc voltage into a ratio that is equal to the ratio of the amplitudes from either side of a discriminator-transformer secondary. With a detector that responds only to ratios, the input signal may vary in strength over a wide range without causing a change in the level of output voltage — FM can be detected, but not AM. In the actual ratio detector, Fig. 43, the required dc voltage is developed across two load resistors, shunted by an electrolytic capacitor. Other differences include the two diodes, which are wired in series aiding rather than series opposing, as in the standard discriminator circuit. The recovered audio is taken from a tertiary winding that is tightly coupled to the primary of the transformer. Diode-load resistor values are selected to be lower (5000 ohms or less) than for the discriminator.

The sensitivity of the ratio detector is one-half that of the discriminator. In general, however, the transformer design values for Q, primary-secondary coupling

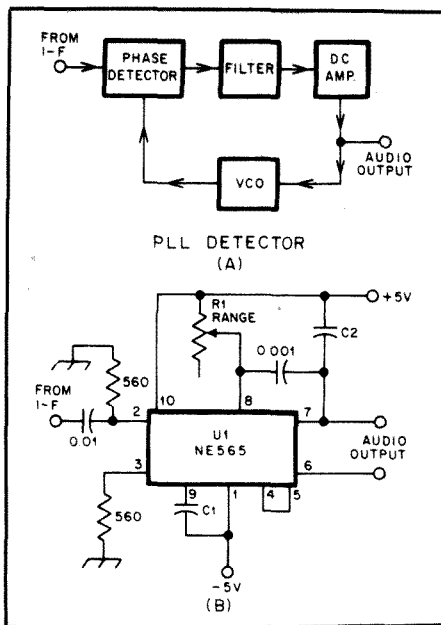

Fig. 45 — (A) Block diagram of a PLL demodulator. (B) Complete PLL circuit.

and load will vary greatly, so the actual performance differences between these two types of FM detectors are usually not significant. Either circuit can provide excellent results. In operation, the ratio detector will not provide sufficient limiting for

communications service, so this detector also is usually preceded by at least a single limiting stage.

#### Other Detector Designs

The difficulties often encountered in building and aligning LC discriminators have inspired research that has resulted in a number of adjustment-free FM detector designs. The crystal discriminator utilizes a quartz resonator, shunted by an inductor, in place of the tuned-circuit secondary used in a discriminator transformer. A typical circuit is shown in Fig. 44. Some commercially made crystal discriminators have the input-circuit inductor, L1, built in (C1 must be added), while in other types both L1 and C2 must be supplied by the builder. Fig. 44 shows typical component values; unmarked parts are chosen to give the desired bandwidth. Sources for crystal discriminators are listed in Table 5.

#### The PLL

Since the phase-locked loop (PLL) was reduced to a single IC package, it has made significant impact on receiver design. Signetics first introduced a PLL in a single flat-pack IC. Motorola and Fairchild are making the PLL in separate building-block ICs. These allow a builder to assemble an

FM receiving system with a minimum of bother.

A basic phase-locked loop consists of a phase detector, a filter, a dc amplifier and a voltage-controlled oscillator (VCO). The VCO runs at a frequency close to that of an incoming signal. The phase detector produces an error voltage if any frequency difference exists between the VCO and the IF signal. This error voltage is applied to the VCO. Any changes in the frequency of the incoming signal are sensed at the detector and the error voltage readjusts the VCO frequency so it remains locked to the intermediate frequency. The bandwidth of the system is determined by a filter on the error-voltage line. See Fig. 45.

Because the error voltage is a copy of the audio variations originally used to shift the frequency of the transmitter, the PLL functions directly as an FM detector. The sensitivity achieved with the Signetics NE565 PLL is good — about 1 mV for a typical circuit. No transformers or tuned circuits are required. The PLL bandwidth is usually 2 to 10 percent of the IF for FM detection. Components R1/C1 set the VCO close to the desired frequency. C2 is the loop-filter capacitor, which determines the capture range — that range of frequencies over which the loop will acquire lock with an unlocked input signal. The NE565 has an upper frequency limit of 500 kHz.

# Digital Communications

There is a growing trend away from analog transmission methods and toward digital communications. This is not limited to systems, such as computers, that use digital codes in their native language. Digital types of transmission are in increasing use for signals that are analog in origin and must be delivered to the ultimate user in analog form.

This chapter covers not only the types of digital communication covered in §97.69 of the FCC rules (Baudot, AMTOR, ASCII and other radioteletype [RTTY] or computer-to-computer communications) but the granddaddy of them all — Morse code. It may be convenient to label these different digital codes and tuck them away in separate categories. To do so, however, limits one's thinking to what already has been done.

The future of digital communication will see rapid expansion. Distinctions between the present categories will become increasingly blurred, and there will be a scramble for new terminology to keep up with technological change. Looking to the future, the FCC has given the Amateur Radio Service wide latitude for the use of digital communication. The preamble of §97.69 will give you the flavor: "...an amateur radio communication may include digital codes which represent alphanumeric characters, analogue measurements or other information. These digital codes may be used for such communications as (but not limited to) radio teleprinter, voice, facsimile, television, communications to control amateur radio stations, models and other objects, transference of computer programs or direct computer-to-computer communications, and communications in various types of data networks (including so-called "packet switching" systems); provided that such digital codes are not intended to obscure the meaning of, but are only to facilitate, the communications..."

The term "radioteletype" has been used to mean communications between typewriterlike machines using a telegraph code known as Baudot (or Murray). There was no serious movement to use other codes,

Fig. 1 — A family portrait of telegraph keys used over this century. At front left is a hand key or straight key. Next is a semiautomatic key, usually called a *bug*, which produced a series of dots automatically but not dashes (which had to be formed individually by the operator). At front right is an electronic paddle keyer that produced both dots and dashes automatically when initiated by the operator. At rear left, a keyboard-operated electronic keyer. At right is a personal computer that has been programmed to generate and receive Morse code.

and the FCC rules permitted only Baudot code for RTTY communications. Before 1975, few amateurs thought about any terminal other than a teletypewriter.

The year 1975 marked the availability of the first affordable personal computers. A number of radio amateurs acquired computers (which used an eight-bit code) and immediately thought of interfacing them to Baudot teleprinters (which used five information bits). One application was to use a teleprinter to produce a paper printout (hard copy) for their computer. Another was to use the computer to send and receive Baudot RTTY and CW on the amateur bands.

### Regulatory Changes

On September 15, 1978, the Canadian Department of Communications (DOC) announced rules creating the Amateur Digital Radio Operator's Certificate and establishing regulations for packet radio

(covered later in this chapter).

On March 17, 1980 the FCC legalized Amateur Radio transmission of the American National Standard Code for Information Interchange (ASCII). U.S. amateurs were then permitted to use either Baudot at 45, 50, 56.25 or 75 bauds or ASCII at 300 bauds below 28 MHz, 1200 bauds between 28 and 225 MHz and 19,600 bauds above 420 MHz.

In response to an ARRL petition (RM-3788), on October 28, 1982, the FCC amended its rules to permit any digital code to be used above 50 MHz. It raised the permissible speeds for ASCII transmission to 19.6 kilobauds between 50 and 220 MHz and 56 kilobauds above 220 MHz. Rather than set maximum speeds for other digital codes, the FCC specified maximum bandwidths of 20 kHz between 50 and 220, and 100 kHz between 220 and 1215 MHz.

In response to another ARRL petition (RM-4122) on February 8, 1983, the FCC

amended its rules to permit amateurs to use Amateur Teleprinting Over Radio (AMTOR) in the high-frequency bands. Officially, AMTOR was described in terms of Recommendation No. 476-2 (1978) of the International Radio Consultative Committee (CCIR). In the same order, they made the maximum speeds for AMTOR and Baudot the same as specified for ASCII.

Another FCC order, which was effective on June 15, 1983, made several other changes that affected digital communica-

tions. The maximum audio- or radio-frequency shift was redefined as not to exceed 1000 Hz (between the mark and space frequencies) below 50 MHz, also that the frequency shift in hertz shall not exceed the sending speed in bauds or 1000 Hz, whichever is greater. The same order eliminated the need for CW or voice identification of digital transmissions and authorized stations to identify in Baudot, AMTOR or ASCII, whichever code is used for all or

part of the communication below 50 MHz or when any digital code is used above 50 MHz. The order also added that for AMTOR either CCIR Recommendation 476-2 (1978) or 476-3 (1982) may be used.

These regulatory changes have done much to clear the way for significant changes in Amateur Radio digital communications in the years ahead. No doubt, there will be more changes designed to facilitate new forms of digital communications.

## Morse Code

Radiotelegraphy by Morse code is the original modulation method used in Amateur Radio. The code is named after its inventor, Samuel F. B. Morse, 1791-1872, an American artist and promoter of the telegraph. Unlike codes designed for teletypewriters, the Morse code consists of elements of unequal length. The short pulse is called a dot (often sounded *dit*), and the

long pulse is a dash (sounded *dah*). There are unique combinations of dots and dashes for the letters of the alphabet, numerals, punctuation marks and procedure signals (prosigns). A comprehensive list of the code combinations and their meanings appears in Table 1. The list shows code combinations for languages that use the Latin alphabet and includes accented letters,

which are needed in some languages.

The listing of all of the code combinations does not imply that amateurs should learn and use all of them. In fact, to satisfy FCC testing requirements and for general use on the ham bands, you need to learn only the 26 letters, 10 numerals, the period, the comma, the question mark, fraction bar (DN), AR, SK and BT. If you do not already

### Notes

- Not all Morse characters shown are used in FCC code tests. License applicants are responsible for knowing, and may be tested on, the 26 letters, the numerals 0 to 9, the period, the comma, the question mark, AR, SK, BT and fraction bar [DN].
- The following letters are used in certain European languages which use the Latin alphabet:

Ä, A	didahdidah	..—...—	Ö, Ö, Ö	dahdahdahdit	—...—
Å, Å, Å, Å	didahdahdidah	..—...—	Ñ	dahdahdidahdah	—...—
Ç, C	dahdidahdidit	..—...—	Ü	dididahdah	...—...—
È, È, È	dididahdidit	..—...—	Ž	dahdahdidit	—...—
É	didahdididah	...—...—	Ž	dahdahdididah	—...—
Ê	dahdidahdit	—...—	CH, \$	dahdahdahdah	—...—

### 3. Special Esperanto characters:

Ĉ	didahdahdit	..—...—
Ĉ	dididahdit	...—...—
Ĥ	didahdahdahdit	..—...—
Ĥ	didahdahdahdit	..—...—
Ĥ	dididahdah	..—...—

### 4. Signals used in other radio services:

Interrogatory	dididandidah	...—...—	INT
Emergency silence	dididididahdah	...—...—	FM
Executive follows	dididahdididah	...—...—	IX
Break-in signal	dahdahdahdahdah	—...—...—	TTTT
Emergency signal	didididahdahdahdidit	...—...—...—	SOS
Relay of distress	dahdidahdidididididit	...—...—...—	DD

know these Morse characters, it is advisable to learn the code in an orderly manner as outlined in Chapter 36, preferably with the help of an instructor. After you have learned the basic characters and have some on-the-air experience, you may wish to expand your vocabulary of Morse code characters as you hear them or have need to send them.

Table 1 will also prove useful to those wishing to develop computer programs to send and receive Morse code. Some such programs have been flawed by omissions of valid characters and bogus combinations resulting from an incomplete listing of existing assignments.

Table 2 lists Morse code combinations for languages that are not based on the

Latin alphabet. While most Amateur Radio CW communications use the International Morse Code (Table 1), you can occasionally hear hams native in the same language chat with one another in the codes listed in Table 2.

#### Timing of Morse Code

The basic unit of time in Morse code is

**Table 2**  
**Morse Codes for Other Languages**

Code	Japanese	Korean	Arabic	Hebrew	Russian	Greek
•	へ he	ㅏ a	ا a	א vav	Е, Э E	Ε epsilon

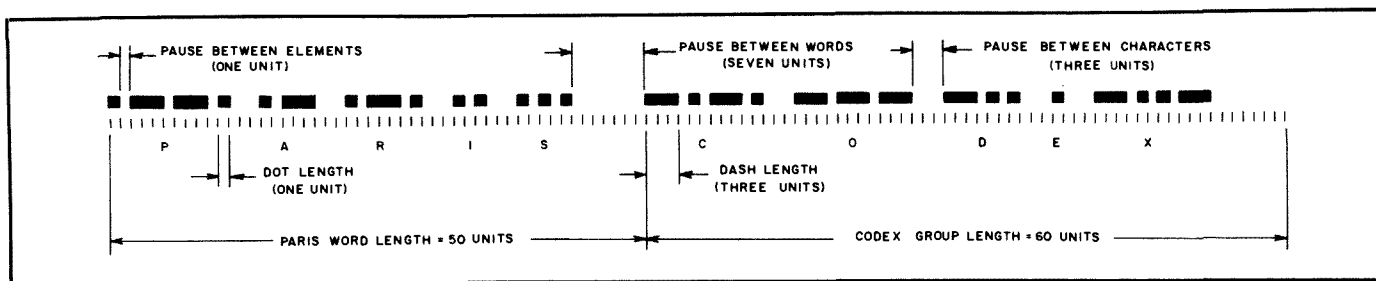

Fig. 2 — Timing of Morse code elements and spaces. The word PARIS is used as the typical word in English plain-language text. CODEX is typical of random-letter groups.

the length of the dot. The duration of the dash is three times that of the dot. The term *element* is used to include both dots and dashes. The space between two elements forming the same character is the same as for the dot. The space between characters is equal to three dots. The space between words or groups is equal to seven dots. These relationships are illustrated in Fig. 2.

Note that the length of characters varies. The letter E is the shortest because it is used most frequently in English plain-language text. T and I are next in line, and the codes get longer for letters that are less frequently used.

Analysis of English plain-language text indicates that the average word (including the space between words) is 50 units long. The word PARIS is of this length and is used to accurately set transmission speed. For example, if you wish to transmit at 10 WPM, adjust the keying speed until the word PARIS is sent 10 times in one minute. If you were to set the speed for PARIS but then send random-letter groups for code practice, you would find that the number of groups sent per minute is smaller. The reason is that the average length of random-letter groups is 60 units — the length of the group CODEX. The code speed for plain-language English can be found from

$$\text{speed (WPM)} = \frac{\text{dots/min}}{25} \\ = 2.4 \times \text{dots/s}$$

For example, a properly adjusted keyer

gives a string of dots that are counted at 10 dots per second: speed =  $2.4 \times 10 = 24$  WPM. For these keyers the code speed may be determined directly from the clock frequency

$$\text{speed (WPM)} = 1.2 \times \text{clock freq. (Hz)}$$

For a quick and simple means of determining the code speed, send a continuous string of dashes and count the number of dashes that occur in a five-second period. This number, to a close approximation, is the code speed in words per minute. A method for checking the speed of a Morse keyboard is to send a continuous string of zeros, with proper interletter spacing. Most keyboards will automatically insert the correct space if the key is released and re-activated before the end of the character. If zeros are sent for one minute, the speed is approximately

$$\text{speed (WPM)} = (\text{zeros/min}) \times 0.44.$$

### Cutting Numbers

You will notice that the numerals 0 through 9 in Morse code are longer than letters. That's fine as long as numbers are only an incidental part of the transmission. Radio services that send lots of numeric text, such as weather information, usually cut the length of the codes for numbers. Table 3 lists both long numbers and cut number substitutions. Cut numbers should be used sparingly whenever in doubt that the receiving operator will understand them. Also, only the long numbers are legal for identification purposes. Cut numbers

are not in widespread use by amateurs except for sending RST reports. Even there, usually only the numeral 9 is sent in cut form. Another exception is that the cut form of zero is frequently used in rag-chewing. The long form of zero should be sent in call signs and in message headings.

### MORSE KEYING AND SWITCHING

Two basic problems involved with Morse code radiotelegraphy are keying the transmitter on and off and switching between transmit and receive states. If the transmitter is switched on and off too slowly, the resultant RF signal will be difficult to read because the keying sounds too soft. If the transitions are too fast, extraneous sidebands, called *key clicks*, are generated. It is the responsibility of the transmitter operator to ensure that unnecessary key clicks are not transmitted.

Ideally, a transceiver should quickly change from receive to transmit states when the key is pressed. Similarly, it should revert to the receiving state as soon as the key is opened. This is called *break-in keying* and allows the sending operator to hear between keying elements in the event that the receiving station is trying to interrupt. This is an important feature for the serious CW operator and is attainable by careful transceiver design.

### Power-Supply Regulation for CW Keying

It is impractical to control the shape of the RF keying envelope unless the transmitter power supply is properly filtered and regulated. Improper regulation could cause the effect shown in Fig. 3D. This type of wave is even richer in harmonics than a square wave. The severity of the problem is a function of power supply load regulation. Note that in a class-C amplifier the change in power output related to plate or collector voltage regulation is proportional to the *square* of the voltage change. The power supply for a solid-state transmitter may be regulated easily and inexpensively by electronic means, but such a scheme applied to a high-power tube type of transmitter is costly and dissipates considerable power. Fortunately, the plate voltage waveform can be corrected with a passive circuit (see Dome, May 1977 *QST*). Note also that the power source must be nearly pure dc to ensure that the transmitter output

signal is not broadened by hum modulation.

## RF Envelope Shaping

On-off keying is a form of amplitude modulation and, as such, generates sidebands whose spacing from the carrier is a function of envelope rise and fall times, which are the highest-frequency components of the keying waveform. An untreated keying waveform approaches *square-wave* modulation, consisting of the keying frequency plus *all of its odd harmonics*. These harmonics create key clicks extending many kilohertz either side of the carrier. Adjusting the rise and fall times of the keying waveform to about 5 ms controls key clicks yet allows a wide range of practical keying speeds, as explained in Chapter 9.

Once the power supply voltage has been brought under control, it is a simple matter to shape the keying envelope with an RC network. The figures in this section illustrate the application of time-constant circuits to various keying methods.

When a circuit carrying current is opened or closed mechanically, a spark is generated. This spark causes the circuit to radiate energy throughout the electromagnetic spectrum. When a transmitter is keyed manually or through a relay, the spark at the contacts can cause local BCI, *but this spark has no effect on the RF output signal*. A simple filter (0.01- $\mu$ F capacitor in series with 10 ohms) across the key or relay contacts will usually reduce the local clicks to a tolerable level. Solid-state switching methods significantly reduce the current and voltage that must be switched mechanically, thereby reducing local clicks and enhancing operator safety. Modern transistorized transmitters incorporate this type of keying. With proper device selection, solid-state keying may be implemented in older tube designs as well.

Fig. 3 — These photos show CW signals as observed on an oscilloscope. At A is a dot generated at 46 bauds with no intentional shaping, while at B the shaping circuits have been adjusted for approximately 5-ms rise and decay times. Vertical lines are from a 1-kHz signal applied to the Z or intensity axis for timing. Shown at C is a shaped signal with the intensity modulation of the pattern removed. For each of these photos, sampled RF from the transmitter was fed directly to the deflection plates of the oscilloscope.

A received signal having essentially no shaping is shown at D. The spike at the leading edge is typical of poor power-supply regulation, as is also the immediately following dip and rise in amplitude. The clicks were quite pronounced. This pattern is typical of many observed signals, although not by any means a worst case. The signal was taken from the receiver's IF amplifier (before detection) using a hand-operated sweep circuit to reduce the sweep time to the order of one second. (Photos from October and November 1966 QST.)

Amplifier tubes may be keyed in the cathode (filament transformer center-tap for directly heated types), grid-bias supply or screen. Transistors should be keyed in one leg of the collector supply. The low impedance of RF power transistor circuits usually requires the emitter to be grounded as directly as possible; therefore, no solid-

state analog of cathode keying exists. Similarly, blocked-grid keying has no transistor equivalent, because a reverse bias sufficient to cut the stage off in the presence of heavy excitation would cause breakdown of the base-emitter junction.

Mechanical contacts frequently bounce several times before stabilizing in the closed

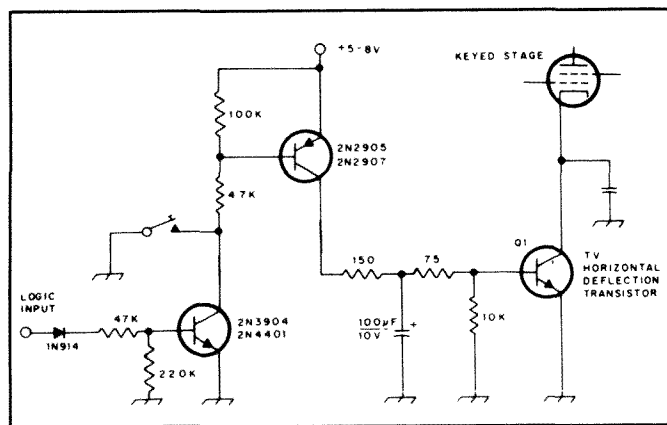

Fig. 4 — Cathode keying. Envelope shaping is accomplished by means of the RC network. Q1 must be able to withstand the plate voltage of the keyed stage. Some suitable types are: DTS-423, 2N6457 (400V), SDT 13305 (500V), DTS-801 (800V), MJ12010 (950V), 2SC1308K, ECG 238 (1500V). These are high-energy devices and are capable of switching any value of plate current the tube is likely to draw. For plate voltages below about 350, the 2N3439 is adequate (and much less expensive).

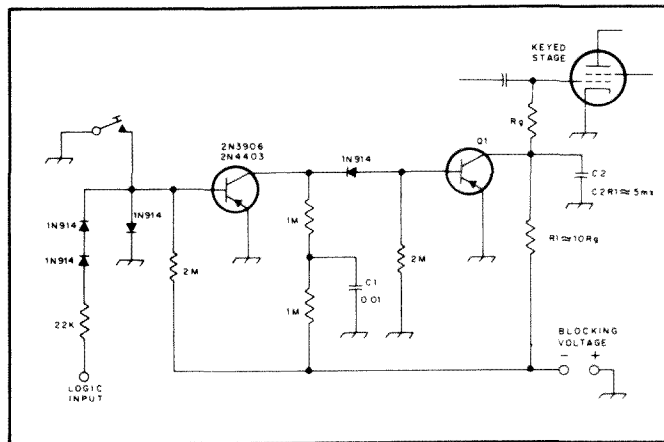

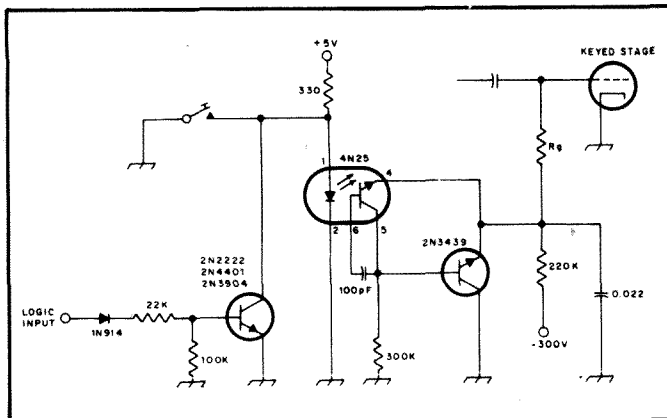

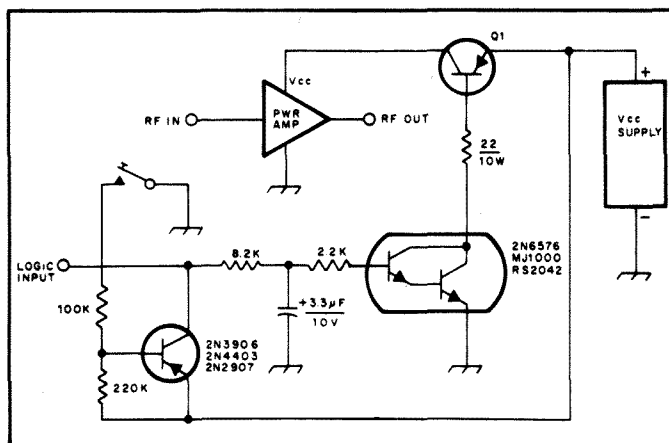

Fig. 5 — Blocked-grid keying. The rise time of the keying pulse is determined by C1 and its associated network. The decay time is governed by the R1C2 product. R<sub>g</sub> is the existing grid leak. Typical values for R1 and C2 are 220 k $\Omega$  and 0.022  $\mu$ F. Some transistors suitable for Q1 are: 2N5415 (200 V), MM4003 (250 V), MJE350 (300 V), 2N5416, RCS882 (350 V), 2N6213 (375 V), 2N6214 (425 V).

**Fig. 6** — if a suitable high-voltage PNP transistor cannot be obtained, an NPN unit can be used with an optical isolator. The rise time of the keying envelope is controlled by the "integrating" capacitor connected to the base of the phototransistor.

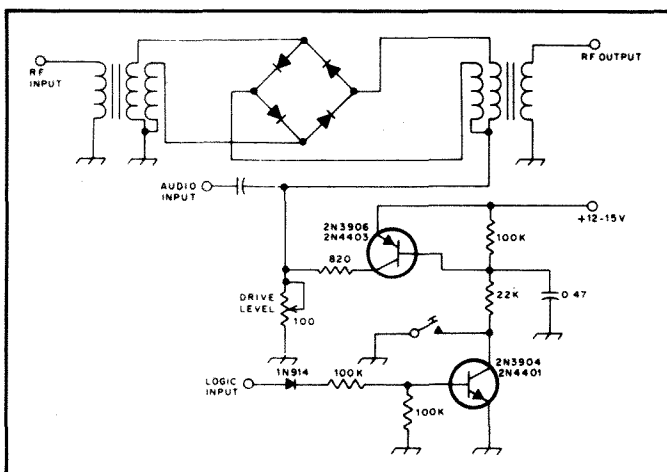

**Fig. 7 — Circuit to interface digital logic with positive or negative key lines. Q1 and Q2 must be able to withstand the expected negative and positive keying voltages and currents.**

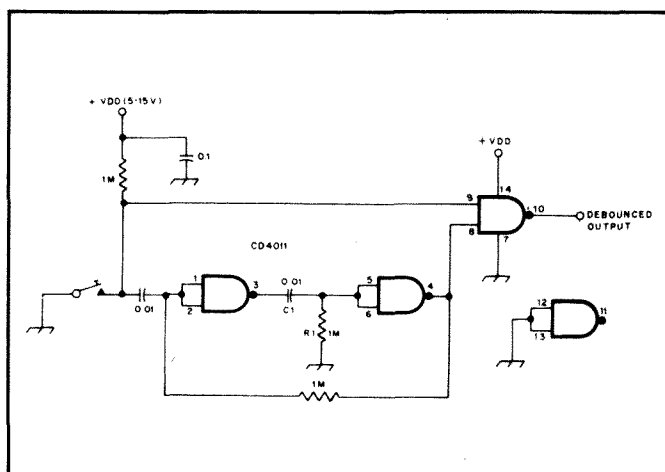

**Fig. 8 — Keying circuit for solid-state class-C amplifiers in the 100-watt class, such as those sold for VHF FM service. Q1 must be able to pass the amplifier collector current without dropping too much voltage. Types 2N6246, SK3173 and RS2043 are good for currents up to 15 amperes.**

**Fig. 9 — Keying a dual-gate MOSFET oscillator. The 741 op amp is used as a comparator. With the input resistors shown, the circuit can be triggered by any +5-volt logic device.**

**Fig. 10 — Keying a doubly balanced modulator in a CW-SSB transmitter.**

**Fig. 11 — Debouncing circuit for hand keys and relay contacts. The minimum dot length is determined by the  $R1C1$  product.**

state. The beginnings of keying pulses formed by bouncing contacts are poorly defined. This defect can degrade the readability of a code signal under adverse

conditions. Relays and semiautomatic keys are especially prone to this malady. The circuit of Fig. 11 will help clean up the pulses generated by mechanical contacts.

A satisfactory CW RF envelope can be amplified by means of a *linear* amplifier without affecting the keying characteristics. If, however, the signal is amplified by one

or more nonlinear stages (e.g., a class-C multiplier or amplifier), the signal envelope will be modified, possibly introducing significant key clicks. It is possible to compensate for this effect by using longer-than-normal rise and decay times in the exciter and letting the amplifier modify the signal to an acceptable one. Any clicks generated by a linear amplifier are likely to be the result of low-frequency parasitic oscillations.

### Oscillator Keying

A change in frequency at the beginning of a keying pulse is called a *chirp*. If the oscillator isn't keyed, chirp is the result of changing dc operating potentials or changing RF load conditions on the oscillator. The voltage to the oscillator can be regulated easily, as most transmitters use fairly low-power oscillators. If the oscillator frequency is pulled by the loading effect of subsequent keyed stages, better load isolation is indicated.

If break-in operation is desired (see below), it may be necessary to key the transmitter's oscillator. Oscillators may be keyed by the same methods used for amplifiers, but greater care is required to obtain good results. In general, the goals of clickless and chirpless oscillator keying are mutually exclusive. This is because a key-click filter will cause the operating voltage to be applied *slowly*, thereby creating a chirp. Crystal oscillators may be keyed satisfactorily if active crystals are used. A keyed oscillator may exhibit a continuous frequency change during a keying pulse. This defect is called a *yoop*. It is caused by RF heating in the tank circuit or crystal. Yoop is usually an indication of a faulty component or excessive oscillator power.

Break-in operation with a VFO-controlled transmitter usually dictates some form of *differential* keying. In this system, the oscillator is turned on as quickly as possible and the amplifier is keyed after the oscillator has stabilized. When the key is released, the oscillator operates until the amplifier output has decayed to zero. Shaping of the keying envelope is accomplished in the amplifier keying circuit. In the past, break-in operation was implemented with VR tubes and relays. The complexity of such systems frightened many hams away from this convenient mode. With modern circuitry, break-in can be simple, quiet and safe. One method of break-in keying is shown in Fig. 12.

A few notes concerning oscillator keying are in order. Do not attempt to key an oscillator unless it is stable while running free, at the same time the other stages are keyed. If the oscillator frequency is multiplied, chirps and yoops will be multiplied also. The transmitter signal should be checked at the highest operating frequency. It may be found that the signal quality is satisfactory on 160 meters but leaves something to be desired on 10. Modern transmitters and transceivers provide multi-

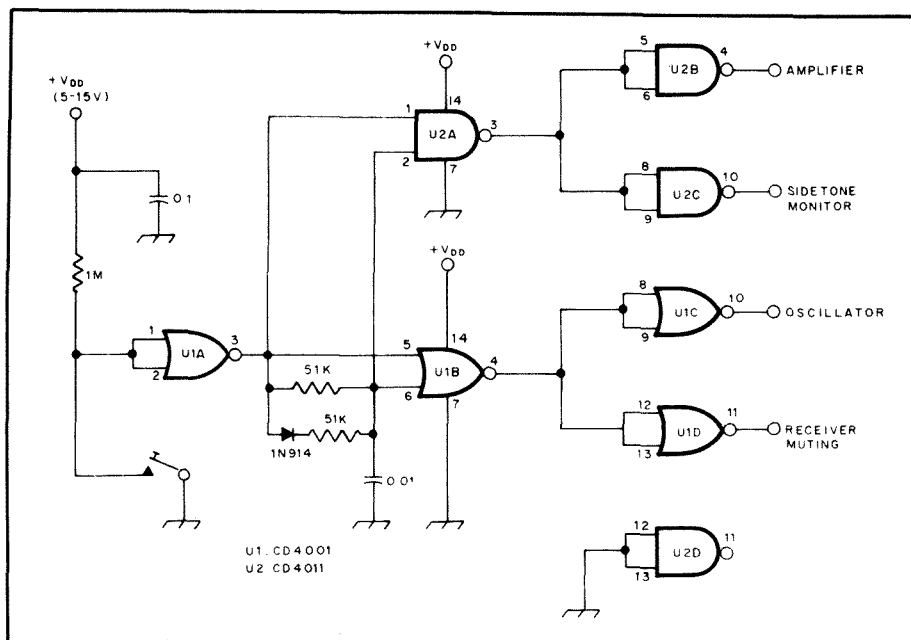

Fig. 12 — Differential (sequential) keying system for fast break-in with oscillator-multiplier transmitters.

band operation by the heterodyne method and should be stable on all bands.

### Backwave

If the transmitter oscillators run continuously, they may be audible as a *backwave* between keying pulses. A strong backwave may indicate the need for neutralizing one or more transmitter stages. In general, if the backwave conforms to the -40 dB spurious signal rule, it won't be objectionable.

### Practical Keying Circuits

The figures in this section illustrate methods by which various solid-state and thermionic devices may be keyed. In these circuits, the armature of the hand key is at ground potential and the voltage across the key is imperceptible. The current through the key is generally less than 1 milliamper. A neon bulb with a proper series resistor across the key will alert the operator to junction breakdown of the high-voltage transistors. As long as safety is given due consideration, the key-at-ground convention need not be followed, but this standardization is useful for equipment interconnections. Digital control is shown in all of the examples. This feature simplifies the simultaneous keying of transmitter stages, TR switches, sidetone oscillators and muting systems. The ICs used to perform the control functions are plentiful and inexpensive. These systems use a logic high to indicate a keydown condition.

### Break-In

Break-in (QSK) is a system of radiotelegraph transmission in which the station receiver is sensitive to other signals between the transmitted keying pulses. This capability is very important to traffic

handlers, but can be used to great advantage in ragchewing as well. Break-in gives CW communication the dimension of more natural conversation.

Most commercially manufactured transceivers feature a "semi break-in" mode in which the first key closure actuates the VOX relay. The VOX controls are usually adjusted to hold the relay closed between letters. With proper VOX adjustment, it is possible for the other operator to break your transmission between words, but this system is a poor substitute for true break-in.

### Separate Antennas

The simplest way to implement break-in is to use a separate antenna for receiving. If the transmitter output power is low (below 50 watts or so) and the isolation between transmitting and receiving antennas is good, this method can be satisfactory. Best isolation is obtained by mounting the antennas as far apart as possible and at right angles. Smooth break-in involves protecting the receiver from damage by the transmitter power and assuring that the receiver will "recover" fast enough to be sensitive between keying pulses. If the receiver recovers fast enough but the transmitter clicks are bothersome (they may be caused by receiver overload and so exist only in the receiver), their effect on the operator can be minimized through the use of an output limiter. The separate antenna method is most useful on the 160-, 80- and 40-meter bands, where the directional effects of the antennas aren't pronounced.

### Switching a Common Antenna

When powers above about 50 watts are used, where two antennas are not available, or when it is desired to use the same an-

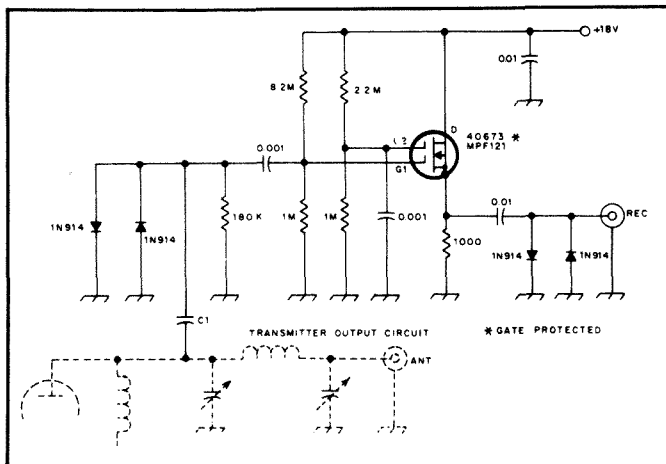

Fig. 13 — A TR switch can be connected to the input side of the transmitter pi network. For powers up to about 100 W, C1 can be a 5-10 pF, 1000-V mica unit. For high-power operation a smaller "gimmick" capacitor made from a short length of coaxial cable should be used.

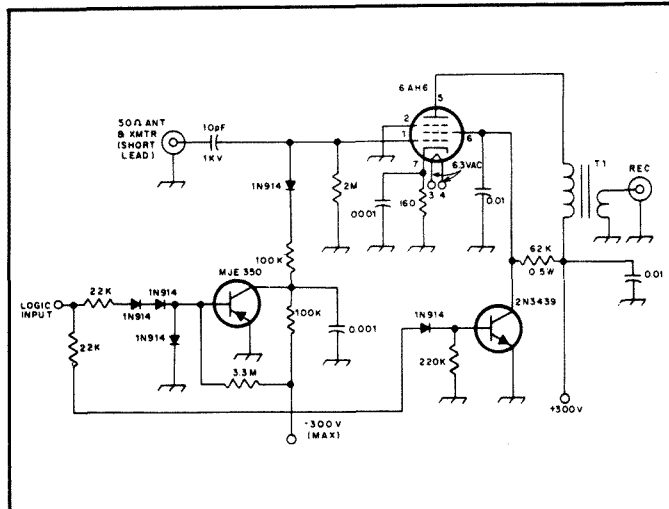

Fig. 14 — An external TR switch. The primary of T1 is 50 turns of no. 30 enameled wire on an FT37-43 toroid core. The secondary is 15 turns of no. 30 wound over the primary.

tenna for transmitting and receiving (a "must" when directional antennas are used), special treatment is required for quiet break-in operation on the transmitter frequency.

Vacuum relays or reed switches may be used to switch the antenna between the transmitter and receiver in step with the keying. This method is satisfactory for power levels up to the legal limit, but the relays are expensive and the system timing is critical.

Perhaps the most modern and elegant approach is the use of PIN diodes to switch the antenna. These devices are available in power ratings up to about 100 watts, but are quite expensive at present. There are no keying-speed constraints when PIN diodes are used, and if the proper devices are selected, the spectral purity of the output signal won't be affected. The important electrical parameter in this regard is *carrier lifetime*.

An easy and economical way to implement break-in with a single antenna is to use an electronic *TR switch*. With such a device the antenna is connected to the transmitter at all times. In the most common type of electronic TR switch, a tube is used to couple the antenna to the receiver. When the transmitter is keyed, the RF output causes the tube to draw grid current through a high-resistance grid leak. The high negative bias thus developed cuts off the plate current, limiting the signal delivered to the receiver.

Unfortunately, when the grid circuit is driven into rectification, harmonics are generated. A low-pass filter between the TR switch and the antenna can help to eliminate TVI caused by the harmonics, but the lower-order harmonics may cause interference to other communications. Another common shortcoming of TR switches is that the transmitter output circuit may "suck out" the received signal. In a transmitter having a high-impedance

tuned-output tank circuit, both of these problems can be circumvented by connecting the TR switch to the *input* side of the tank circuit. With this configuration, the grid rectification harmonics are suppressed and the received signal peaked by means of the tuned circuit. Fig. 13 shows a MOSFET TR switch that works on this principle.

A TR switch for use external to any transmitter is shown in Fig. 14. The tube is grid-block keyed, and the fixed-value bias prevents any grid current flow at power levels up to 800 watts. This power figure assumes a 50-ohm system with a unity SWR. The circuit can withstand peak RF voltages up to 300. The power capability must be derated if the impedance at the point of connection is higher than 50 ohms. Although the signal path has a diode, it is effectively "linearized" by the high-value series resistor, and should not significantly degrade the spectral purity of the transmitter output.

External TR switches should be well

shielded and the power leads carefully filtered. In general, the coaxial cable to the transmitter should be as short as possible, but some experimenting may be necessary to eliminate "suck out" of the received signal. It is commonly stated that electronic TR switches are usable only with transmitters having class-C output stages because the "diode noise" generated by the resting current of a linear amplifier will mask weak signals. Actually, the class-of-service designation is not related to key-up conditions, so there is no reason a linear amplifier can't be biased off during key-up periods.

### Reduction of Receiver Gain During Transmission

For absolutely smooth break-in operation with no clicks or thumps, means must be provided for momentarily reducing the gain through the receiver. A muting function completely disables the receiver audio during key-down periods. Assuming the transmitter signal at the receiver is held

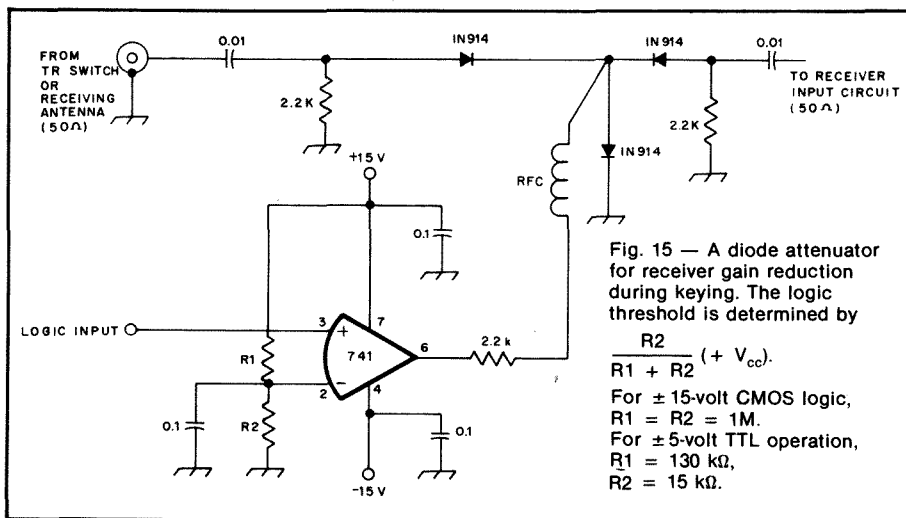

Fig. 15 — A diode attenuator for receiver gain reduction during keying. The logic threshold is determined by

$$\frac{R_2}{R_1 + R_2} (+V_{cc}).$$

For  $\pm 15$ -volt CMOS logic,  
 $R_1 = R_2 = 1\text{M}$ .  
 For  $\pm 5$ -volt TTL operation,  
 $R_1 = 130\text{ k}\Omega$ ,  
 $R_2 = 15\text{ k}\Omega$ .

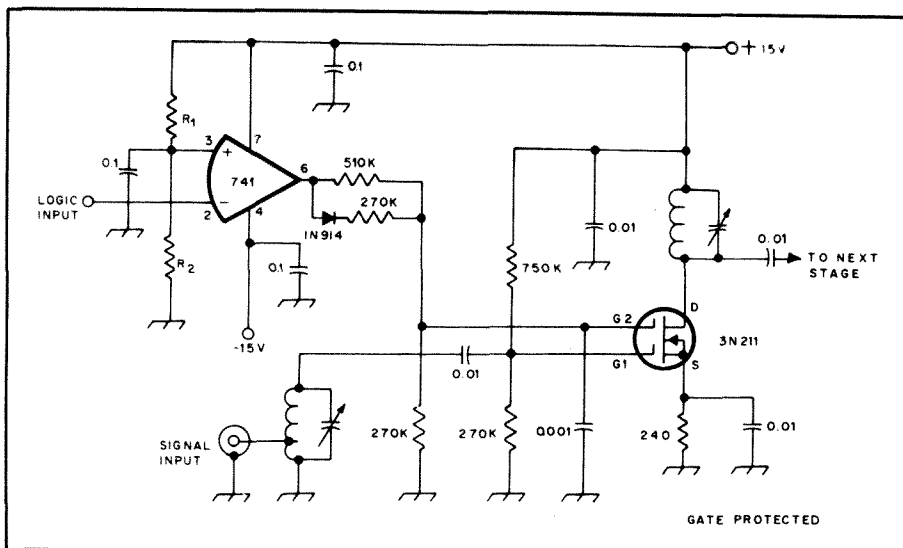

Fig. 16 — Gain-reduction circuit for receivers using a fixed-bias dual-gate MOSFET in the first stage. As much as 40 dB of attenuation is possible with this method. The logic threshold is calculated as in Fig. 15.

below the damage level, muting the audio output can be an effective means of achieving smooth break-in *provided no AGC is used*. AGC systems suitable for CW operation are characterized by long “hang” times. Unless the transmitter signal in the receiver is at a level similar to that of the other station, the AGC system will seriously desense the receiver, rendering the break-in system useless. A diode attenuator suitable for use with TR switches or separate antennas is shown in Fig. 15. If the receiver uses a dual-gate MOSFET with no AGC in the first stage, the method of Fig. 16 may be used.

### Monitoring

If the receiver output is muted, an audio sidetone oscillator must be used to monitor one's sending. A 555 timer connected as an astable multivibrator is commonly used for this purpose. This device delivers rectangular output pulses, and the resulting signal often sounds quite raucous. A variation of the standard 555 circuit appears in Fig. 17. The diodes maintain the symmetry of the waveform independently of the pitch and the RF filter removes many of the objectional harmonics. A keying monitor can be powered by the RF output of the transmitter. Such a circuit is shown in Fig. 18. Keying monitors often have built-in loudspeakers, but it is less expensive and more convenient to inject the monitor signal into the audio output stage of the

receiver. With this system one always hears the sidetone from the same source (speaker or headphones) as the other station's signal.

If the audio output isn't muted, the receiver can be used to monitor one's keying, provided both stations are on the

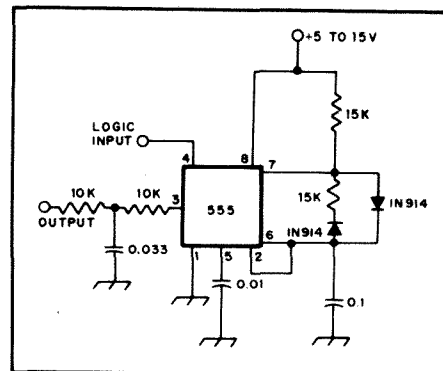

Fig. 17 — A 555 universal timer used as a sidetone generator. Pin 4 is taken to ground to interrupt the tone. The frequency of oscillation is about 500 Hz with the constants shown.

same frequency. Some DX operators transmit and listen on separate frequencies. When using your receiver as a monitor, you should be careful about drawing any conclusions concerning the quality of your signal. The signal reaching the receiver must be free of any line voltage effects induced by the transmitter. To be certain of your signal quality you should listen to your station from a distance. Trading stations with a nearby amateur is a good way to make signal checks.

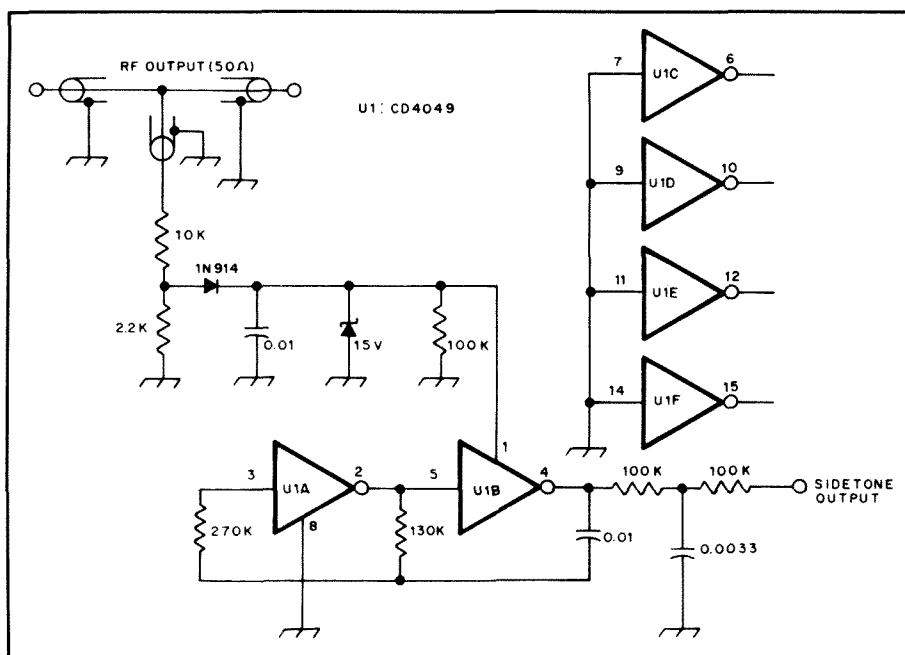

Fig. 18 — An RF-powered keying monitor suitable for power outputs from about 20 to 100 W. This circuit should be installed inside the transmitter or a shielded enclosure to minimize RFI.

## Narrow-Band Direct-Printing Telegraphy

The term “narrow-band direct-printing telegraphy” (NBDP) is used by the ITU to mean communications between two teletypewriters. Isn't that what we've been

calling “radioteletype” (RTTY) all along? Yes, but there may be a subtle distinction, or at least a clarification. “Direct-printing” makes it rather clear that typewriterlike

printers are involved and not data communications between computers. The two direct-printing telegraph systems Baudot and AMTOR used in the Amateur Radio

Service are presented here. ASCII and packet radio are covered later in this chapter.

## BAUDOT RADIOTELETYPE

The commercial- or military-surplus Baudot-encoded teletypewriter (TTY) was the mainstay of amateur RTTY operators from 1946 through around 1977. There are still numerous TTY machines in use, but many RTTY operators are now using computer-based terminals. In some cases, the terminal was designed from the outset as a multimode RTTY and CW terminal. In others, amateurs adapted personal computers to send and receive the Baudot code.

### The Baudot Telegraph Code

One of the first data communications codes to receive widespread use had five information pulses (or levels) to present the alphabet, numerals, symbols and machine functions. In the United States, the current five-level code is commonly called the Baudot code. In Great Britain the almost-identical code is called the Murray code.

There are many variations in five-level coded character sets, principally to accommodate foreign-language alphabets.

Current FCC rules in §97.69(a) identify the Baudot code as the International Telegraph Alphabet Number 2 (ITA2). This code is recognized by the International Telegraph and Telephone Consultative Committee (CCITT) and allows for national variations. The ITA2 coded character set is shown in Table 4.

As ITA2 is a five-level code, and there are only two conditions for each level (A or Z, space or mark, binary 0 or 1). Therefore, a total of  $2 \times 2 \times 2 \times 2 \times 2 = 2^5 = 32$  different code combinations are possible. Because it is necessary to provide 26 Latin letters, 10 numerals and punctuations, the 32 code combinations are not sufficient. This problem is solved by using the codes twice; once in the *letters* (LTRS) case and again in the *figures* (FIGS) case. Two special characters, LTRS and FIGS are used to indicate whether subsequent characters will be in letters or figures case. The receiving

terminal stores the last received LTRS or FIGS characters so it remains in the last-received case until changed. Control functions such as LTRS, FIGS, carriage return (CR), line feed (LF), space (SP) and blank are assigned to both the letters and figures cases so that they can be used in either case. The remaining 26 code combinations have different character meaning, depending on whether preceded by a LTRS or FIGS character.

FCC rules provide that ITA2 transmissions must be single channel and sent using start-stop pulses as illustrated in Fig. 19. The bits in Fig. 19 are arranged in a left-to-right order, as would be observed on an oscilloscope.

FCC rules also permit ITA2 figures case positions not used for numerals and the slant sign or fraction bar to be used for the remote control of receiving printers. They may also be used for other purposes indicated in §97.69 of the rules.

### Baudot Teletypewriters

Mechanical teletypewriter equipment consists of these basic components:

A *printer* prints on a continuous supply of paper (in a roll or fan folded) about the width of letter-size paper. Although it has been known as a *page printer*, it prints a character at a time. A printer, often called a *Receive-Only* or *RO* terminal, will allow you to decode and print what RTTY operators are sending.

A *keyboard* is used by an operator to originate messages. Most mechanical keyboards have encoders to send out the character code in start-stop (asynchronous) sequence. A teleprinter with keyboard and printer may be known as *KSR*, which stands for *Keyboard Send-Receive* terminal.

A *perforator* is a unit that punches paper tape and may be controlled by a keyboard by direct mechanical connection. The term *reperforator* (*reperf*) signifies that the perforator punches tape from electrically received signals and usually prints the corresponding characters on the tape. A *Receive-Only Typing Reperforator* (*ROTR*) receives serial data and perforates and prints on the tape.

A *Transmitter-Distributor* (*TD*) set is a tape reader that senses the perforations in the tape and produces encoded start-stop pulses. A teletypewriter with a tape capability may be called *Automatic Send-Receive* or *ASR*.

### Computer-Based Baudot Terminals

Electronic Baudot terminal equipment, as shown in Fig. 20, is similar to counter-part mechanical teletypewriter units.

A *microcomputer* is the foundation of the system and is used to encode and decode ASCII characters, convert them to and from the comparable Baudot codes, and provide for the start-stop code sequence for transmission and reception. The heart of the microcomputer is the

#### Notes

<sup>1</sup> represents the mark condition (shown as Z in ITU recommendations) which is the higher emitted radio frequency for FSK, the lower audio frequency for AFSK. 0 represents the space condition (shown as A in ITU documents). Bits are numbered 0 (least significant bit) through 4 (most-significant bit). The order of bit transmission is LSB first, MSB last. Symbols A and Z are defined in CCIR Rec. R.140.

<sup>2</sup> represents the mark condition (shown as B in CCIR recommendations), which is the higher emitted radio frequency for FSK, the lower audio frequency for AFSK. 0 represents the space condition (shown as Y in CCIR recommendations). Bits are numbered 0 (LSB) through 6 (MSB). The order of bit transmission is LSB first, MSB last.

<sup>3</sup> Many U.S. teletypewriters have these figures case characters.

<sup>4</sup> At present unassigned. Reception of these signals, however, should not initiate a request for repetition.

<sup>5</sup> The pictorial representations of ☒ or ✚ indicate WRU (Who are you?), which is used for an answer-back function in telex networks.

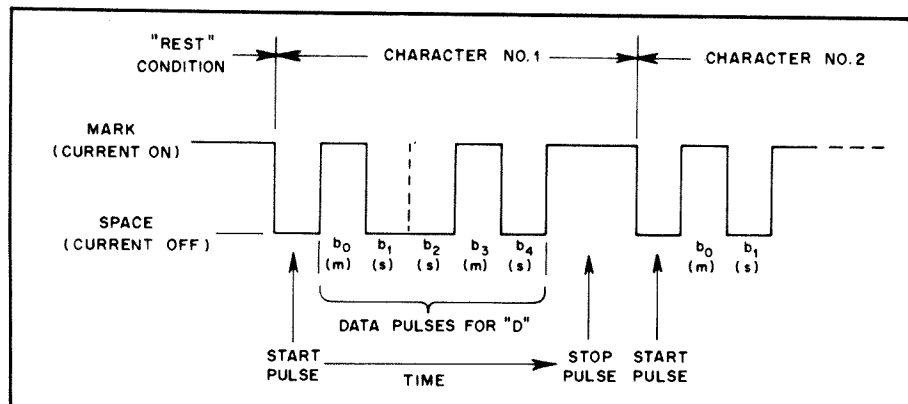

Fig. 19 — Time sequence of typical Baudot character, the letter D.

Fig. 20 — Many RTTY operators now use all-electronic systems.

Table 5  
CCIR Rec. 476 Service Information Signals

Mode A (ARQ)	Bit No.	Hex	Mode B (FEC)
Control signal 1 (CS1)	1100101	65

Table 6  
Baudot Signaling Rates and Speeds

Signaling Rate (bauds)	Data Pulse (ms)	Stop Pulse (ms)	Speed (WPM)	Common Name
45.45	22.0	22.0	65.00	Western Union
	22.0	31.0	61.33	"60 speed"
	22.0	33.0	60.61	45 bauds
50.00	20.0	30.0	66.67	European; 50 bauds
56.92	17.57	25.00	76.68	"75 speed"
	17.57	26.36	75.89	57 bauds
74.20	13.47	19.18	100.00	"100 speed"
	13.47	20.21	98.98	74 bauds
100.0	10.00	15.00	133.33	100 bauds

microprocessor. There is also *random-access memory (RAM)* for volatile (temporary) storage of data and *read-only memory (ROM)* for nonvolatile (permanent) storage. *Erasable programmable read-only memory (EPROM)* is nonvolatile but can be erased and reprogrammed.

The other units described below can be considered *peripherals* from the standpoint of the microcomputer.

A *keyboard* usually produces an ASCII-encoded parallel output.

A *video-display terminal* or *VDT* is the normal display device. Many VDTs use cathode-ray tubes (CRTs). But flat-screen character displays are coming into use.

A *character printer* is used when a paper (hard) copy is desired.

A *disk drive* may be added to the system to store text or software on flexible (floppy) diskettes. Alternatively, an audio cassette tape recorder may be used.

#### Baudot Speeds and Signaling Rates

The operating speed of mechanical teletypewriter machines is determined by motor speed and gearing ratios or electronic timing circuits. Common speeds are 60, 67, 75 or 100 WPM. See Table 6 for the relationship of speeds and signaling rates and pulse times.

The speed is given in the *approximate* number of five-letter-plus-space combinations transmitted in a *continuous sequence* in start-stop format over a one-minute

interval. Convenient choices of gearing ratios and motor-shaft speeds have resulted in noninteger WPM rates. Common usage, however, has rounded the exact speeds to easily remembered numbers. Thus, "60 speed" Baudot actually is sent at 61.33 WPM, and "75 speed" is really 76.67 WPM.

A problem occurs with the use of words per minute or characters per second as TTY speed specifications because of the varying length of stop pulses in use. For example, "60 speed" Baudot TTY has 22-ms-long start and data pulses and a 31-ms stop pulse (1.42 times the data pulse width); the Western Union "65 speed" also has 22-ms start and data pulses, but the stop pulse is also 22 ms long (a 1:1 ratio); some electronic terminals use 22-ms start and data pulses and 33-ms stop pulses (a 1.5:1 ratio).

In light of the above character-length variation from the different stop-pulse-to-data-pulse ratios in use, it is now common to refer to the number of shortest pulses per second. The *baud* is a unit of signaling speed equal to one pulse (event or symbol) per second. The signaling rate in bauds can be found by dividing the shortest pulse length into one; for example,  $1/0.022 = 45.45$ , commonly abbreviated to 45.5 or even 45 bauds.

#### Teletypewriter Loop Circuits

Teletypewriter printing mechanisms use selector magnets to sense the presence

(mark) or absence (space) of the loop current. The characters typed on the sending keyboard are encoded with proper mark and space pulses. Since the keyboards and selector magnets of both machines are series connected, text typed on one keyboard is reproduced on both printers. Connection of the keyboard directly to its associated printer is called a *local loop*, giving local copy of transmitted text.

Selector magnets used in older machines such as the Teletype Corp. model 15 were designed for a mark loop current of 60 mA dc. Newer machines use a 20-mA loop, and some electronic interface circuits accept a wide range of loop currents (10 to 120 mA for the HAL DS3100, for example).

Since the dc resistance of the selector magnets is rather low (100 to 300 ohms, typically), it would at first seem that a low-voltage loop supply could be used. However, the inductance of the magnet is usually quite high (on the order of 4 henrys for a model 15), causing a delay in the current rise time. This, in turn, delays the selector magnet response to a mark pulse, distorting the signal. This distortion can be severe enough to cause misprinting of received text, particularly if other forms of distortion are present (such as caused by variations in the radio signal). In general, the higher the loop voltage and loop resistance used, the lower the distortion. In practice, loop power-supply voltages between 100 and 300-V dc are common.

Newer loop supplies use a 150- to 200-volt loop supply and a 2000- to 3000-ohm loop resistor to set the 60-mA loop current. Amateur Baudot RTTY demodulators normally contain loop power supplies and current-limiting resistors.

### Baudot RTTY Modems

The term *modem* is a contraction of *modulator-demodulator*. Some amateurs use the term *terminal unit* or *TU* to mean modem or sometimes just a demodulator.

It is possible to transmit teleprinter signals by on/off keying (OOK) as is used for regular Morse code CW transmission. In the early days of amateur RTTY, OOK was the only legal way of operating RTTY on the HF bands. OOK demodulators had problems distinguishing between signal and no signal because the no-signal condition contains both natural and man-made noise. This method of keying worked only when there was a sufficiently high signal-to-noise ratio.

In 1953, the FCC changed its rules to permit frequency-shift keying (FSK) in the HF amateur bands. FSK has the advantage of providing either a mark or space signal during transmission. Thus the receiving demodulator has the easier decision between two on-the-air signals rather than comparing the mark signal against noise. With proper demodulation, FSK transmission provides much better performance than OOK.

### Frequency-Shift Keying

Below 50 MHz, FSK (F1B emission) is used for Baudot RTTY. The nominal transmitter frequency is the mark condition. The space condition causes the transmitter to shift downward in frequency, normally 170 Hz. The frequency shift on the HF bands is limited to a maximum of 1000 Hz. Direct frequency-shift keying of HF transmitters is possible using a diode and a variable capacitor or a voltage-variable-capacitance diode in an oscillator circuit. Some commercial transceivers have frequency-shift keyers of this type built in.

### Audio-Frequency-Shift Keying

Above 50 MHz where A2B or F2B emissions are permitted, audio-frequency-shift keying (AFSK) is generally used. In this case the RF carrier stays on the air throughout the transmission and a modulating audio tone is shifted in frequency. U.S. amateurs traditionally have used an audio frequency of 2125 Hz for mark and a somewhat higher frequency for space. At one time, when 850-Hz shift was used by amateurs on HF, this same shift was used for VHF AFSK, making the space tone 2975 Hz. After the shift on HF was reduced to 170 Hz, the common VHF AFSK space frequency was changed to 2295 Hz.

### AFSK of SSB Transmitters

Probably most modern RTTY stations

simply feed AFSK tones to the microphone input of an SSB transmitter or transceiver. When properly designed and adjusted, this method of modulation, while technically J2B emission, cannot be distinguished from F1B emission on the air. The user should make certain that audio distortion, carrier and unwanted sidebands are not present to the degree of causing interference. The user should also make certain that *the equipment is capable of withstanding the 100-percent duty cycle* needed for the duration of an RTTY transmission. For safe operation, it is often necessary to reduce the transmitter power output to 25 to 50 percent of the power level that is safe for CW operation.

In the U.S. it has been customary to use the same modems for both VHF AFSK and HF via an SSB transmitter. This proved difficult when the 850-Hz shift tones of 2125 Hz mark and 2975 Hz space were used because of the narrow filtering used in most SSB equipment. So some amateurs, particularly those in IARU Region 1 (Europe and Africa), went to the "low tones" of 1275 Hz mark and 2125 Hz space to operate more in the center of the SSB filter passbands. When the shift was reduced to 170 Hz, 1275 Hz was retained mark, and 1445 Hz was used for space. Both high and low tones can be used interchangeably on the HF bands because only the amount of shift is important. The slight frequency difference is unnoticed on the air because each station tunes its transmitters and receivers for best results. On VHF AFSK, however, the high and low tone pairs are not compatible.

Because the convention on HF is that the *higher* frequency is the mark condition, and as the AFSK modem uses the *lower* frequency for mark, it is normal to use the *lower sideband* mode for RTTY on SSB radio equipment. If you want to tune to an exact RTTY frequency, remember that most SSB radio equipment will display the frequency of its (suppressed) carrier, not the frequency of the mark signal. For example, if you want to operate on 14,083 kHz and you are using a 2125-Hz AFSK mark frequency, your SSB radio (suppressed-carrier) frequency should be  $14,083 + 2.125 = 14,085.125$  kHz.

### AFSK Modulators

The audio tone produced by the AFSK modulator must be nearly sinusoidal. A nonsinusoidal waveform contains harmonics of the fundamental frequency. If, for example, a nonsinusoidal (low) tone of 1275 Hz is used, the audio outputs will be 1275, 2550 and 3825 Hz. Any properly designed SSB transmitter can be expected to filter out 3825 Hz but may not be able to reduce 2550 Hz to an acceptable level, depending on the filter characteristics. Particularly when using the low tones, the harmonic distortion of the tones should be kept to a few percent.

Most modern AFSK generators are of

the *continuous-phase (CPFSK)* type. Older types of noncoherent-FSK (NCFSK) generators had no provisions for phase continuity and produced sharp switching transients. The noise from phase discontinuity caused interference several kilohertz around the RTTY signal.

### AFSK Demodulators

An AFSK demodulator takes the shifting tones from the audio output of a receiver and produces TTY keying pulses.

Many AFSK demodulators are of the FM type. In this type of demodulator, the signal is first sent through a band-pass filter to remove out-of-band interference and noise. It is then limited to remove amplitude variations. The signal is FM-demodulated (in a discriminator or a phase-locked loop or PLL). The output of the detector is run through a low-pass filter to remove noise at frequencies above the keying rate. The result is fed to a circuit that makes the ultimate decision between mark and space.

Other demodulator designs use AM (limiterless) detectors in place of a discriminator or PLL. These types of demodulators, when properly designed, permit continuous copy even when the mark or space frequency fades out completely. However, at 170-Hz shift, the mark and space frequencies tend to fade more at the same time than they do independently. In other words, when one fades chances are that the other will fade about the same time. For this reason, FM and AM types of demodulators are comparable at 170-Hz shift. However, at wider shifts (say 425 Hz and above), the independently fading mark and space can be used to achieve an *in-band frequency-diversity* effect if the demodulator is capable of processing it. To conserve spectrum, it is generally desirable to stay with 170-Hz shift for 45-baud Baudot and forego the possible in-band-frequency-diversity gain. However, the inband-frequency-diversity gain should be kept in mind for higher signaling rates that would justify greater shift.

### Diversity Reception

Another type of diversity can be achieved by using two antennas, two receivers and a dual demodulator. This setup is not as far fetched as it may sound; some amateurs are using it with excellent results. One of the antennas would be the normal station antenna for that band. The second antenna could be either another antenna of the same polarization located at least 3/8-wavelength away, or an antenna of the opposite polarization located at the first antenna or anywhere nearby. A problem is to get both receivers on the same frequency without having to carefully tune both. While rare, some RTTY diversity enthusiasts have located slaved receivers on the surplus market. ICOM has produced the IC-7072 Transceiver Unit, which slaves an IC-720(A) transceiver to an IC-R70

receiver. Other methods could include a computer controlling two receivers so that both would track.

Two demodulators are needed for this type of diversity. Also, some type of diversity combiner or selector is needed. Many commercial or military RTTY demodulators are equipped for diversity reception.

The payoff for using diversity is a worthwhile improvement in copy. Depending on fading conditions, adding diversity may be equivalent to raising transmitter power sevenfold (8 dB).

### Autostart

Mechanical teletypewriters cannot print until their motors are running at the proper speed. Rather than letting the motor run continuously, many Baudot RTTY stations employ an *autostart* circuit that senses the presence of a mark signal and turns on the motor.

### AMTOR

RTTY circuits are plagued with problems of fading and noise unless something is done to mitigate these effects. Frequency, polarization and space diversity are methods of providing two or more simultaneous versions of the transmission to compare at the receiving station. Another method of getting more than one opportunity to see a given transmission is time diversity. The same signal sent at different times will experience different fading and noise conditions. Time diversity is the basis of *AMTOR* or *Amateur Teleprinting Over Radio*.

AMTOR always uses two forms of time

Fig. 21 — W1AW AMTOR operating position.

diversity in either Mode A (ARQ or Automatic Repeat Request) or Mode B (FEC or Forward Error Correction). In Mode A, a repeat is sent only when requested by the receiving station. In Mode B, each character is sent twice. In both Mode A or Mode B, the second type of time diversity is supplied by the redundancy of the code itself.

This new type of RTTY was introduced to Amateur Radio by Peter Martinez, G3PLX, through several articles that appeared in RSGB's *Radio Communication*, *QST* and elsewhere. AMTOR was derived from a commercial system, SITOR, which was designed for use in the Maritime Mobile Service. It is used for ship-to-shore, ship-to-ship and between a ship and a subscriber of the (international) telex network. If you listen to shore station CW traffic lists, you will probably hear references to both TOR (SITOR) and TLX (telex).

Bill Meyn, K4PA, and a small group of U.S. amateurs operated AMTOR under a Special Temporary Authority (STA) that was granted by the FCC for tests that began in January 1982. His test report was published in the July 1983 *QST* Technical Correspondence column. Also in the same *QST* issue was "An Introduction to AMTOR," by Paul Newland, AD7I, one of the AMTOR experimenters under the STA. Additional references are listed at the end of the AMTOR part of this chapter.

As a result of a January 27, 1983 FCC order, AMTOR was made part of the U.S. Amateur Radio rules. The rule provided that "the code, baud rate and emission timing shall conform to the specifications of CCIR Recommendation 476-2 (1978) Mode A or B." In a later action, the FCC

also recognized Recommendation 476-3, a later document which corrected some inconsistencies in the earlier one. The latest (1986) CCIR documents are Rec. 476-4 and Rec. 625. Anyone interested in the design aspects of AMTOR should refer to these recommendations. You may obtain a complete reprint of Rec. 476-3 as part of the proceedings of the Third ARRL Amateur Radio Computer Networking Conference, available from ARRL Hq.

### An Overview of AMTOR

In the Maritime Mobile Service, this type of system was devised as a means of improving communications between 5-unit, asynchronous teleprinters using the ITA2 (Baudot) code. The system converts the 5-unit code to a 7-unit code for transmission. There is a one-for-one correspondence between the 5- and 7-unit codes for all 32 combinations of the 5-unit code, as can be seen in Table 4. Ordinarily, a 7-unit code could have up to  $2^7$  or 128 possible combinations. In this case, there is a constant ratio of four marks (Bs or Is) to three spaces (Ys or Os). If a received character does not have this constant ratio, the receiving station knows it is erroneous. The constant ratio limits the number of usable combinations to 35. So 32 of the combinations equate to the 32 ITA2 combinations, and there are 3 left over for use as *service information signals* as shown in Table 5. These three unique combinations are Idle Signal Beta, Idle Signal Alpha and *RQ or Repeat Request*. In addition to these three unique service information signals, three others (CS1, CS2 and CS3) are not unique but are borrowed from the 32 combinations that equate to ITA2. They are not confused with the message characters

because they are sent only in the reverse direction.

#### Mode A (ARQ)

This is a synchronous system, transmitting blocks of three characters from the *Information Sending Station (ISS)* to the *Information Receiving Station (IRS)*.

The station that initiates the QSO is known as the *Master Station (MS)*. The MS first sends the selective call of the called station in blocks of three characters, listening between blocks. Four-letter calls are used in AMTOR and are normally derived from the first character and the last three letters of the station call sign. As an example, for a call sign of W1AW the AMTOR call would be WWAU. The *Slave Station (SS)* recognizes its selective call and answers that it is ready. The MS now becomes the Information Sending Station and will send traffic as soon as the Information Receiving Station says it is ready.

After contact is established, the ISS sends its message in groups of three characters and pauses between groups for a reply from the IRS. Each character is sent at a rate of 100 bauds, amounting to 70 ms for one character or 210 ms for a three-character block. The block repetition cycle is every 450 ms, so there are 240 ms during each cycle that the ISS is not sending. This 240-ms period is taken up by propagation time from the ISS to the IRS, 70 ms for the IRS to send its service information signal, and the return trip back to the ISS. Turnaround or switching time associated with the modem and the radio transmitter and receiver (known as *equipment delay*, or  $t_E$  in CCIR Rec. 476-3) must occur within this 240-ms period. A receive-transmit turnaround time of less than 20 ms is desirable.

When an ISS is done sending, it can enable the other station to become the ISS by sending the three-character sequence FIGS Z B. A station may end the contact by sending an "end of communication signal" consisting of three Idle Signal Alphas.

On the air, AMTOR Mode A signals have a characteristic chirp-chirp sound to them. Because of the 210/240-ms on/off timing, Mode A can be used with some transmitters at full power levels.

#### Mode B (FEC)

When transmitting to no particular station (for example calling CQ, net or

bulletins) there is no (one) station to act as IRS, thus no one to send in the reverse direction. Even if there were one, his or her ability to receive properly may not be representative of others desiring to copy the signal.

Mode B uses a simple forward-error-control (FEC) technique of sending each character twice. If the repetition were sent immediately, a single noise burst or quick fade could mutilate both. Burst errors can be virtually eliminated by delaying the repetition for a period thought to exceed the duration of most noise bursts. In AMTOR, the first transmission (DX) of a character is followed by four other characters, after which the retransmission (RX) of the first character occurs. At 70 ms per character, this leaves 280 ms between the end of the first transmission and the beginning of the second. From the start of the first to the start of the second, the duration is 350 ms.

In Mode B, the receiving station tests for the constant 4-mark/3-space ratio and prints only unmutated DX or RX characters, or prints an error symbol or space, if both are mutilated.

The sending station's transmitter must be capable of 100%-duty-cycle operation for Mode B. Thus it may be necessary to reduce transmitter power level to 25% to 50% of full rating.

#### AMTOR Operation

Hundreds of U.S. and overseas stations are now active on AMTOR. It no doubt will grow in popularity as soon as amateurs realize the virtually error-free operation that it offers.

The frequency shift is 170 Hz for both Maritime Mobile and amateur use of CCIR Rec. 476-3. Existing 170-Hz-shift (Baudot RTTY) modems may be used for AMTOR. However, some demodulators designed for 45- or 50-baud Baudot RTTY service have narrow filter bandwidths and may require modification before they are suitable for 100-baud AMTOR operation. Most modem manufacturers will have modification instructions or kits available. If you have built a modem according to someone else's design, an s.a.s.e. to the designer probably will bring you the modification information.

Some of the commercially built AMTOR converters have built-in modems (for example, the I.C.S. Electronics AMT-1 uses the low-tone pair of 1275 Hz and 1445 Hz).

AMT-1 AMTOR converters sold by AEA for marketing in the U.S. provide the high-tone pair of 2125 Hz and 2295 Hz. One commercial unit (the Hal Communications Corp. ARQ1000) has an optional 170-Hz-shift modem with a 1700-Hz center frequency as specified in CCIR Recommendation 476-3. Other manufacturers of AMTOR equipment are Digital Electronic Systems, Inc., Kantronics and Microlog. Most AMTOR activity is around 14,075 and 3637.5 kHz, which are used as calling frequencies. Operators usually move off the calling frequency to free it for others. However, there are some automatically controlled stations that just stay on these frequencies. At this writing, unattended automatic control of an AMTOR station in the U.S. requires an FCC Special Temporary Authority.

You can listen for W1AW AMTOR Mode B transmissions following the Baudot and ASCII bulletins. Check *QST* for the W1AW schedule.

## American National Standard Code for Information Interchange (ASCII)

The American National Standard Code for Information Interchange (ASCII) is a coded character set used for information-processing systems, communications

systems and related equipment. Current FCC regulations provide that amateur use of ASCII shall conform to ASCII as defined in American National Standards In-

stitute (ANSI) Standard X3.4-1968. ANSI has issued a revision X3.4-1977, which differs only in terminology and elimination of two choices for certain graphics. Its inter-

national counterparts are International Organization for Standardization Standard ISO 646-1973 and International Alphabet No. 5 (IA5) as specified in CCITT Recommendation V.3.

ASCII uses seven bits to represent letters, figures, symbols and control characters. Unlike ITA2 (Baudot), ASCII has both upper- and lower-case letters. The ASCII coded character set is shown in Table 7. The bits in the table are arranged according to standard binary representation ( $b_6$  through  $b_0$ ). In the international counterpart codes, £ usually replaces #, and \$ may be replaced by the international currency sign ₤.

Some early video display terminals and teleprinters, such as the Teletype Corp. Model 33, implemented only the upper-case letters. They usually display the upper-case letters when the lower-case letters are received. On newer terminal equipment, a CAPS-LOCK feature on the keyboard may be used to shift all letters to upper case.

### Control Characters

ASCII has 32 control characters plus the special characters for space and delete. They are not consistently used as specified in the ANSI X3.4 standard. However, it will be helpful to know the standard uses. There are five groups in the control set: Logical Communication Control, Physical Communication, Device Control, Information Separators and Code Extension. Below is an explanation of each control character. The first line of each entry follows the following format:

**Table 7**  
**The ASCII Coded Character Set**

Bit Number	6	5	4	3	2	1	0	Hex 1st	Hex 2nd								
3	2	1	0														
0	0	0	0	0						NUL	DLE	SP	0	@	P	'	p
0	0	0	1	1						SOH	DC1	!	1	A	Q	a	q
0	0	1	0	2						STX	DC2	"	2	B	R	b	r
0	0	1	1	3						ETX	DC3	#	3	C	S	c	s
0	1	0	0	4						EOT	DC4	\$	4	D	T	d	t
0	1	0	1	5						ENQ	NAK	%	5	E	U	e	u
0	1	1	0	6						ACK	SYN	&	6	F	V	f	v
0	1	1	1	7						BEL	ETB	'	7	G	W	w	w
1	0	0	0	8						BS	CAN	(	8	H	X	x	x
1	0	0	1	9						HT	EM	)	9	I	Y	y	y
1	0	1	0	A						LF	SUB	*	:	J	Z	j	z
1	0	1	1	B						VT	ESC	+	;	K	[	k	{
1	1	0	0	C						FF	FS	,	<	L	\	l	
1	1	0	1	D						CR	GS	-	=	M	]	m	}
1	1	1	0	E						SO	RS	.	>	N	^	n	~
1	1	1	1	F						SI	US	/	?	O	_	o	DEL

ACK = acknowledge	FF = form feed
BEL = bell	FS = file separator
BS = backspace	GS = group separator
CAN = cancel	HT = horizontal tab
CR = carriage return	LF = line feed
DC1 = device control 1	NAK = negative acknowledge
DC2 = device control 2	NUL = null
DC3 = device control 3	RS = record separator
DC4 = device control 4	SI = shift in
DEL = (delete)	SO = shift out
DLE = data link escape	SOH = start of heading
ENQ = enquiry	SP = space
EM = end of medium	STX = start of text
EOT = end of transmission	SUB = substitute
ESC = escape	SYN = synchronous idle
ETB = end of block	US = unit separator
ETX = end of text	VT = vertical tab

**Notes**  
1. "1" = mark, "0" = space.  
2. Bit 6 is the most-significant bit (MSB), bit 0 the least-significant bit (LSB).

ASCII Keyboard Binary  
Char. Character Dec Hex 6543210 Name

#### Logical Communication Control Group

SOH	Control A	1	01	0000001	Start of Heading	⌈
Used at the beginning of a message heading.						
STX	Control B	2	02	0000010	Start of Text	⌊
Used at the beginning of a message heading.						
ETX	Control C	3	03	0000011	End of Text	┘
Terminates text.						
EOT	Control D	4	04	0000100	End of Transmission	⚡
Indicates conclusion of a transmission, which may have contained one or more texts and any associated headings. It may be used to turn off the receiving device.						
ENQ	Control E	5	05	0000101	Enquiry	⊠
Requests a response from a remote station. The response may be the remote station's station of identification (Who are you?).						
ACK	Control F	6	06	0000110	Acknowledge	✓
Transmitted by a receiver as an affirmative response to a sender.						
DLE	Control P	16	10	0010000	Data Link Escape	⊞
Changes the meaning of a limited number of continuously following characters. It is used exclusively to provide supplementary controls in data-communication networks. DLE is normally terminated by a shift in (SI) character.						
NAK	Control U	21	15	0010101	Negative Acknowledgment	✗
Transmitted by a receiver as a negative response to a sender.						
SYN	Control V	22	16	0010110	Synchronous Idle	⌋
Used by a synchronous transmission system in the absence of any other character to provide a signal from which synchronization may be achieved or retained.						
ETB	Control W	23	17	0010111	End of Transmission Block	⌋
Used to indicate the end of a block of data for communication purposes.						

#### Physical Communication Group

NUL	Control @	0	00	0000000	Null	□
Media or time fill. It may be inserted into, or removed from, a stream of data without affecting the information content of that stream.						

Graphic  
Symbol

CAN	Control X	24	18	0011000	Cancel	⌘
Indicates that the data with which it is sent is in error or is to be disregarded. It usually means cancel the line (data back to the last CR).						
EM	Control Y	25	19	0011001	End of Medium	⚡
Identifies the physical end of the medium, or the end of the used or wanted portion of information recorded.						
SUB	Control Z	26	1A	0011010	Substitute	?
A substitute for another character in the same position to keep data fields correct.						

#### Device Control Group

BEL	Control G	7	07	0001111	Bell	⚡
Used to call for operator attention. It may trigger an alarm or other attention devices.						
BS	Control H	8	08	0001000	Backspace	↶
A format effector that controls the movement of the printing position to one space backward on the same printing line. It is used for things such as: underlining, restriking for boldness and forming composite characters by overstriking. It is a very unpredictable character, that is implemented differently on printers and video-display terminals.						
HT	Control I	9	09	0001101	Horizontal Tab	→
A format effector that controls the movement of the printing position to the next in a series of predetermined positions along the same printing line.						
LF	Control J	10	0A	0001010	Line Feed	≡
A format effector that controls the movement of the printing position to the next printing line.						
VT	Control K	11	0B	0001011	Vertical Tab	↓
A format effector that controls the movement of the printing position to the next in a series of predetermined printing lines.						
FF	Control L	12	0C	0001100	Form Feed	↓
A format effector that controls the movement of the printing position to the first predetermined printing line on the next form or page.						
CR	Control M	13	0D	0001101	Carriage Return	↶
A format effector that controls the movement of the printing position to the first printing position on the same printing line. In some cases, the CR will incorporate an automatic line feed (LF) as either a default or an option. This feature, called New Line (NL), is used to make computer keyboards more like those of typewriters.						

DC1	Control Q	17	11	0010001	Device Control 1
DC2	Control R	18	12	0010010	Device Control 2
DC3	Control S	19	12	0010011	Device Control 3
DC4	Control T	20	14	0010100	Device Control 4

These are the control of ancillary devices associated with data processing or telecommunications systems, especially for switching devices on or off. While DC1 and DC3 are often used to start and stop the flow of data, these control signals are "wild cards" that are used for nearly any switching purposes.

#### Information Separators

FS	Control \	28	1C	0011100	File Separator
GS	Control	29	1D	0011101	Group Separator
RS	Control ^	30	1E	0011110	Record Separator
US	Control _	31	1F	0011111	Unit Separator

FS, GS, RS and US is a hierarchical group of information separators used for formatting and string processing. FS is the most inclusive, and US the least inclusive. A *file* is a grouping of all related records. A *group* is a collection of *records* within a file. A *record* is a collection of related fields of data. A *unit* is a number of fields 1 to 80 characters long.

#### Code Extension Group

SO Control N 14 0E 0001110 Shift Out  
Indicates that the code combinations that follow are to be interpreted as outside of the standard character set until a shift in (SI) character is reached.

SI Control O 15 0F 0001111 Shift In  
Indicates that the code combinations that follow are to be interpreted according to the standard code table.

ESC ESC 7 1B 0011011 Escape  
Intended to provide code extension (supplementary characters). The ESC character itself is a prefix affecting the interpretation of a limited number of continuously following characters. It may be terminated by a shift in (SI) character.

## Parity

While not strictly a part of ASCII (ANSI X3.4), an eighth bit (P) may be added for *parity* checking. FCC rules permit optional use of the parity bit. The applicable U.S. standard (ANSI X3.16-1976) and international standard (CCITT Rec. V.4) recommend an *even* parity sense for asynchronous data communication and *odd* parity sense for synchronous data communication. However, there is very little standardization within the computer industry, and you will find five variations: (1) no parity, (2) always mark, (3) always space, (4) odd parity or (5) even parity. See Chapter 8 for details of parity checking.

## Code Extensions

By sacrificing parity, the eighth bit can be used to extend the ASCII 128-character code to one having 256 possibilities. Work is now underway to produce an international standard on extended coded character sets for text communication that will provide supplementary sets of graphic characters. Use of these extended character sets by U.S. amateurs is permitted above 50 MHz but not below 50 MHz where only specified codes (Baudot, AMTOR and ASCII) are authorized by FCC rules.

## ASCII Serial Transmission

Serial transmission of ASCII is covered

in ANSI Standards X3.15 and X3.16, and CCITT Recommendations V.4 and X.4. They specify that the bit sequence for serial transmission of an ASCII character shall be least-significant bit first to most-significant bit or  $b_0$  through  $b_6$  (plus the parity bit P if used).

Serial transmission may be either *synchronous* or *asynchronous*. In synchronous transmissions, only the information bits (and optional parity bit) are sent, as shown in Fig. 22A.

Asynchronous (start-stop) serial transmission adds a *start pulse* at the beginning and a *stop pulse* at the end of each character. The start pulse is the same length as for the information pulses. The stop pulse may be one or two bit periods long. Although there is some variation, the convention is that the stop pulse is one bit period long except for 110-baud transmissions where mechanical teletypewriters may be involved.

## ASCII Data Rates

Personal computers usually provide a choice of ASCII serial input/output data rates ranging from 110 to 19,200 bits per second, as shown in Table 8.

Data communications signaling rates depend largely on the medium and the state of the art when the equipment was selected. Numerous national and international stan-

Table 8

## ASCII Asynchronous Signaling Rates

Bits per Second	Data Pulse (ms)	Stop Pulse (ms)	CPS	WPM
110	9.091	18.182	10.0	100
150	6.667	6.667	15.0	150
300	3.333	3.333	30.0	300
600	1.667	1.667	60.0	600
1200	0.8333	0.8333	120	1200
2400	0.4167	0.4167	240	2400
4800	0.2083	0.2083	480	4800
9600	0.1041	0.1041	960	9600
19200	0.0520	0.0520	1920	19200

CPS = characters per second

$$= \frac{1}{\text{START} + 7 (\text{DATA}) + \text{PARITY} + \text{STOP}}$$

$$\text{WPM} = \text{words per minute} = \frac{\text{CPS}}{6} \times 60$$

= number of 5-letter-plus-space groups per minute

dards that recommend different data rates, are listed in Table 9. The most-used rates tend to progress in 2:1 steps from 300 to 9600 bits per second and in 8000 bits-per-second increments from 16,000 bits per second. For Amateur Radio serial ASCII transmissions the data rates of 75, 110, 150, 300, 600, 1200, 2400, 4800, 9600, 16,000,

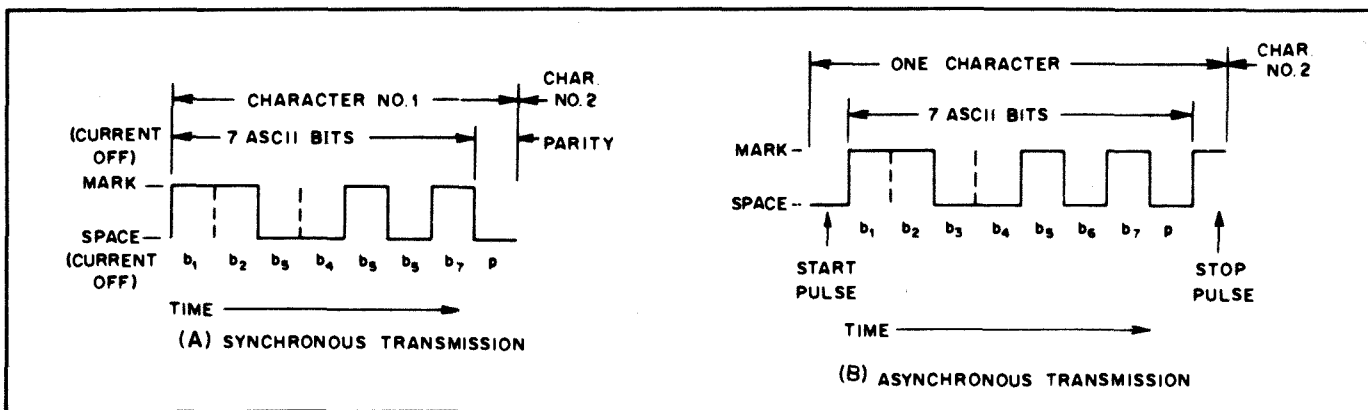

Fig. 22 — Time sequence of typical ASCII character, the letter S sent serially.

19,200 and 56,000 bits per second are suggested.

### Bauds vs. Bits Per Second

The term *baud* is a unit of signaling speed equal to one discrete condition or event per second. In single-channel transmission, such as the FCC prescribes for Baudot transmissions, the signaling rate in bauds equals the data rate in bits per second. However, the FCC does not limit ASCII to single-channel transmission. There are digital modulation systems that have more than two (mark and space) states. In *dibit* modulation two ASCII bits are sampled at a time. The four possible states for a dibit are 00, 01, 10 and 11. In four-phase modulation, each state is assigned an individual phase of 0, 90, 180 and 270 degrees, respectively. Using dibit phase modulation, the signaling speed in bauds is half the information-transfer rate in bits per second. As the FCC specifies the digital sending speed in bauds, amateurs may transmit ASCII at higher information rates by using digital modulation systems that encode more bits per signaling element. This technology is open for exploration by Amateur Radio experimenters.

### Amateur ASCII RTTY Operations

On April 17, 1980 the FCC first permitted ASCII in the Amateur Radio Service. U.S. amateurs have been slow to abandon Baudot in favor of asynchronous serial ASCII.

Some of the reluctance to use it arises from the reasoning that asynchronous ASCII has two (or three with a parity bit added) more bits than asynchronous Baudot and is usually sent at higher speeds. Thus, it was felt that the greater data rates and increased bandwidth needed for ASCII would make its reliability lower than that of Baudot. This is true as far as it goes but does not exhaust the theoretical possibilities, which will be discussed below.

On the practical side, some amateurs tried ASCII on the air and experienced poor results. In some cases, this can be traced to the use of modems that were optimized for 45-baud operation. At 110 or 300 bauds, the 45-baud mark and space filters are too narrow. On the HF bands, speeds above 50 or 75 bauds are subject to intersymbol interference (ISI) (slurring one pulse into the next) from multipath propagation. Multiple paths can be avoided by operating at the maximum usable frequency (MUF) where there is only one ray path. The amount of multipath delay varies according to operating frequency with respect to the MUF and path distance. Paths in the 600- to 5000-mile range are generally less bothered by multipath than shorter or longer ones, with paths of 250 miles or less being difficult from a multipath standpoint. As a result, successful operation at the higher ASCII speeds depends on using the highest frequency band possible as well as having

**Table 9**  
**Data Transmission Signaling-Rate Standards**

Standard	Signaling Rates (bit/s)	Tolerance
<b>CCITT</b>		
V.5	600, 1200, 2400, 4800	± 0.01%
V.6	Preferred: 600, 1200, 2400, 3600, 4800, 7200, 9600 Supplementary: 1800, 3000, 4200, 5400, 6000, 6600, 7800, 8400, 9000, 10200, 10800	± 0.01%
V.21	200 300 (where possible)	≤ 200 bit/s ≤ 300 bit/s
V.23	600 1200 75 (backward channel)	≤ 600 bit/s ≤ 1200 bit/s ≤ 75 bit/s
V.35	Preferred: 48000 When necessary: 40800	± 1 bit/s ± 1 bit/s
V.36	Recommended for international use: 48,000 Certain applications: 56000, 64000, 72000	
X.3	Packet assembly/disassembly speeds: 50, 75, 100, 110, 134.5, 150, 200, 300, 600, 1200, 1200/75, 1800, 2400, 4800, 9600, 19200, 48000, 56000, 64000	
<b>ANSI</b>		
X3.1	Serial: 75, 150, 300, 600, 1200, 2400, 4800, 7200, 9600 Parallel: 75, 150, 300, 600, 900, 1200	
X3.36	Above 9600 bit/s, signaling rates shall be in integral multiples of 8000 bit/s. Selected standard rates: 16000, 56000, 1344000 and 1544000 Recognized for international use: 48000	
<b>EIA</b>		
RS-269-B	(Same as ANSI X3.1)	
<b>FED STD</b>		
-1001	(Same as ANSI X3.36) For foreign communications: 64000	
-1041	2400, 4800, 9600	

suitable modems at both ends of the circuit.

Returning to the theoretical comparison of Baudot and ASCII, recall that the FCC requires asynchronous (start-stop) transmission of Baudot. This means that the five information pulses must be sent with a start pulse and a stop pulse, usually of 1.42 times the length of the information pulse. Thus, an asynchronous Baudot transmitted character requires 7.42 units. In contrast, 7 bits of ASCII plus a parity bit, a start and a two-unit stop pulse has 11 units. However, it is possible to send only the 7 ASCII information bits synchronously (without start and stop pulses), making the number of units that must be transmitted (7 vs. 7.42) slightly smaller for ASCII than for Baudot. Or, it is possible to synchronously transmit 8 bits (7 ASCII bits plus a parity bit) and take advantage of the error-detection capability of parity. Also, there is nothing to prevent ASCII from being sent at a lower speed such as 50 or 75 bauds, to make it as immune to multipath as 45- or 50-baud Baudot RTTY is. So it is easy to see that ASCII can be as reliable as Baudot RTTY if care is used in system design.

While 45- or 50-baud RTTY circuits can

provide reliable communications, this range of signaling speeds does not make full use of the HF medium. Speeds ranging from 75 to 1200 bauds can be achieved on HF with error-detection and error-correction techniques similar to those used in AMTOR. Reliable transmission at these higher speeds can be accomplished by means of packet radio, which is described later in this chapter.

## Code Conversion

Conversion between International Morse, Baudot and ASCII is tricky business. In fact, it is virtually impossible to come up with a perfect conversion between any two of these codes, let alone all three. Anyone who has given this serious consideration will confirm this.

The root of the problem is that each code has a somewhat different character set. All three have all the numerals (0-9), a word space, certain punctuation marks and the Latin alphabet upper case in common. If you have original text with upper- and lower-case letters in ASCII, the case information will be lost when converting to Baudot or Morse, both of which assume that all letters are in upper case. Once lost, the case information cannot be regained except, perhaps, by a computer program designed to guess the case.

Another problem with code conversion is that the conversion tables cannot be bilateral. Using the case example, above, both upper- and lower-case ASCII will translate to upper-case Baudot and Morse, but Baudot and Morse letters cannot translate to both ASCII cases. There are some subtleties to this game. Thus, if you want to design a versatile code-conversion scheme, it is useful to build unilateral conversion tables, one for translating code a to b, another for converting code b to a.

The differences between the international and national implementations of Baudot add some further complications. On most U.S. teletypewriters, the figures-case characters for D, F, G and H are used for \$, !, & and # (or motor stop), respectively. In ITA2, these characters are unassigned, meaning they are set aside for national use. So, you can't use these characters for international communications unless you have an agreement with the other station as to what each means. Perhaps even worse is that the figures-case characters for J, S, V and Z, while specified to be audible signal (bell), ', = and +, respectively, for ITA2, show up as ', bell, ; and " on many U.S. TTYs. You can use these characters internationally as long as you bear in mind that hams in other countries will probably interpret them within their ITA2 meanings.

There are some more complications when considering conversion to and from ASCII or its international versions, IAS

and ISO 646. The ASCII characters #, \$, @, [, \, ], ^, ` , {, |, } and ~ may be assigned to different graphic characters in other countries. Some languages need these wild cards for accented letters.

Morse code presents a few dilemmas too. One is that few hams know the complete Morse character set shown in Table 1. To limit the character set to just those known by most amateurs might be advisable for QSOs that will be aurally read by the average operator. However, it could be unnecessarily restrictive when sending to the expert operator or to a computer that knows the whole code. A code-conversion program that produces Morse might include a menu-selectable feature to vary the conversion table according to the receiving audience.

### Code Conversion Standards

International standards, ISO/DIS 6936 and CCITT Rec. S.18, exist for conversion from ITA2 to ASCII and the reverse. They include direct conversion for all common characters and change both upper- and lower-case ASCII into upper-case ITA2 in a straightforward manner. When translating from ITA2 to ASCII, ITA2 characters for which there are no corresponding ASCII characters are translated to SUB. Going the other way around, SOH, STX, ETX, EOT, ACK, DLE, NAK, SYN, ETB and DEL are removed; the other nontranslatable characters are replaced by the question mark (?). Bear in mind that ISO/DIS 6936 is based on ITA2, not the version of Baudot that is found on many U.S. teletypewriters.

Limiting code conversion simply to direct equivalents may not be the best approach for Amateur Radio. In this respect, it is important to note that some characters (in Morse, Baudot and ASCII) change their meanings according to the context, or protocol, in which they are used. For example, the Morse code combination •-• is an accented letter A for certain European languages but is also used as a separator in Amateur Radio message headings. The meanings of ASCII control characters change as different implementors of computer systems or data-communications networks reassign them to meet specific needs. What is ETX (end of text) to one system

is Control C (crash the program) to another.

To go beyond the direct equivalents requires that the context(s) be carefully defined and standardized. In other words, if you know how a certain character (or sequence of characters) is used in one code using one protocol, there must be a corresponding character or set of characters in the other code and protocol.

Now that you're completely confused, let's look at how to say that a message is coming. ASCII has its SOH (start of heading) — just one control character can do the job. In Baudot it's a problem, but not insurmountable. CCITT Rec. S.4 (see Chapter 38) comes to the rescue by using ZCZC as the start of the heading. And in Morse — ah Morse! — we have two possibilities: HR (meaning here is, or hear the following message) and KA, a starting signal. There are similar correspondences between ASCII EOT, Baudot (CCITT Rec. S.4) NNNN, and Morse AR.

These examples illustrate the practicality of developing contextual code-conversion tables for Amateur Radio. This is not to suggest that everyone rush out there and implement one on the assumption that any right-thinking person would go along with your conversion table. Beware of the mines, quicksand, traps and low doorways! How many programmers made up their own ASCII character for the Morse code combination •-• (KN) when left parenthesis [(] was part of International Morse? Many other radio services, even other IARU Member Societies, have been using --••• for left parenthesis all along.

The ARRL Digital Communications Committee will be working on standardized code-conversion tables for use by amateurs. This will dovetail with other work on standardizing message formats.

### CODE-CONVERSION TABLES

Tables 10 through 14 are based on direct character-for-character translations between Morse, Baudot and ASCII. They are conservative and do not conflict with international standards. Conversions between ITA2 and ASCII comply with ISO/DIS 6936. The tables have numerous blanks where there are no exact equivalents in the other codes. The order of characters for

**Table 10**

**Notes**

<sup>1</sup> In Baudot code, it is necessary to check to see if the terminal is in the correct case (↓ = letters, ↑ = figures). If not, a LTRS or FIGS must be inserted before the code shown.

<sup>2</sup> Figures-case characters are the same for both ITA2 and U.S. teletypewriters except where indicated. If only (U.S.) is shown, this is an unassigned character in ITA2.

**Notes**

<sup>1</sup> In Baudot code, it is necessary to check to see what the current case is before conversion (↓ = letters, ↑ = figures, ↓↑ = either).

<sup>2</sup> Figures-case characters are the same for both ITA2 and U.S. teletypewriters except where indicated. If only (U.S.) is shown, this is an unassigned character in ITA2.

each table is determined by the digital value of the code from which conversion is to be made.

**Conversion from Morse to ASCII and Baudot**

Table 10 starts with the Morse E and progresses through the code to the longest characters. This progression has been used in code-conversion programs written in BASIC. All Morse Latin letters translate directly to Baudot letters and upper-case ASCII letters. All direct equivalents of punctuation marks are included.

Table 12

## Notes

<sup>1</sup> In Baudot code, it is necessary to check to see what the current case is before conversion (l = letters, f = figures, lf = either case).

<sup>2</sup> Figures-case characters are the same for both ITA2 and U.S. teletypewriters except where indicated.

International Morse has specific code combinations for accented letters. However, they cannot be translated out of context to either Baudot or ASCII because individual national implementations of these codes place them differently.

The programmer is left to determine how

to display nonconvertible Morse characters. For example, an incoming SK cannot be displayed or printed as such because an overlining capability is not usually provided in computer peripherals. Perhaps it could be shown as SK if there is an underlining capability or <END OF WORK> if not.

Alternatively, it could be ignored at the expense of losing that meaning.

When converting from Morse (or ASCII) to Baudot, the program has to check to see what case the Baudot is in. If, for example, you just received WB and the next character is 4, you have to check to see that

Note 1: For complete specifications of these codes see the following International Telecommunication Union documents: ITA1 and 2 — Telegraph Regulations (Geneva Revision, 1958), ITA3 — CCITT Rec. S.13, ITA4 — CCITT Rec. R.44.

Note 2: In ITA1, + indicates positive current, - negative current. In ITA2 through ITA4, 1 represents mark condition (shown as Z in ITU recommendations, which is the higher emitted radio frequency for FSK, the lower for AFSK). 0 represents the space condition (shown

as A in ITU recommendations). For meanings of A and Z see CCITT Rec. 140. The normal order of bit transmission is lowest significant bit (LSB) first.

Note 3: At the disposal of each administration for its internal service.

Note 4: At present unassigned. Reception of these signals, however, should not initiate a request for repetition. See CCITT Rec. S.4.

Note 5: Permanent 0 polarity.

Note 6: Permanent 1 polarity.

the device is in letters case before giving it the B. In this case it is so no LTRS function need be issued. Then, having checked or remembered that the device is in letters case for the B, a FIGS function must be sent before sending the Baudot device the 4.

### Conversion from Baudot to ASCII and Morse

Table 11 is arranged by binary progression starting with 00000 (blank). Note that blank translates to an ASCII NUL, but the letters-shift (LTRS) character does not convert to an ASCII DEL. When a mistake is made during preparation of paper tape, the operator may backspace the tape and use LTRS or DEL to punch all hole positions to erase erroneous characters. If this is done when preparing Baudot tapes, the LTRS function will be read as a change from figure case (if it was there) to letter case. If letter case was not wanted, a figures-shift character must be inserted after the LTRS functions. DEL causes no

case change, so LTRS and DEL are not equivalent.

The bell and apostrophe (') translate nicely from ITA2 to ASCII. But note that these codes in ITA2 are just exactly reversed in the code used in most U.S. Baudot TTYs. Because of this difference, it is usually desirable to send both characters in Baudot. This causes both ITA2 and U.S. machines to ring the bell and print an apostrophe. In that other stations may send one code, the other or both together, this makes an interesting puzzle for the code conversion programmer.

The WRU (Who are you?) character in ITA2 converts to ENQ (enquiry) in ASCII. They are both used to request the identity of the other terminal. However, ENQ may also be used to request the status of the other terminal.

Figures H (10100) is messy. It is unsigned in ITA2 and available for national use. On U.S. TTYs, it is probably a pound sign (#), and thus will translate # to an

ASCII #. On older machines, it may be used as a motor stop.

When using figures case, you should be aware of a feature called *unshift on space* that may be implemented on some Baudot terminals. If you send a group of numbers and a space, the machine will print letters-case characters after the space if it has the unshift-on-space feature. To avoid this problem, it is a good idea always to send a FIGS just before each group of figures that are preceded by a space.

Some terminals have a "nonoverline" feature. An automatic LF is sent every time a CR is received. Others have a "wrap-around" feature that automatically moves to the first printing position of the new line when the old line is full. If your terminal has these features, don't assume everyone has them.

### Conversion from ASCII to Morse and Baudot

This conversion is probably the most-

needed one because many amateurs are using, or would like to use, an ASCII keyboard to generate Morse and Baudot codes. Table 12 shows that most code combinations needed in Morse and Baudot can be translated from the ASCII character set. However, there are some Morse characters (accented letters,  $\overline{SN}$ ,  $\overline{INT}$ ,  $\overline{AS}$ ,  $\overline{AU}$ ,  $\overline{HM}$ ,  $\overline{SK}$ ,  $\overline{IX}$ , or  $\overline{HH}$ ) that don't appear on an ASCII keyboard. Some of the control characters or graphic characters could be used until an Amateur Radio standard code conversion table is developed.

#### Code Conversion ITA1 through 4

Table 13 gives character-for-character

code equivalents for these CCITT codes. ITA1 was used on cables. ITA2 is in standard use in the Amateur Service and in telex services worldwide. ITA3 is found in Table A-1 of Annex A to CCITT Recommendation S.13, "Use on Radio Circuits of 7-Unit Synchronous Systems Giving Error Correction by Automatic Repetition." ITA4 is specified in Annex A to CCIR Rec. R.44 entitled "6-Unit Synchronous Time-Division 2-3-Channel Multiplex Telegraph System for Use over FMVFT Channels Spaced at 120 Hz for Connection to Standardized Teleprinter Networks." The abbreviation FMVFT means frequency modulated voice-frequency telegraph. ITA1, 3 and 4 are not currently used in the

Amateur Radio Service but would be legal in the U.S. above 50 MHz. They are included herein primarily for information.

#### Conversion Between ASCII, EBCDIC and Selectric

Although they are not common in the Amateur Radio Service, it is possible to transmit EBCDIC and IBM Selectric® codes in the U.S. above 50 MHz. It is more likely that surplus equipment using these codes would be used as peripherals in a computer setup. Table 14 is included for the individual who wants to write ASCII conversion tables for EBCDIC or Selectric devices.

## Packet Radio — Integrated Digital Communications

The term *data communications* is virtually synonymous with transfer of information between computers. In fact, the term includes any types of signals that can be expressed in digital form. It is no secret that every major communications system is changing to digital transmission and phasing out many older analog systems. Analog communications systems can be made to work well over one or two relays without problems with background noise or distortion. However, if you add dozens of relays then the noise and distortion are not simply that of the weakest link but the accumulation of the ill effects.

With digital transmission, these effects are eliminated on a link-by-link basis by regenerating the digital information on each relay. Also, error-control techniques are brought into play to eliminate any missed or wrong bits. Thus the end-to-end noise and distortion are simply that of the digitizing process, not the transmission of the digital information.

The larger commercial and governmental communications carriers have embarked on *integrated* digital networks, that is, ones that will handle voice, images and data. Amateur Radio has taken bold steps in that direction under the banner of *packet radio*. The ultimate goal is to have a global amateur packet-radio network capable of automatically sending keyboard data, speech and images to other amateurs anywhere in the world. Much of the technology is now available to us, and agreement on standards is well underway. The ARRL has provided a framework for packet-radio experimenters to exchange ideas through its Amateur Radio Computer Networking Conferences held since 1981. The ARRL Ad Hoc Committee on Amateur Radio Digital Communication was established by the Board of Directors to develop standards. The committee has representation from the major packet-radio clubs and has been successful in developing cooperative standards.

The foundation for a global amateur

packet-radio network has been laid. Current Amateur Radio packet technology will support direct connections (read that error-free two-way communications) between two stations with as many as eight digital repeaters in between. Packet radio is currently active on a local-area basis in a number of North American locations and some other countries. While most of the activity has been on VHF, 1984 became the year of growing packet-radio operation on HF and via amateur satellite. Also, a number of groups on the East and West Coasts of the United States have successfully chained a number of packet repeaters, which by 1986 should support relaying of packets from San Diego to Vancouver and from Miami to Montreal.

In the 1984 *Handbook*, we estimated that over 300 U.S. amateurs were active on packet radio. That number has grown to 3900 as the 1986 *Handbook* is being edited. Additional rapid growth will continue as more amateurs realize the error-free communications available now from packet radio. Further expansion is inevitable as more amateurs understand the potential services that a global amateur integrated data network will provide:

- Two-way terminal-to-terminal communications between your station and any other within the network.

- Computer file transfer between stations.

- If the desired station is not logged onto the network at the time you wish, you can leave a message on the computer-based message system (CBMS) used by that station.

- Host computers will be scattered through the network to provide a variety of services such as data bases with information of interest to amateurs.

- Access to the network will be open to those with even the most modest Amateur Radio station. If you can presently use a hand-held transceiver to work into a 2-meter repeater, you could use the same hand-held to get into a 2-meter packet

repeater if there is one in your local area.

- Routing of packets throughout the network will be automatic and will take advantage of VHF/UHF terrestrial relays, meteor-scatter, HF and satellite packet-radio links.

- Third-party traffic, where permitted, will be automatically handled through the network.

- The latest bulletins will be available to you whenever you are signed on to the network.

Is all of this *blue sky*? Not really. Many of the capabilities mentioned above are already available in a growing number of North American metropolitan areas. However, internetworking between these locations is not yet a reality except for linking some packet repeaters up and down the East and West Coasts, and in several inland areas. Internetworking is contingent on some further developments, namely:

- Agreement on networking standards (now under development by the ARRL Digital Committee),

- Design and installation of high-speed (9.6- to 56-kbit/s) packet-radio stations for the terrestrial *backbone* that will interconnect metropolitan areas.

- Participation by more clubs with the technical and funding resources to establish packet-radio facilities in their areas and link with neighboring areas.

- Individual amateurs interested in getting their own station on packet radio and willing to help others do the same.

When 2-meter FM began, who would have guessed that today there would be over 9000 VHF/UHF FM repeaters in North America? A look through the ARRL *Repeater Directory* will show that there are few places within the United States and southern Canada that are not served by at least one FM repeater. Packet radio has the same potential but is in an early stage of its growth. A number of packet radio repeaters are shown in the *Repeater Directory*; others are not yet listed and more are planned by various groups. The eventual

number of packet repeaters is left to speculation. However, it is a safe bet that the number will be in the thousands.

### Amateur Packet Radio History

The Canadian Department of Communications authorized packet radio in 1978. Amateurs in Montreal were the first to get on the air. In Vancouver, BC, Doug Lockhart, VE7APU, began experimenting with *bit-oriented* packet radio based on the International Organization for Standardization (ISO) high-level link control (HDLC) protocol. Bit-oriented protocols permit different meanings to be assigned to each bit and are more efficient than *character-oriented* protocols, which need to send an entire character for each morsel of information.

Doug also designed a special-purpose computer called a terminal-node controller (TNC). He founded the Vancouver Amateur Digital Communications Group (VADCG) that arranged for the manufacture of over 500 TNC boards and sold them to amateurs in North America and to a few overseas amateurs. These TNCs and VADCG's newsletter, *The Packet*, helped many experimenters get started in packet radio. VADCG provided North American "packetees" a way to check their TNC boards by transmitting packet beacon messages on 14.0765 MHz. They also cooperated with Ontario amateurs and exchanged packets via Canada's ANIK B satellite.

The Canadian Radio Relay League awarded a CRRL Certificate of Merit to Doug Lockhart in August 1984 in recognition of his packet-radio pioneering work.

### Genesis in the United States

In 1980, two groups in the U.S. began experimenting with the VADCG TNC boards. One was near San Francisco where Hank Magnuski, KA6M, activated the first U.S. amateur packet-radio repeater on 2 meters on December 10, 1980. KA6M/R did not use the VADCG TNC but was equipped with a homemade TNC based on an STD-bus Z80<sup>®</sup> microprocessor and a Western Digital 1933 HDLC chip. Following the VADCG pattern, KA6M/R used a Bell 202 modem, chiefly because of their surplus availability. Hank founded the Pacific Packet Radio Society (PPRS), pioneered sending packets through the OSCAR 10 satellite, and has been an important contributor to the development of amateur packet radio in the United States.

In the Washington, DC area, the Amateur Radio research and Development Corporation (AMRAD) began spreading the word about packet radio through its *AMRAD Newsletter*. Bill Moran, W4MIB, was the first East Coast packeteer to get on the air on May 4, 1981. AMRAD used an unmodified 2-meter FM voice repeater instead of building a simplex (single-frequency) packet-only repeater as KA6M had done. A simplex repeater was later ac-

tivated to serve the Washington, DC area (currently WB4JFI/R on 145.01 MHz).

Early witnesses of packet-radio operation were amazed to see the one- or two-second bursts turn into almost instant displays of error-free text across the CRT screen. It took no convincing for them to visualize a packet-radio network spanning North America if not the globe. It became clear that the local-area groups needed to be interconnected by means of terrestrial VHF/UHF *backbone* network, HF and satellite. Commercial experience strongly suggested that meteor-scatter communications would be excellent for packet radio over 600- to 1200-mile paths.

### First Computer Networking Conference

Greater forces were needed to solve some immediate technical problems and to establish packet-radio activities in other areas. It was time to get the existing packet experimenters together to exchange ideas and to invite others to get involved. Thus, in October 1981, AMRAD and AMSAT organized the first ARRL Amateur Radio Computer Networking Conference, which convened at the National Bureau of Standards headquarters in Gaithersburg, Maryland. The conference was attended by 80 amateurs, many of whom presented their views on how an amateur packet-radio network should be designed. Participation by Canadian and Swedish amateurs made the conference an international event. The second day of the conference was held at the Goddard Space Flight Center as a prelude to the AMSAT annual meeting.

After the first conference, Den Connors, KD2S, moved to Tucson, Arizona and founded the Tucson Amateur Packet Radio Corporation (TAPR). This group designed three successive TNCs. The alpha test TNC was built in small quantities. TAPR then designed their beta test TNC and had 180 of them fully assembled for field testing in a number of geographical areas. The feedback that they received was used in the design of the TAPR TNC kit, over 2000 of which have been sold throughout the world. In recognition of TAPR's contribution to packet radio, TAPR President Lyle Johnson, WA7GXD, was given the Dayton ARA Technical Excellence Award in 1984.

Packet-radio protocols were the subject of discussion and diversity of views. The original software supplied by VADCG underwent some evolutionary changes. However, that software provided only one-byte addresses, meaning that the number of stations that could be addressed was quite small. Some thought that the packet-radio addressing system should be based on amateur call signs, while others proposed dynamic-addressing schemes wherein the specific address would be assigned at the time of signing onto the network. AMRAD and the Radio Amateur Telecommunications Society (RATS) of New Jersey held meetings to see whether the CCITT X.25

public packet-switched network protocol could become the basis for an Amateur Radio packet protocol. There were problems, but most were solved by Eric Scace, K3NA, who served on the CCITT committee and was one of the authors of X.25. What emerged from these meetings was called AX.25 (Amateur X.25). AX.25 was based on the use of Amateur Radio call signs for the address field of the HDLC frame. AX.25 was not instantly accepted.

### AX.25 Agreement

By mid 1982, there was some concern that the various packet groups would not be able to agree on a common protocol by the time OSCAR 10 was launched. In October 1982, Tom Clark, W3IWI, as president of AMSAT, called a meeting of active U.S. packet-radio groups. His strategy was to lock them all in a room until they agreed. It worked. The outcome was a new version of AX.25 that would allow a repeater call sign as an optional third address in the HDLC frame.

At the October 1982 meeting mentioned, AMSAT's packet-satellite (PACSAT) project was started. The concept for a low-orbiting packet "mailbox" that would serve the whole earth was accepted by the AMSAT membership. KD2S was designated the project leader and later passed that role to Harold Price, NK6K. PACSAT is now scheduled to be launched in 1987.

Within weeks after the October 1982 meeting, KA6M and NK6K had early versions of AX.25 software written for the VADCG and TAPR TNCs. The VADCG and TAPR versions of AX.25 wouldn't talk to each other immediately, but some software patches took care of that in early 1983.

### Second Computer Networking Conference

The second ARRL Amateur Radio Computer Networking Conference was held in March 1983, in San Francisco. This conference served to consolidate gains made thus far and to introduce others to packet radio.

In July 1983, a meeting was held at the home of Harold Price, NK6K, to talk about linking of packet repeaters from San Diego to San Francisco. WESTNET was born and with it a proposal to permit up to eight repeater call signs in the AX.25 frame. This proposal was accepted by the ARRL Digital Communications Committee in November 1983 and made part of AX.25 until a true networking protocol could be agreed to and implemented.

Word of WESTNET's creation prompted formation of EASTNET to link Washington, DC to the packet repeater in Lowell, Massachusetts operated by the New England Packet Radio Association (NEPRA). As a part of this network, ARRL HQ activated the WIAW packet repeater on February 18, 1984. The

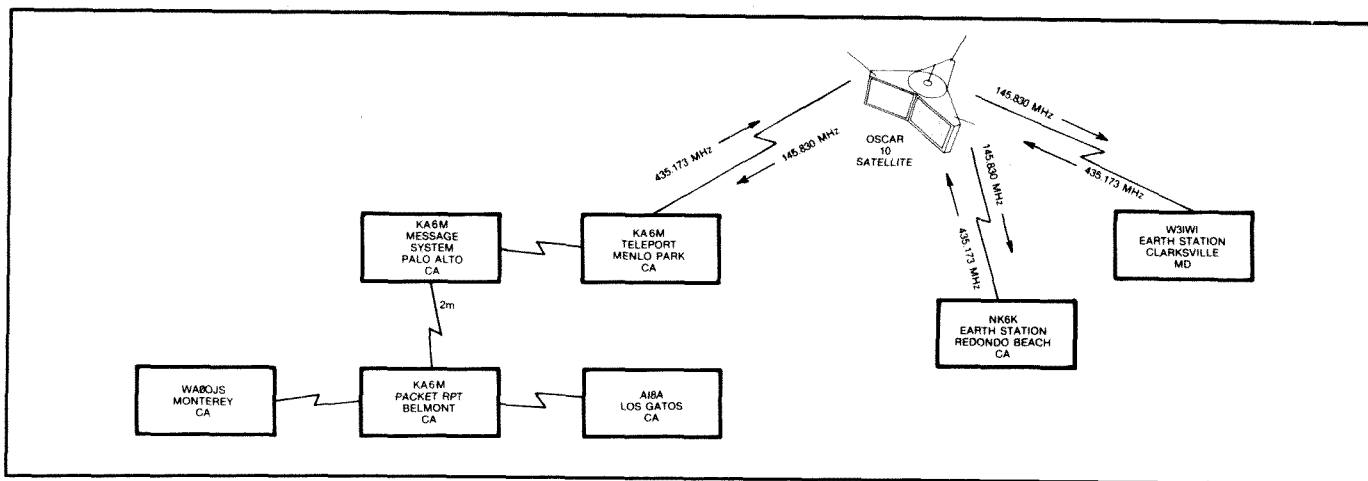

Fig. 23 — Link diagram of the first teleport experiments via OSCAR 10 on March 11, 1984.

southeast part of the country was subsequently served by SOUTHNET, operated by the Florida Amateur Digital Communications Association (FADCA). EASTNET and SOUTHNET are to be joined through the Carolinas.

### Third Computer Networking Conference

A third ARRL Amateur Radio Computer Networking Conference was held in Trenton, New Jersey in April 1984. Incidentally, printed proceedings of each of the three conferences are available from ARRL Hq.; see the bibliography at the end of this section. The Dayton Hamvention followed in two weeks and held a packet-radio forum with a record turnout of over 300 in attendance. It was clear from the meetings in Trenton and Dayton that packet radio was no longer the exclusive province of bearded experimenters but was a proper topic for discussion in "polite company." At this time, it was estimated that about 1700 TNCs (or software equivalents) had been sold and that about 1300 of them were considered operational.

On November 14, 1984, the ARRL filled a Petition for Rule Making (RM-4879) with the FCC requesting permission for automatic control of an amateur station on frequencies above 30 MHz when using digital communications. This addition to the rules would clear away obstacles to computer based message system (CBMS) operation and various forms of networking under automatic control. In response, on April 5, 1985, the FCC adopted a Notice of Proposed Rule Making (PR Docket No. 85-105) in which they proposed that any Amateur Radio station be permitted to operate under automatic control, except when transmitting on frequencies below 29.5 MHz.

An FCC Order adopted March 25, 1985, eliminated the special requirement that a description of special digital codes used above 50 MHz be included in the station

log and provided to the Commission upon request.

### Teleport Experiments

On March 11, 1984, several stations demonstrated the interconnection of packet-radio stations through terrestrial repeaters and the teleport via the OSCAR 10 satellite. Those involved were Tom Clark, W3IWI, Hank Magnuski, KA6M, Harold Price, NK6K, Jim Tittsler, A18A, and Ron McMurdry, WA0OJS. The first contact was between W3IWI and WA0OJS. Then NK6K chatted with A18A for about 10-15 minutes. The links were as shown in Fig. 23. During each contact text was transmitted in both directions. A total of five TNCs had to be properly connected for all this to work. Not suspecting that anything special was going on, WA0OJS and A18A connected with KA6M to pick up their mail. Instead they found that they were connected to stations in remote geographic areas via satellite.

The FCC granted a joint ARRL/AMSAT request for a special temporary authority (STA) to permit automatic teleport operation of 24 stations for a six-month period beginning in October 1984. On October 28, 1984, a unique packet-radio test was conducted. Amateur packet-radio stations VE1PAC/VE6 in Alberta, K7PYK in Arizona, W4DAQ in Alabama, and N5AHD in Texas successfully used the W3IWI bulletin board via OSCAR 10. K7PYK maintained contact for about an hour and acquired about 50 kbytes of documentation from W3IWI.

### HF Packet Operation

Around March 1984, Bob Bruninga, WB4APR, in Annapolis, Maryland, began regular 30-meter packet-radio operation with W9TD, W0RPK, N0AN, W9HLY and others. On weekends, WB4APR acted as a bridge between 30 and 2 meters to give midwest packeteers immediate access to

VHF packet repeaters in the Washington, DC area.

### Aeronautical Packet Repeater

In July and August 1984, Gordon Bass, K2UIR, operated what may be the first airborne amateur packet-radio repeater on weekend flights between Rochester, New York and Rockport, Maine. Operating under the call sign W2DUC, the repeater used a GLB Electronics PK-1 TNC at an altitude of about 10,000 feet.

### Packet Bulletin Boards

In mid 1984, Hank Oredson, W0RLI, activated a "packet bulletin board system" (PBBS) using software written in Z80<sup>®</sup> assembly language, run on a Xerox 820 computer board with a TAPR TNC. The PBBS was designed to originate, receive and automatically forward messages in the National Traffic System (NTS) format. The W0RLI PBBS software is used by numerous stations.

### Packet Meteor Scatter Experiments

On August 1, 1984, well before the peak of the Perseids meteor showers, Ralph Wallio, W0RPK, in central Iowa held 6-meter packet radio schedules with Bob Carpenter, W3OTC, in Maryland. W3OTC received about 2% of the packets sent by W0RPK. Four nights later, these two stations had what is believed to be the first two-way amateur packet-radio meteor-scatter contact.

### Formal Approval of AX.25

At its meeting on September 15, 1984, the ARRL Ad Hoc Committee on Amateur Radio Digital Communication finalized the AX.25 protocol specification. To distinguish it from previous versions, the protocol was called Version 2.0.

AX.25 Version 2.0 was approved by the ARRL Board of Directors at their October 26, 1984 meeting. An article describing the

Board action and the protocol appeared in December 1984 *QST*. The protocol specification was printed in a booklet entitled *Amateur Packet-Radio Link Layer Protocol, AX.25*, which is available from ARRL HQ. The booklet gives the complete specification in sufficient detail for those wishing to write software implementations.

#### UoSAT-OSCAR 11 and PACSAT Progress

Packet-radio messages were successfully exchanged between a station assembled by WH6AMX, WA3ZIA and VE3FLL in Honolulu, NK6K in Los Angeles and the UoSAT command station in Surrey, England, using the data communications experiment (DCE) on board UoSAT-OSCAR 11, on January 16, 1985. The Hawaii end of this experiment was conducted at the Pacific Telecommunications Conference in Honolulu. The DCE was intended to prove the concept of worldwide store-and-forward packet communications as a precursor to PACSAT and JAS-1 satellites.

A critical design review for the PACSAT project was held in Arlington, Virginia in early March. The digital store-and-forward subassembly is to have 2 to 4 Mbytes of memory and will be designed by the Tucson Amateur Packet Radio group and the Ottawa Group. The University of Surrey is to fabricate the actual PACSAT spacecraft.

#### Fourth Computer Networking Conference

The Fourth ARRL Amateur Radio Computer Networking Conference was held in San Francisco on March 30, 1985. A significant paper was presented by Steve Goode, K9NG, on his 9600-bit/s FSK modem. A number of groups were eagerly awaiting the availability of a practical 9600-bit/s modem for terrestrial intercity linking as well as 6-meter meteor-scatter operation.

The ARRL Ad Hoc Committee for Amateur Radio Digital Communication met that same weekend. It approved work done by Doug Lockhart, VE7APU, to develop amateur standards based on CCITT X.3, X.28 and X.29 protocols. The committee made plans to develop message protocols after study of the CCITT X.400 series. At that meeting, Hank Magnuski, KA6M, announced that the Pacific Packet Radio Society "Golden Packet" award for stations participating in the first transcontinental terrestrial VHF/UHF/microwave linking was to be established.

#### Fifth Computer Networking Conference

On March 9, 1986, Orlando, Florida was the site of the Fifth ARRL Amateur Radio Computer Networking Conference. The number of packet-radio stations had grown to around 14,000 worldwide, and 2-meter frequency congestion had become a major problem. At the conference, working prototypes of two networking technologies were demonstrated: virtual circuit and datagram. Key players in these developments were J. Gordon Beattie, N2DSY,

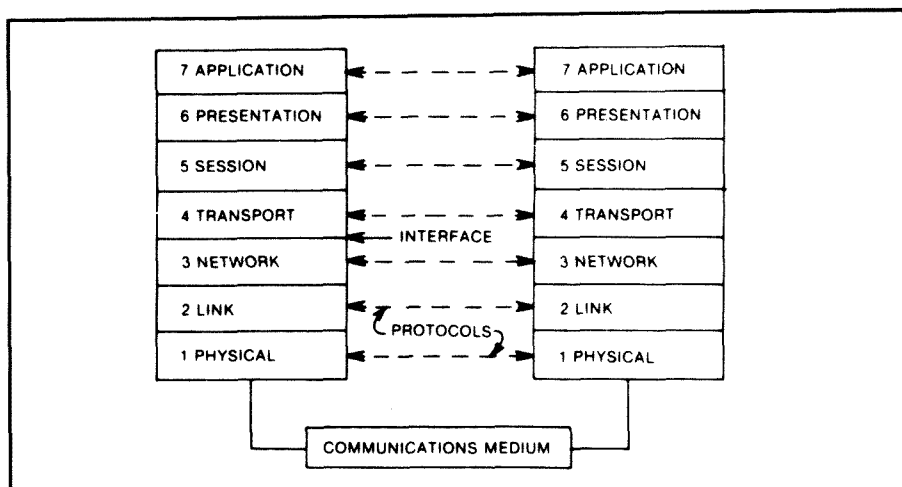

Fig. 24 — Open Systems Interconnection reference model protocol levels. The solid lines between layers, as shown between 3 and 4, are interfaces. The dashed lines indicate logical communications between peer layers.

Thomas Moulton, W2VY, Howard Goldstein, N2WX, Terry Fox, WB4JFI, and Philip Karn, KA9Q. Printed proceedings of the 5th conference are available from ARRL HQ.

### OPEN SYSTEMS INTERCONNECTION REFERENCE MODEL

Introduced in 1978, the Open Systems Interconnection (OSI) Reference Model (RM) is a long-term project of the International Organization for Standardization (ISO). The OSI-RM was developed to promote compatible communications among a wide variety of systems. In it, the communications structure is specified in seven distinct levels. The terms *level* and *layer* are used almost synonymously in the OSI-RM context. More often than not, the term *level* is used when referring to the function, and the term *layer* is used when referring to the name. This usage can be seen in the following list of the seven levels that make up the OSI-RM:

- Level 7 — Application Layer (highest level)
- Level 6 — Presentation Layer
- Level 5 — Session Layer
- Level 4 — Transport Layer
- Level 3 — Network Layer
- Level 2 — Link Layer
- Level 1 — Physical Layer (lowest level)

Primary documents for the OSI Reference Model are ISO 7498 and CCITT Recommendation X.200. Protocols for each level are in various stages of development. ISO documents progress through three stages before adoption: draft proposal (DP), draft international standard (DIS) and international standard (ISO). At each level there are normally two parts: a service specification (defines *what* the layer is supposed to do) and a protocol specification (defines *how* the layer is supposed to do it).

The OSI-RM has won general international acceptance in the telecommunications industry and in amateur packet-radio circles. One advantage is that the levels are

modular. This allows different people to work on individual levels with some assurance that the various levels can be made to work together in a system. Modularity also permits more than one protocol at a level. Each level must communicate with the level(s) above and below it, and must follow agreed rules for these interlevel interfaces. In order for distant systems to communicate, *peer* levels (for example, the link layer on one system and the link layer on the other) must exchange data in an agreed protocol. The interlevel and peer-to-peer relationships between two systems in direct communication are shown in the "apartment-house" diagram in Fig. 24.

#### Level 1 — The Physical Layer

The Physical Layer is the lowest level in the OSI Reference Model. Its function is to send and receive *bits* (binary ones and zeros — marks and spaces). This level is concerned with the following:

- Physical connections — allows duplex or half-duplex transmission
  - Physical service data units (PSDUs) — one bit in serial transmission, "n" bits in parallel transmission
  - Circuit identification
  - Bit sequencing
  - Notification of fault conditions
  - Deriving quality of service parameters
- In addition, these functions are associated with the physical layer:
- Modulation and demodulation (modems)
  - Signaling speed
  - Transmission of data and handshaking signals
  - Characterization of communications media (radio circuit)

The physical layer is the only level that maintains an actual electrical connection with its peers. The higher levels communicate with their peers through *logical* or *virtual* connections.

#### Level 2 — The Link Layer

The link layer (also known as the data-link control layer) arranges the bits into *frames*. The most common protocol is ISO

High-Level Data Link Control Procedures (ISO 3309). The link layer performs the following services:

- Establishes and releases one or more link connections
- Exchanges data-link service data units (DLSUs) — frames
- Identifies endpoints
- Keeps DLSUs/frames in proper sequence
- Notifies network layer when errors are detected
- Controls data flow
- Selects optional quality-of-service parameters

### Level 3 — The Network Layer

The network layer organizes data into *packets*, which are frames with network information added. In CCITT X.25 protocol, it is called the *packet layer*. Services provided by the network layer are:

- Network addressing and identifiers
- Network connections and release
- Transmission of network service data units (NSDUs) — packets
- Quality of service parameters
- Notifies transport layer of errors
- May provide sequenced delivery
- Flow control
- Expedited service through network

There are two basic types of network-layer protocols: connection-oriented and connectionless. Connection-oriented protocols set up a specific *virtual circuit* (VC) between the two end points. Connectionless protocols use the *datagram* (DG) with complete addressing information in each packet so they can follow any available route through a network.

Some view the network layer as two sublayers: Level 3 (or Level 3A) — the network (or *intranet*) sublayer and Level 3.5 (or Level 3B) — the internetworking (*internet*) sublayer. As an example, CCITT X.25 is an intranet protocol, while X.75 is an internet protocol.

### Level 4 — The Transport Layer

The transport layer organizes data into a *transport protocol data unit* (TPDU), which is a packet with transport-layer data added. This layer ensures that all data sent is received completely and in proper sequence at the destination. The following functions are performed at all times during a transport connection:

- Transmission of TPDU — messages.
- Multiplexing and demultiplexing — used to share a network connection between two or more transport connections
- Error detection — detect loss, garbling, duplication, misdelivery or missequencing of TPDU
- Error recovery — recovery from detected errors.

Other functions are:

- Connection establishment
- Data transfer
- Release — disconnection of transport connection

The CCITT transport protocol in Recommendation X.224 specifies transport service in five classes, each of which is designed according to the error behavior of network connections. These are:

- Class 0 — Simple class
- Class 1 — Basic error-recovery class
- Class 2 — Multiplexing class
- Class 3 — Error-recovery and multiplexing class
- Class 4 — Error-detection and recovery class

The amount of work to be done at the transport layer is dependent on the type of protocol (virtual circuit or datagram) used at the network layer. As it is possible for individual datagrams to arrive via different routes through a network, the transport layer in a connectionless network needs to buffer messages to return them to their original order. Connection-oriented networks permit use of a leaner transport layer.

### Level 5 — The Session Layer

The session layer organizes data into *session protocol data units* (SPDUs). This layer is concerned with:

- Dialog management
  - Data-flow synchronization, and resynchronization
  - Mapping addresses with names (so users may retain a name if they move)
  - Graceful or abrupt disconnection
  - Buffering data until delivery time
- Session services are grouped into the following phases:
- Connection establishment
  - Data transfer
  - Connection release

### Level 6 — The Presentation Layer

The presentation layer is responsible for terminal management. It performs the following services:

- Transfer of syntax for character sets, text strings, data display formats, graphics, file organization and data types
- Encoding, decoding and compaction of data
- Interpret character sets (example: ASCII)
- Code conversion

### Level 7 — The Application Layer

The application layer serves as a window between the OSI communications environment and the application process. It is the only level that does not interface with a higher one. The application layer provides the following functions:

- Log in — identification of communications partners
- Password checks and authority to communicate
- Determine adequacy of resources
- Determine acceptable quality of service
- Synchronization of applications programs
- Selecting the dialog procedures
- Agreement on error-recovery responsibility

- Procedures for control of data integrity
  - Identifying data syntax constraints
- Application layer protocols are classified in five groups:
- Group 1 — System-management protocols
  - Group 2 — Application-management protocols
  - Group 3 — System protocols
  - Group 4 — Industry-specific protocols
  - Group 5 — Enterprise-specific protocols

## PHYSICAL-LAYER CONSIDERATIONS

Layer 1 of the OSI model defines the electrical and mechanical standards such as connector configuration and which pins are used for different signals. The physical layer is responsible for getting individual *bits* transferred from one piece of equipment through the communications medium to the other equipment.

## DATA INTERFACE STANDARDS

It is common for digital communications equipment to have one or more serial binary data ports to connect to the next piece of equipment. Serial ports send and receive data one bit at a time. In Electronic Industries Association (EIA) and CCITT terminology, they are defined as *interchange circuits* at the interface between the DTE and DCE for the transfer of binary data, control and timing signals, and analog signals where appropriate. DTE is the abbreviation for *data terminal equipment*, meaning a video display terminal (VDT) or a computer that serves as a data terminal. DCE stands for *data circuit-terminating equipment* — typically a modulator-demodulator (modem) that terminates the analog communications circuit.

With some equipment configurations it is difficult to tell which is the DTE and which is the DCE. It is necessary to know one from the other in order to know how to interpret the standard. A fairly safe rule is that the DTE is the farthest from the communications channel. So in a setup with a terminal, a computer, a packet-assembler/disassembler (PAD) and a modem:

- at the terminal-computer interface, the terminal is the DTE, and the computer is the DCE.
- at the computer-PAD interface, the computer is the DTE, and the PAD is the DCE.
- at the PAD-modem interface, the PAD is the DTE, and the modem is the DCE.

Internationally, data-interchange interfaces are defined in CCITT Recommendations V.24 and V.28 for data rates up to 20,000 bit/s. V.35, which is primarily a 48 kbit/s modem specification, is finding use as an interchange-circuit standard for data rates above 20,000 bit/s.

In the United States, the most common standard is EIA RS-232-C for speeds up to 20,000 bit/s. EIA also has issued other standards, known as RS-422, RS-423 and RS-449, although these interfaces are not

yet common in personal computers or Amateur Radio equipment. When looking at surplus military equipment, bear in mind that interfaces may be designed against military interface standards such as MIL-STD-188C (similar to RS-232-C), MIL-STD-188-114 (similar to RS-422), MIL-STD-188-144 (similar to RS-423), and MIL-STD-1397 (42 and 250 kbit/s).

Also, but not as often, some parallel ports are found in amateur digital equipment. In parallel interfaces, the eight bits in a byte move into and out of the equipment simultaneously on eight separate wires. Two parallel interface standards are of interest to amateurs. One is the Institute of Electronics and Electrical Engineers (IEEE) Standard 488, also known as the IEEE 488 bus, IEC 625, Hewlett-Packard Interface Bus (HPIB) and General Purpose Interface Bus (GPIB). The other is the Centronics parallel interface, a de facto standard interface for parallel printer ports (see Chapter 8 for pin assignments).

### Balanced vs. Unbalanced Interfaces

Both balanced and unbalanced circuits are used in digital interfaces, much the same as for RF circuits. In fact, data signals sent at speeds of megabytes per second are RF and need to be treated as such. The rise and fall transitions of much slower data rates may be in the RF range. Like any transmission line, if the line is not terminated at both ends in its characteristic impedance, the conductors will radiate. The line will also be susceptible to electromagnetic interference from nearby conductors.

An unbalanced circuit has one signal conductor, and perhaps one or more timing- and control-signal conductors; the return path for each is through a common signal ground. Yet, unbalanced circuits are commonly used for circuits operating at speeds below 20,000 bit/s and for wire lines not exceeding 50 feet or 15 meters, as in EIA RS-232-C. In this standard, longer cables may be used if the load capacitance does not exceed 2500 pF. In office buildings twisted-pair RS-232-C cables are successfully run as long as 500 feet, but the standard guarantees only 50 feet.

Balanced interface circuits use two conductors balanced to ground. When one wire is positive, the other is negative, and vice versa. Balanced circuits are a little more trouble from a design standpoint but offer higher data rates over longer distances with less tendency for interference. Balanced data circuits should be considered for data rates over 20,000 bit/s.

### Bipolar vs. Neutral Interfaces

Most data interface circuits between equipment use bipolar signaling; that is, the circuit switches between a positive voltage (say 5-V dc) for a binary 0 and a negative voltage (say -5-V dc) for a binary 1. (For a discussion of polar and neutral keying, see Chapter 8.) A problem with polar

Fig. 25 — Electronic Industries Association RS-232-C data interface standard and several DB25 connectors.

25	TM	Test Mode			

\*Most abbreviations in this column are generally recognized by association with their full names. Exceptions are: ETxC = External Transmitter Clock, RxC = Receiver Clock and TxC = Transmitter Clock.

signaling is that the power supply must be able to supply both positive and negative voltages, thus adding complexity and cost. Another is that integrated circuits called line drivers and receivers are needed to convert the normal neutral signals used in most digital circuits to and from polar line signals.

Some designers avoid the extra power-supply and bipolar line-driver/receiver-chip

requirements by simply transferring neutral signals between equipment, typically at so-called TTL levels of approximately 0 and +5-V dc. Neutral TTL-level signaling has the disadvantages of poor noise immunity and signal distortion. This method of interfacing is viable only for short lines and where the designer is confident that the equipment at the other end of the line will be using TTL levels, not a standard inter-

face circuit. It is considered to be an expedient, and as such, may cause incompatibility when equipment is used for different purposes.

#### RS-232-C, V.24 and V.28

EIA Standard RS-232-C has to be the ubiquitous interface standard of the age. Its DB25 connector, shown in Fig. 25, is manifest everywhere you go these days: on office equipment, on the customer side of point-of-sale terminals at check-out counters, on personal computers. It is not unknown for avid packeteers to have RS-232-C receptacles in various rooms of the house, even the bathroom.

RS-232-C's international counterparts are CCITT Recommendations V.24 and V.28. V.24 describes the functions of each circuit. V.28 specifies the electrical parameters: voltages, impedances, load capacitance and signal characteristics. Specifications for the 25-pin connector will not be found in these documents but in ISO 2210 which also assigns pin numbers to V.24 circuits. The commercial types are the TRW-Cinch D-Subminiature DB25P and DB25S or equivalent by other manufacturers. The male pin connector (DB25P) is normally installed on the DTE and the female connector (DB25S) on the DCE. Pin assignments for RS-232-C and V.24 are shown in Table 15. Designers should find EIA Industrial Electronics Bulletin No. 9 useful, as it contains application notes for RS-232-C.

#### Signal Levels

The voltage ranges for RS-232-C and V.24 are shown in Fig. 26. Most signals more positive than +5 V and more negative than -5 V will operate the circuit successfully. It is common practice to supply +12-V and -12-V power to MC1488 quad line drivers, which are used in conjunction with MC1489 quad line receivers.

If you do much RS-232-C and V.24 interfacing, you will soon memorize the functions most-used pins: 1 through 8 and 20. These nine pins are virtually always used. The remaining pins may or may not be used depending on the circumstances. You will find RS-232-C cables with anywhere from the basic 9 to all 25 lines. Similarly, modems and other digital equipment advertised as "RS-232-C compatible" can be expected to use signal voltage levels specified in RS-232-C and V.28, and at least do not violate the standard. However, they may not implement the entire standard and may leave out certain control lines which may or may not be needed for your applications. Also, particularly where space is at a premium, a connector smaller than the DB25 may be used.

DB25 connectors come in many varieties — designed for mounting on panels or printed-circuit boards and for terminating cable assemblies. If possible, use shielded hoods and cables to reduce the possibility of electromagnetic interference. Keep an

Fig. 26 — RS-232-C and V.28 voltage limits.

eye peeled for the types of DB25 hardware you need at flea markets.

#### Gender Changes

Although the standards are clear that the male DB25P goes on the DTE and the female DB25S on the DCE, many designers get them mixed up. It is not uncommon to see equipment with only the female DB25S connectors and cable assemblies with male DB25Ps. It is a good idea to have a gender changer handy when connecting equipment, just in case someone got it backwards. A gender changer can be easily made by physically mounting two DB25Ss or DB25Ps back to back and connecting correspondingly numbered pins together with ribbon cable or individual wires.

#### Null Modems

Another useful gadget to have handy is a so-called *null modem*. That is a pair of DB25 connectors of the appropriate gender(s) mounted back to back and wired pin for pin except that pins 2 (transmit data) and 3 (receive data) are crossed and pins 4 (request to send) and 5 (clear to send) are crossed. This may take care of the problem of connecting two pieces of equipment both wired as DCEs or DTEs. For example, a computer serial port intended for a printer is usually wired as a DCE, and the printer as a DTE. If one or the other is not wired that way, you may find that the equipment has an internal jumper to swap lines 2 and 3. If not, a null modem will do the trick.

#### RS-422-A, V.11 and X.27

The RS-422-A specifies differential, balanced circuits for rates up to 100 kilobauds at distances up to 4000 feet or 10

**Table 16**

35	to DCE	TT	Terminal timing
36	from DCE	SB	Standby indicator
37	to DCE	SC	Send common

megabauds up to 40 feet. D-Subminiature DB37 (37-pin) connectors wired according to ISO 4902 are used. RS-422-A is compatible with CCITT Recommendations V.11 and X.27. However, it is not interoperable with RS-232-C, MIL-STD-188C or CCITT V.28 and V.35. It is not compatible with RS-423-A without some reconfiguration.

#### RS-423-A, V.10 and X.26

RS-423-A is an unbalanced, bipolar circuit capable of distances up to 4000 feet at 3 kilobauds or 40 feet at 300 kilobauds. It is compatible with CCITT Recommendations V.10 and X.26. RS-423-A can interoperate with RS-232-C circuits; EIA Industrial Electronics Bulletin No. 12 deals with implementation. RS-423-A and V.10/X.26 use D-Subminiature DB37 (37-pin) connectors wired according to ISO 4902.

#### RS-449

RS-449 is capable of signaling rates up to 2 Mbit/s at a cable length of 667 feet. The standard has 10 more interchange circuits than RS-232-C and specifies two D-Subminiature DB37 and DB9 (37- and 9-pin) connectors. EIA Industrial Electronics Bulletin No. 12 has application

Table 17

Fig. 27 — ISO 2593 rack-and-panel connector. This connector is usually identified with V.35 and is found on modems operating at speeds in excess of 20,000 bit/s.

notes on interconnection between RS-449 and RS-232-C.

**V.35**

CCITT Recommendation V.35 was written as a standard for modems operating at 48 kbit/s. However, its interface specifications and the 34-pin Winchester rack-and-panel connector (specified in ISO 2593, not V.35) have become standard in the United States for interchange circuits operating at 48, 56 and 64 kbit/s. The ISO 2593 connector is shown in Fig. 27.

**IEEE 488 Parallel Interface**

This is a parallel bus for limited distances on the order of 67 feet. It is of interest to amateurs as a control bus for test equipment and some communications equipment. The Commodore PET personal computer used the IEEE 488 bus for control of its peripherals (disk drive, printer, etc.). Most new test instruments being purchased for industrial use have the IEEE 488 bus so that testing can be computer controlled. Since instruments with IEEE 488 are rela-

tively new, they are not generally available at prices that amateurs can afford. However, that should change as laboratories get newer equipment and older equipment with the IEEE 488 bus becomes available on the surplus market. This bus uses a unique 24-pin connector as shown in Fig. 28.

**OPERATIONAL MODES**

There are a number of terms that describe the operation of circuits or connections, grouped under the category variously called *operational*, *communication* or *transmission* modes. There are some minor differences between data-communications and telephone-company usage within the United States, and between U.S. and international usage. Since packet radio is used internationally, it is important to remember that different interpretations of the same terms may cause problems in understanding terminology between packeteers in different

Table 19

23	GND(11)	Ground for pin 11
24	GND(iologic)	Ground for pins 5 and 27

countries. Also, some confusion can occur between the operational mode of the communications and how many radio frequencies are being used. For example, it is possible to have a half-duplex data exchange using one frequency (often called simplex) or two frequencies (called duplex).

Although this subject is treated here under physical-layer considerations, there are parallel uses of the terms defined below at higher ISO protocol levels.

Fig. 29 will help in understanding the terms discussed below.

**Simplex (SX)**

According to the IEEE, simplex operation is "A method of operation in which communication between two stations takes place in one direction at a time." The ITU

Fig. 28 — 24-pin connector used for IEEE 488 cables.

Radio Regulations define it as an “Operating method in which transmission is made possible alternately in each direction of a *telecommunication* channel...” A footnote says that simplex operation may use either one or two frequencies. CCIR Rec. R.140 says “simplex (circuit) permitting the transmission of signals in either direction, but not simultaneously.”

Radio amateurs often use the term simplex to indicate that only one frequency is used for a VHF FM circuit. This is the current amateur digital transmission mode, where two or more stations involved in a contact operate on exactly the same frequency and take turns transmitting and receiving. Simplex operation keeps equipment requirements to a minimum by permitting sharing of some equipment for both transmitting and receiving. A transceiver (in contrast with separate receiver and transmitter) and a common antenna may be used.

In some other uses of the term, simplex transmission is in only one direction with no reverse direction possible. CCIR R.140 calls this a *unidirectional connection*. One-way operation is seldom used in data communications since there is no return channel or way of reversing the channel to detect and correct errors. Nevertheless, there are some Amateur Radio one-way transmission applications, usually point to multipoint, such as for transmission of bulletins and beacon operation.

### Half Duplex (HDX)

A half-duplex circuit can transmit in either direction, but only one direction at a time; so sayeth the IEEE and other references. That sounds just like simplex, doesn't it? The clue to understanding the difference between simplex and half-duplex operation is in the CCITT R.140 definition: “half duplex circuit (or connection) — A circuit (or connection) capable of duplex operation, but which, on account of the nature of its termination, can be operated alternately only.” In plain English, the transmission channel is capable of simultaneous operation in both directions but the terminal equipment can only send or receive, not do both at the same time.

### Full Duplex (FDX)

In a full-duplex circuit, information can flow both ways simultaneously. The IEEE

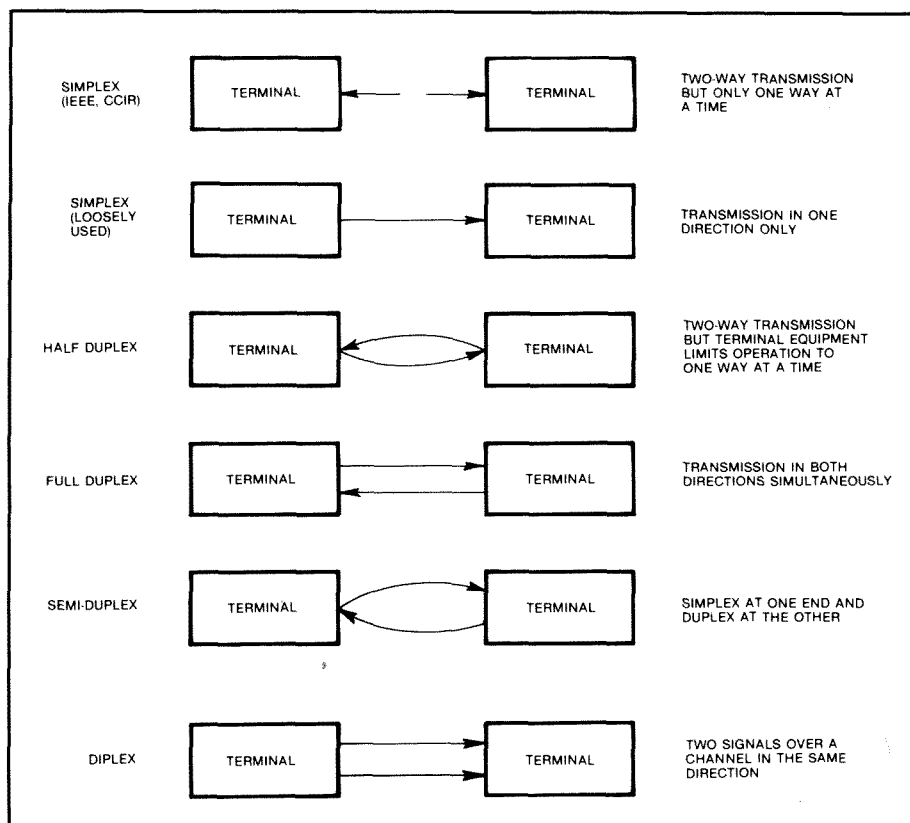

Fig. 29 — Operational modes. U.S. and international usage of these terms varies. See discussion in text.

and CCIR definitions agree on this, although CCIR calls it simply *duplex* operation. The CCIR Radio Regulations include a footnote to the effect that “duplex operation require(s) two frequencies in radiocommunication.” CCIR Rec. R.140 has another term: “duplex, two way simplex (connection) — A circuit permitting the exchange of signals in both directions.”

Full-duplex operation is not yet in general use in packet radio. But it will be required for high-speed packet trunks where simplex or half-duplex circuits cannot provide sufficient peak capacity. Full duplex is inherently more complex than simplex because the transmitter and receiver at the same site must operate simultaneously. This requires separation or duplexing of receiving and transmitting

antennas as is normal practice in FM voice repeaters.

### Semi-Duplex

This is a term found in the ITU Radio Regulations to describe “A method which is *simplex operation* at one end and *duplex operation* at the other.”

### Diplex

CCIR Rec. R.140 defines this as “Permitting simultaneously and in the same direction, the transmission or reception of two signals over a circuit or channel.”

### MODEMS

*Modem* is a contraction of *modulator-demodulator*. In telephone terminology, it is called a *data set*. A modem is used to convert digital baseband signals to and

from analog form for transmission over analog media. Analog communications systems designed to transmit speech have an analog baseband bandwidth of about 3 kHz. There is a relationship between the analog bandwidth and the data rates that can be accommodated. It is relatively easy to design a modem that can handle up to 1200 bit/s in a 3-kHz analog channel. Modems operating at 300 and 1200 bit/s can be obtained at surplus prices, and can be inexpensively fabricated by the amateur. The state of the art permits transmission at speeds as high as 9600 bit/s within a 3-kHz analog channel using complex modulation techniques. Modems capable of operating at 2400, 4800 and 9600 bit/s over unconditioned telephone lines are commercially available but presently at greater cost than 1200-bit/s modems. The higher speeds generally require circuits with higher signal-to-noise ratios; so when the circuit is not the best, the higher-speed modems have slower *fallback* speeds.

### Modem Parameters

When they work, modems are taken for granted. When they don't, people get interested in the subject. Modems live on the line of demarcation between the digital and analog worlds, in both of which Murphy's Law claims sovereignty.

### Modulation

The most-used form of modulation for Amateur Radio data transmission is binary frequency-shift keying (FSK). Using this technique, a binary 1 is translated to a mark tone at (say) 1200 Hz, while a binary 0 produces a space tone of (say) 2200 Hz. A special case of FSK is called minimum-shift keying (MSK) in which the frequency shift in hertz is exactly one half that of the signaling rate in bauds. Thus a 1200-baud signal that is shifted 600 Hz is MSK.

Phase-shift keying (PSK) is another popular form of angle modulation used for data transmission. Its use in Amateur Radio, thus far, has been limited to satellite telecommand and telemetry, but interest is growing in using various forms of PSK for high-speed packet radio. While binary phase-shift keying (BPSK) is robust, it is not particularly spectrum efficient. *M*-ary PSK schemes such as 4-ary PSK (4PSK) or 8-ary PSK (8PSK) permit transmission of more bits per second at a lower baud rate and are used in many high-speed modems designed for telephone use.

Amplitude-shift keying (ASK) is not presently used in amateur packet radio but is a possibility for the future, particularly in combination with PSK, to achieve high speeds within relatively narrow bandwidths.

Some additional information on digital modulation techniques is presented in Chapter 9.

### Demodulation

The function of a demodulator in a data

modem is to convert the analog signal back to its digital baseband. Designers will testify that the modulator is the easy part of modem design. Demodulators are the downfall of most modem projects. They take even longer than the usual project-completion rule of multiplying the time estimate by 2 and using the next larger time increment.

FSK demodulators are among the simpler ones. There are two main design approaches: the FM type and the AM type. The FM type of demodulator first hard-limits the signal to a constant amplitude to eliminate amplitude variations. It then looks for zero crossings to produce a square-wave output. Many FM demods nowadays use phase-locked loops. While adequate in most respects, they suffer from dropouts when either the mark or space frequency fade below a certain threshold level. An AM demodulator has a filter for the mark frequency and a filter for the space frequency. The amplitudes of the outputs of these filters are compared to see which frequency is present. A properly designed AM type demod can produce good digital output during periods when only one signal (mark or space) is present.

PSK demodulators need some way of determining phase shifts. There is no ready source of absolute phase reference at the demodulator, so some phase reference must be derived by the demodulator. In normal PSK, it is necessary to compare the phase of the received signal with a fixed phase-reference source. Some systems transmit phase-reference information in short bursts. Differential phase-shift keying (DPSK) demodulation does not need a fixed phase reference signal but decides whether a phase shift has occurred by comparing one symbol with the last symbol received.

### Synchrony

Most of the lower-speed modems are asynchronous and operate at a variable rate. You will note this when seeing a speed reference such as "0-300" bit/s. Of course, a 0-bit/s modem is nothing but a power supply, but this designation tells you that the modem is capable of maintaining a 0 or 1 logic state indefinitely. When each character is started and when transitions may occur therein are functions of the data keying the modulator. When receiving data, the demodulator will recognize changes of state that occur at any time, perhaps within certain limits to reject noise.

Higher-speed modems are usually synchronous. The modulator clocks out data at a fixed rate. The demodulator duplicates or regenerates the clock from the received data. Bit-synchronous demodulators have the advantage of knowing when a bit is to occur and can use various decision strategies to determine which of two binary states (or which of 4 dibit states, which of 8 trit states, etc.) was received. Synchronous demodulators are usually assigned a 3-dB S/N

advantage over asynchronous demodulators.

### Frequency Modes: Originate and Answer

Modems designed for full-duplex telephone-line communications divide the audio-frequency spectrum into high and low frequency bands. Transmission in one direction is possible by modulating a tone (or tones) in the higher-frequency band, while transmission in the opposite direction is possible using lower-frequency tone(s). To eliminate confusion on the telephone, the calling (originating) station (say) transmits on the low tone(s), and the called (answering) station transmits on the high tone(s). The two stations stay with the tone(s) they chose when the circuit was established; the tones are not changed as communications go back and forth.

In the early days of time-shared computers, many terminals were equipped with *originate-only* modems because they only called the computer center, never answered calls. This was a way of cutting costs at the terminal stations. Similarly, computer centers that only answered calls minimized cost by installing *answer-only* modems. These one-way modems saved money, but when they became available on the surplus market were a source of frustration for personal-computer users who wanted to both originate and answer calls. Amateur Radio operators found that originate-only or answer-only modems could be modified to change the tones to the same frequency band (high or low) for packet radio simplex operation.

### Carrier Detection

Most demodulators have a carrier-detect (CD) output. It is more formally called "Received Line Signal Detector." In telephone modems, a 0 condition on the CD output means that no signal is being received or that the signal being received is unsuitable for demodulation. In a half-duplex circuit, whenever there is a 1 output on the CD line, the modem is inhibited from transmitting. That way your modem knows that there is a live modem of its own species on the other end of the circuit.

In Amateur Radio, our need for this signal is different from that of the telephone system. Generally, we want the modem to know when there is anyone else using the channel. Increasingly, VHF packet-radio channels are coordinated for that use and not voice, so anyone else on the channel is likely another packet station. However, there are situations where VHF voice and packet communications are mixed, as in some 2-meter repeaters. Unfortunately, modem CD outputs will not always go to 1 when there are voice signals on the line. In this case, squelch output should be used to inhibit packet transmission. That way, the packet transmissions avoid stepping on voice users of the repeater.

Similarly on HF, packet operations usually share frequencies with RTTY ac-

tivities. If both sets of users equip their modems/transceivers with a carrier-detect feature, then the number of collisions will be reduced.

### Transmission Impairments

Most modems now in use are intended for use with radios designed for voice communications. The human ear is very tolerant of distortion. Thus, you may not even suspect that your trusty hand-held transceiver has audio that would gag a data modem. Of course, we are talking about a whole system, not just your radio. The radio at the other end of the circuit and any artifacts introduced by the propagational medium need to be taken into account. When using voice radios for packet radio, one way to find out if it will work is to simply try it. Most amateurs do not have the test equipment to accomplish all the testing that is needed to check out a system piece by piece. We would hope, however, that such testing would be performed before offering radio equipment for general data-communications use.

### Frequency Response

Many radios have nonuniform amplitude-vs.-frequency responses. Fig. 30 illustrates an audio-frequency response that might be seen through a radio system. This may be the result of roll-off high frequencies in an audio amplifier or using an IF filter that is too narrow. Low-frequency losses could be caused by use of too small a value capacitor used for interstage coupling in an amplifier. An IF filter with excessive ripple in the passband could wreak havoc with the frequency response. Similar problems could be the fault of poor IF alignment. Virtually all voice radios can be used for packet operation — many without modification of any kind. Others may require some minor surgery to make them suitable for data communications.

### Phase-Shift and Envelope-Delay Distortion

Propagation through an audio communications channel should vary uniformly with frequency. If the propagation time is not uniform, the components of a complex waveform (for example, the fundamental frequency and several harmonics) will arrive out of their proper phase relationships. This will result in a distorted waveform. Fig. 31 illustrates linear and nonlinear phase-shift characteristic, as well as the corresponding envelope delays.

### Amplitude Nonlinearity

This is not usually a serious problem with using voice radios for data communications systems with binary amplitude states. However, any nonlinear distortion in the voice-frequency channel adds harmonics to the fundamental modulating signal. Amateur Radio transmitter microphone-input circuits typically have substantial amounts of compression with time constants optimized for speech. Unwanted

products may be generated, especially if a data signal is at a level high enough to be well into the compression or clipping region.

Nonlinear distortion becomes serious in certain high-speed modems which use quantized amplitude modulation, possibly in combination with phase-shift keying. In such modems nonlinear response in the channel will make the amplitude differences between adjacent levels uneven and could result in falsing, particularly in the presence of noise.

### Equalization

Various forms of distortion, such as nonuniform frequency response and envelope-delay distortion can be corrected by equalization. An equalizer is a circuit designed to compensate for undesired amplitude-frequency and/or phase-frequency characteristics. Equalizers can be designed to overcome the poor response in a radio receiver or an entire system if the distortion at the transmitter and that introduced by the medium are known. An equalizer works by setting the gains of an audio-frequency filter. *Automatic equalization* and *adaptive equalization* are techniques that can automatically compensate for circuit distortion. Automatic equalizers adjust to circuit conditions upon reception of a special bit sequence, called *training*, sent just before transmission of data. Adaptive equalizers make continuous adjustments during reception.

### Frequency-Translation Error

When an FM voice radio is used with an AF modem, the received tones are at the exact frequencies produced by the modulator at the transmitting station. However, if the modulator and demodulator are not tuned to precisely the same frequencies, some distortion in the received data should be expected, particularly under poor S/N conditions.

Data transmission with AF modems through SSB voice radios is a different matter. Even small mistuning of the receiver relative to the transmitter frequency can cause distortion. Doppler shift, if not corrected, can also corrupt received data. Under these circumstances accurate frequency control and a demodulator tuning indicator are recommended.

### Noise

Periodic or random noise will affect the performance of a digital demodulator. Some types of noise, particularly transients, may simply be an annoyance to voice communications. It takes only one bit error to corrupt a packet. Impulse noise on the order of 1-ms duration and decaying over 4 ms will likely have little effect on a 45-baud RTTY signal with a 22-ms data pulse. But at 1200 bauds, that same pulse could wipe out 1 to 4 bits.

Just as in any other radio application, it is necessary to minimize the noise level

Fig. 30 — Amplitude-vs.-frequency response of a radio system designed for voice communications. Note the attenuation of both highs and lows.

Fig. 31 — At A is the phase-shift-vs.-frequency response of a radio system. B shows the corresponding envelope delay distortion.

presented to the data demodulator. Proper siting, use of directive antennas with minimal noise pickup and low-noise receiving preamps are desirable for packet-radio stations. These considerations are of great importance for meteor-scatter and satellite reception. Careful selection of demodulator input filter shape and bandwidth can contribute to reducing the impact of the noise received by the modem. While most demodulators perform flawlessly in the absence of noise, some fail sooner than others as the signal-to-noise ratio is decreased. What separates the best radio modems from the pack is their ability to perform in the presence of interference.

### Jitter

Jitter comes in many flavors and may be introduced almost anywhere throughout a system. *Phase jitter* consists of abrupt variations in phase or unwanted angle modulation. It can be described as the received data signal zero crossings occurring at the wrong time. Phase jitter can be introduced in the modulation process. It may be introduced by power-supply hum

modulating the master oscillator or by the data modulator clocking on the wrong pulse in a train. Jitter on the order of 15 degrees or more can be expected to cause misinterpretation of data by a demodulator, depending on how sampling is performed. If the demodulator is designed to look for edges of pulses any jitter is likely to introduce errors. If the demodulator samples in the middle of the pulse period, or integrates energy over the entire pulse period, jitter may not be a serious problem. In addition to phase jitter, which may occur throughout a transmission, *phase hits* are a transient unwanted angle modulation that may last 4 ms or longer, according to the telephone definition.

*Amplitude jitter* is not usually a problem for angle-modulated data communications but could be for systems using quantized amplitude modulation. In telephone terminology, *gain hits* are transient phenomena lasting 4 ms or more where changes in amplitude exceed 12 dB. Gain hits in the negative direction are called *dropouts*.

### Modem Standards

Two organizations that have written the lion's share of modem standards are the AT&T and CCITT. A summary of these standards is given in Table 16. Many modems for different applications were developed by AT&T and are known by their Bell designations (for example, Bell 103). CCITT modems closely parallel Bell types but are not necessarily interoperable with them. For example, both the Bell 103 and the CCITT V.21 can operate at 300 bit/s, and are alike in many respects, but the two use different sets of tone frequencies and cannot intercommunicate. There is the same similarity and incompatibility between Bell 202 and CCITT V.23. While international technocrats have been having their disagreements, IC designers have been designing single-chip modems, such as the Am7910 that will do Bell 103, V.21, Bell 202 and V.23. "The man wants a Bell 202, pull MCI high!" See the construction project, An LSI Modem for Amateur Radio, in Chapter 29.

### Bell and CCITT Modems

#### Bell 103/113 Family

The Bell 103/113, usually abbreviated Bell 103, is of particular interest to amateurs for both telephone-line and packet-radio communications. Many personal computers use Bell 103-compatible modems for 300 bit/s phone-line data transmission, although the Bell 212A (1200-bit/s) modems are gradually replacing them.

These modems are part of the Bell 100-series data sets and are also called the Bell 103/113 family. Model number 103 designates an originate/answer modem, whereas the letter suffix denotes the configuration. Model number 113 can be either

**Table 21**  
**Bell 103/113 Modem Frequency Scheme**

Mode	Originate	Answer
Transmit	F1M 1270 Hz mark	F2M 2225 Hz mark
	F1S 1070 Hz space	F2S 2025 Hz space
Receive	F2M 2225 Hz mark	F1M 1270 Hz mark
	F2S 2025 Hz space	F1S 1070 Hz space

Fig. 32 — Bell 103/113 modem frequencies. The call-originating station transmits on the lower-frequency band and receives on the higher-frequency band. The called (answering) station does the opposite.

originate or answer, as differentiated by the letter suffix. Specific models are:

103A: Older originate/answer, single-channel modem for installation in Model 33 or 35 Teletype® equipment.

103E (Computer Site): Originate/answer, up to 40 in a cabinet.

103F: For leased lines only.

103G: Originate/answer, single-channel modem that includes an integrated telephone set.

103H: Originate/answer, single-channel modem for direct installation in Model 37 Teletype sets.

103J, 103JR: Originate/answer, single-channel modem. The 103J was the model used prior to the FCC Registration Program. The "R" suffix indicates registration under Part 68 of the FCC rules.

113A: Originate-only, single-channel "bare-bones" modem for terminal installations. Early 113A-L1 and -L1A versions did not require ac power supplies as they were powered from the telephone line. Later models with L1/2 and L1A/2 suffixes require ac power supplies.

113AR: Registered version of the 113A.

113C: Full-featured originate-only, single-channel modem used prior to registration.

113CR: Registered version of 113C.

113B: Answer only, in 20-channel increments. Older modem used in multiline computer installations.

113D: Unregistered version of 113DR.

113DR: Answer-only registered modem in current use by the Bell System. Available in individual and multiline configurations.

The Bell 103/113 family operates at

speeds up to 300 bit/s. Although used since its introduction for 110-bit/s ASCII teleprinters, it is used nowadays almost exclusively for computers at 300 bit/s.

The spectrum is divided into two bands. Each band has a carrier which uses frequency-shift keying (FSK) between two frequencies. The two lower-band frequencies are called F1M (frequency 1 mark) and F1S (space). The frequencies in the higher band are called F2M and F2S. The originating station transmits on F1 and receives on F2. The answering station transmits on F2 and receives on F1. See Table 21 and Fig. 32.

Bell 103/113 modems normally use the EIA RS-232-C interface. The Clear to Send circuit (from modem to DTE) is on when the modem has established a connection. The Transmitted Data circuit can be used only when Clear to Send is on. Received Data (modem to DTE) is the circuit that delivers the data received from the other modem. When on, the Carrier Detect (modem to DTE) shows that the data carrier is being received from the modem at the other end of the circuit. When Carrier Detect is off, this circuit is held in a marking condition. An on condition on the Data Set Ready circuit (modem to DTE) indicates that the modem is connected to the telephone line and in the data mode. An on condition on the Ring Indicator (modem to DTE) circuit tells the DTE that a ringing signal has been received. Data Terminal Ready (DTE to modem), when on, permits the modem to answer incoming calls automatically. An off condition tells the modem to disconnect from the line when the call is completed.

#### CCITT V.21

This is the modem used for low-speed (110, 200 and 300-bit/s) asynchronous data transmission in Europe and elsewhere outside of North America. The frequency scheme for the V.21 is shown in Table 22 and Fig. 33. V.21 is similar to, but incompatible with, Bell 103/113. It is unfortunate that you cannot use a Bell 103 modem on the telephone to call a computer in Europe using a V.21 modem, or vice versa. However, you *can* use a Bell 103 to communicate with a V.21 modem when using HF packet radio. Although the specific frequencies are different, the mark and space frequencies for both modems are 200 Hz apart.

#### Bell 202

The Vancouver Amateur Digital Communications Group (VADCG) selected the Bell 202 modem for their 2-meter packet-radio network because some were available on the surplus market. It is widely used in North America for VHF packet radio using AFSK on an FM carrier and has been used experimentally on 10 meters using FSK (AFSK to an SSB transceiver).

The Bell 202 is a half-duplex modem designed for asynchronous, binary, serial

**Table 22**  
**CCITT V.21 Modem Frequency Scheme**

Mode	Channel 1 (Calling station)	Channel 2 (Called station)
Transmit	F <sub>A</sub> 1180 Hz 0 bit F <sub>Z</sub> 980 Hz 1 bit	F <sub>A</sub> 1850 Hz 0 bit F <sub>Z</sub> 1650 Hz 1 bit
Receive	F <sub>A</sub> 1850 Hz 0 bit F <sub>Z</sub> 1650 Hz 1 bit	F <sub>A</sub> 1180 Hz 0 bit F <sub>Z</sub> 980 Hz 1 bit

Fig. 33 — CCITT V.21 modem frequencies. The call-originating station transmits on the lower-frequency band and receives on the higher-frequency band similar to Bell 103/113 modems.

Fig. 34 — Bell 202 modem frequencies. The 387-Hz reverse channel on some Bell 202 modems is not used for amateur packet radio.

data transmission at speeds up to 1200 bit/s. The maximum bit rate is also a function of the transmission circuit; Bell 202 modems can handle up to 1800 bit/s on conditioned lines. It uses FSK modulation with the mark and space frequencies of 1200 Hz and 2200 Hz, respectively. See Fig. 34. Some models have a 5-bit/s on/off-keyed (OOK) reverse channel on 387 Hz used primarily for a break signal to signal when to turn the circuit around and for certain forms of error control. To defeat echo suppressors found on North American long-distance telephone lines, the modem sends a 2025-Hz echo-suppressor disabling tone for  $300 \pm 50$  ms. Because echo suppressors turn on after 100 ms of no signal, the modem is designed to keep its forward- or reverse-channel transmitter on at all times. Bell 202 modems use EIA RS-232-A, -B or -C interfaces, according to when they were designed.

Specific Bell model numbers are: 202A and 202B: Superseded by 202C and 202D.

**Table 23**  
**Summary of Bell and CCITT Modem Characteristics**

Standard	Speed in bit/s			Sync/async	Modulation	Transmitting frequencies
	Forward	Fallback	Reverse

Fig. 35 — CCITT V.23 modem frequencies. Those for Mode 1 (600 bauds) are at A. Mode 2 (1200-baud) frequencies are at B.

- 202C: Older modem with handset, single channel, self contained. Switched lines — 0-1200 bit/s. Leased lines — 0-1800 bit/s.
- 202C5, 9 or 11: Without reverse channel.
- 202C6, 10 or 12: With reverse channel.
- 202D: Same as 202C without handset; requires 804A auxiliary set.
- 202E: Older transmit-only data set with telephone set. Reverse channel is optional.
- 202R: 0-1800 bit/s modem similar to 202D, no auto answer.
- 202S: 0-1200 bit/s auto answer before FCC registration.
- 202SR: Registered version of 202S.
- 202T: 0-1800 bit/s, for leased lines, 1 to 8 in housing.

You may see some newer Bell 202-compatible modems with 75-baud or 150-baud reverse channels. This feature has been added to some modems for leased-line and videotex service. The Am7911 is a single-chip modem with a 150-baud reverse channel in both Bell 202 and V.23 modes.

#### CCITT V.23

The CCITT V.23 is similar to the Bell 202. Although V.23 1200-baud mark and space frequencies are 100 Hz different than those of the 202, the two type of modems are interoperable under certain conditions. In addition, V.23 has a fallback speed of 600 bauds and uses a different space frequency for that speed. The fallback speed is used when the channel is noisy. Another difference is that the V.23 backward channel uses FSK and is capable of data rates up to 75 bauds. V.23 frequencies are shown in Fig. 35. V.23 also has an echo-suppressor disabling tone of 2100 Hz. V.23 modems use the V.24 interface. Pin 23, data signaling rate selector (circuit no. 111) is used to

tell the modem to change speed.

#### Bell 212A

In late 1976, the Bell System introduced a full-duplex 1200-bit/s modem — the Bell 212A. Bell 212AR denotes the FCC-registered version now in use. To achieve this within the audio passband of a telephone channel, the bandwidth of each 1200-bit/s signal was reduced by using *dibit*-encoded, differential phase-shift keying (DPSK). In dibit encoding of a PSK signal, two bits are used to determine the phase of the transmitted signal:

Dibit	Phase
00	90°
01	0°
10	180°
11	270°

The originating station transmits on 1200 Hz, whereas the answering station transmits on 2400 Hz, as shown in Fig. 36. In addition, the 212A has a low-speed FSK modem for communication with Bell 103 modems. The operating speed is selected by the modem originating the call. An answering 212A can tell which type of modem it has connected with and automatically adjusts to the right speed and protocol.

The Bell 212A employs a bit-sequence encoder, called a *scrambler*, to prevent transmitting a pathological bit sequence such as a long string of 0s. The scrambler operates according to a fixed algorithm designed to produce a pseudorandom bit pattern, thus having control over the shape of the spectrum produced by keying. Without scrambling, the demodulator would lose synchronization with the dibit clock.

Bell 212A modems are becoming popular with amateurs for telephone-line use as most computer services and some bulletin boards now use 212A modems. Little or no experimentation with the 212A for packet-radio is known as this is written.

#### CCITT V.22

The CCITT V.22 is similar to the Bell 212A and can interoperate synchronously at 1200 bit/s. V.22 uses the same frequencies as the 212A, namely 1200 Hz (channel 1) for the calling station (originate) and 2400 Hz (channel 2) for the called station (answer). Whenever channel 2 is in use, V.22 modems transmit an 1800-Hz guard tone at all times to suppress in-band telephone signaling.

V.22 has the following alternative modes:

Mode	Operation
I	1200 bit/s sync
II	1200 bit/s async
III	600 bit/s sync
IV	600 bit/s async
V	1200 and 0-300 bit/s async

Fig. 36 — Bell 212A modem frequencies for 1200-bit/s full-duplex operation. See Fig. 32 for frequencies when in the Bell 103 mode.

Like the 212A, V.22 uses dibit DPSK. Below are phase changes for the various modes:

<i>Mode</i>	<i>00</i>	<i>01</i>	<i>10</i>	<i>11</i> (dibits)
I, II	90°	0°	270°	180°
V	270°	180°	90°	0°
<i>Mode</i>	<i>0</i>	<i>1</i>	(bits)	
III, V	90°	270°		

V.22 modems are supplied in various configurations. Alternative A is synchronous, B is A plus asynchronous, and C is B with Mode V added. Some V.22 modems do not have the 600-bit/s fallback speed.

The V.22 is becoming more widely used in Europe. There is no known packet-radio use known at this time.

#### Amateur Packet-Radio Modems

The Bell 202 modem predominates 1200-baud VHF packet-radio operation. It has proven to be a good initial choice for VHF FM packet radio because of its surplus availability. It has some problems, however. It is North American standard, not international, although it is to some extent interoperable with CCITT V.23 modems. Bell 202 modems have been used to copy UoSAT-OSCAR 11 signals using the "Kansas city standard", which uses 1200- and 2400-Hz tones. There is the growing belief that the Bell 202 is too slow and should be replaced, initially for inter-city trunks, with a modem capable of 9600 bit/s. Also, while the Bell 202 is usable for communications through the OSCAR 10 satellite with its limited signal-to-noise ratio, a more robust form of modulation is needed to reduce the bit error rate. On HF, Bell 202 frequency shift of 1000 Hz, while legal in the U.S., is excessive for operation at 300 bauds — the speed limit below 28 MHz. Even at 1200 bauds, 1000-Hz shift is not necessary, and a narrower shift of 800 Hz (CCITT V.23) or 600 Hz (minimum-shift keying — MSK) would be in the interest of spectral efficiency.

Bell 103 modems are used for 300-baud HF packet-radio communications because of their ready availability and reasonably narrow 200-Hz frequency shift (compared to 1000 Hz for Bell 202 used for VHF packet radio). Before the Bell 103 caught on for this application, some packet

transmissions were made using 170-Hz-shift RTTY modems. They were not always successful, however, because the RTTY modems have filters optimized for lower speeds (45 to 100 bauds). Widening RTTY demodulator filters has proven difficult in some cases. Some have found it possible to carry on packet-radio contacts between one station with a Bell 103 200-Hz shift modem and another using an RTTY 170-Hz shift modem if carefully tuned.

Receiver tuning when using a telephone-type modem can be difficult as there is usually no tuning indicator of any kind except for a Carrier Detect LED. External tuning indicators have been added to some packet-radio modems to facilitate HF operation. An oscilloscope is generally superior to LED tuning indicators and can be configured to display circles, flags or "crossed bananas" as in RTTY demodulators or eye patterns described in this chapter.

### 1200-Baud Modems

The VADCG terminal-node controller (TNC) was designed without a modem, as the plan was to use surplus Bell 202 modems. In late 1982, VADCG produced a Bell 202-like modem in both kit and PC-board-only form. It used an Exar XR-2206 function generator as the modulator and an XR-2211 phase-locked loop as the demodulator. The VADCG radio modem is no longer available.

When TAPR designed their TNC 1, they decided to add the modem to the TNC board to simplify getting on the air. The same Exar chips were used, but with a National MF10 switched-capacitor filter (SCF) for equalization. TAPR found that equalization was required to compensate for the audio responses of different VHF radios. A modem-disconnect arrangement was built in to permit use of an external modem. This same modem design was carried over to the TAPR TNC 2. The TAPR modem can be reconfigured for 300-baud, 200-Hz FSK.

A number of packeteers have built 1200-baud modems around the Advanced Micro Devices Am7910 chip. A modem built around the Am7910 is described in Chapter 29. The following modes are programmable:

- Bell 103 originate, 300 bit/s, full duplex
- Bell 103 answer, 300 bit/s, full duplex
- Bell 202 1200-bit/s, half duplex
- Bell 202 1200-bit/s, half duplex, with equalizer
- CCITT V.21 originate, 300 bit/s, full duplex
- CCITT V.21 answer, 300 bit/s, full duplex
- CCITT V.23 Mode 2, 1200 bit/s, half duplex
- CCITT V.23 Mode 2, 1200 bit/s, half duplex, with equalizer
- CCITT V.23 Mode 1, 600 bit/s, half duplex
- Loopback in above modes.

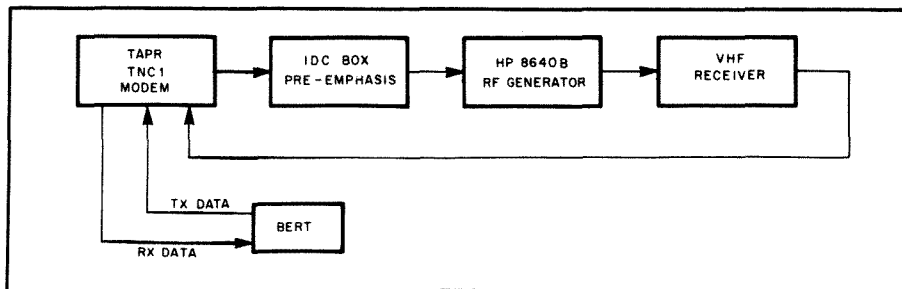

Fig. 37 — K9NG's bit-error-rate-test setup for the TAPR TNC 1 modem.

A number of manufacturers have introduced so-called "single-chip" modems, and more are anticipated in the years ahead. The "single-chip" description is more wishful thinking than reality in that additional support chips are usually needed. Nevertheless, they represent a significant breakthrough in modem-design simplification. Switched-capacitor-filter chips are also part of most new modem designs.

### Packet Adaptive Modem

A multispeed HF packet-radio modem designed by Robert Watson and W4RI is currently being tested. It uses a standard 600-Hz shift at all speeds (75, 150, 300, 600 and 1200 bauds). At 1200 bauds, a 600-Hz shift FSK modem becomes MSK. The 600-Hz shift is wide enough to take advantage of in-band frequency diversity. Design details were included in the proceedings of the Second ARRL Amateur Radio Computer Networking Conference.

### 9600-Baud Modems

As this is being written, there is a widespread need for a modem that will operate at 9600 bauds for terrestrial trunking, meteor-scatter and satellite communications. This speed seems to be a natural next step as it is a worthwhile speed increase over 1200 bauds and because existing TNCs will function at 9600 bit/s. Several amateurs have taken different design approaches.

Phil Karn, KA9Q, designed a 9600-baud modem using BPSK primarily for use in PACSAT. The design proved difficult to reproduce, and it has been included with other candidate designs being investigated at the University of Surrey, U.K. BPSK is considered to be a robust modulation method, but occupies more bandwidth than some newer schemes. Filtering to restrict bandwidth introduces amplitude modulation. If a filtered BPSK signal is amplified by a nonlinear power amplifier, the AM is removed, and the full bandwidth is restored.

Gary Field, WA1GRC, has been developing a 9600-baud FSK 21.4-MHz RF modem with 9600-Hz shift. He is also working on a transverter board to convert 21.4 MHz to a frequency in the 220-MHz band. Twenty units are planned for alpha testing.

At the Fourth ARRL Amateur Radio Computer Networking Conference, Steve Goode, K9NG, introduced a new 9600-baud FSK RF modem that uses a 3-kHz shift. Circuit details are printed in the conference proceedings. The Tucson Amateur Packet Radio Corporation is producing PC boards for the K9NG modem.

### Higher-Speed Modems

Spectrally efficient modem designs will be needed for speeds in excess of 9600 bit/s. Current thinking is that the next jump in speed will be to 56 kbit/s. Commercial 56-kbit/s modems are available but at prices beyond most amateurs. If an amateur 56-kbit/s modem were completed now, it would not be useful until a packet assembler/disassembler capable of that same speed is available. There is the future possibility of even higher speeds, such as 1.544 Mbit/s, for amateur packet radio. This entire area of high-speed modems and PADs is a challenging one for Amateur Radio development.

### Modem Testing

#### Bit Error Rate

**Bit-error-rate (BER) testing (BERT)** is done by sending a known pseudorandom bit sequence, comparing the received bit sequence with the known one and analyzing the results. BER is the basic, but not the only, measure of overall performance of a digital communications system. The bit error rate is the probability of not properly receiving a bit. BER is expressed in terms of the number of errors  $\times 10^{-n}$  or in a percentage.

A test setup described by Steve Goode, K9NG, in the August 1983 issue of *QEX* is shown in Fig. 37. It was used to test the BER performance of the TAPR TNC 1 modem, the results of which are presented in Fig. 38. BERT results of the K9NG 9600-bit/s modem are shown in Fig. 39.

#### Block Error Rate

**Block error rate (BLER, also seen as BKER)** is probably more meaningful in packet radio than BER. "Block" refers to a transmission block, which is the length of one transmission — in this case the length of a packet. Thus BLER testing (BLERT) tells you how many transmission blocks can be sent without any errors. A

Fig. 38 — BER results of test setup in Fig. 37. BER for 1200 bit/s and 300 bit/s are shown at A and B, respectively. In both tests, an RF input signal of  $-121$  dBm represents 20 dBq (decibels of quieting).

Fig. 39 — BER results of testing the K9NG 9600-bit/s modem.

typical VHF FM radio channel with a full-quieting signal could be expected to allow a BER of  $1 \times 10^{-5}$  or higher. That means that, on average, an error would occur every 100,000 bits. If a 2000-bit packet is sent repeatedly, on average, one out of every  $(100,000/2000 =) 50$  packets would be rejected because of a bit error introduced by the channel. Such a circuit would have a BLER of  $(1/50 =) 2 \times 10^{-2}$ .

It might seem at first that bit errors would be fairly evenly spread throughout various blocks. While largely random, bit errors tend to occur in bursts. Three bit

errors may be clustered and destroy only one block, not three. Thus, BER and BLER are not necessarily proportional.

### Modem Testing Techniques

Some telephone modems have a *self-test* feature. The self-test may activate automatically with power on, or the operator pushes a test button, to activate an integral word generator. A comparison of the output of the word generator and the same data sent through the modem is made, and the operator is signaled the results.

*Loopback* testing connects the output of the modulator to the input of the demodulator, either inside the modem or through a full-duplex communications channel. In the case of full-duplex modems which use separate originate and answer tones, the modem must be programmed to send and receive the same tones. For example, the modem is set up to send on its originate tones and receive on its answer tones, and vice versa.

In packet radio, *remote testing* of not just the modem but the entire packet-radio system can be accomplished by "connecting to yourself" through a digipeater. A simple way to do this is to make the connection then send a test sequence on the keyboard and observe the results on the screen. If any errors occur in transmission, it is extremely unlikely that the sequence will be repeated by the digipeater.

Another packet-radio testing method for equipment and the propagational path has provided some interesting results. In it, two stations agree that one station is to send a series of brief packets. In order to tell which packets get through and which do not, the data sent in the packet is simply the time in hours, minutes and seconds. The receiving station saves the times received on disk and can use the times for statistical analysis of the system over the path. A simple analytical technique is to print all times beginning with the same hour and minute on one line. The hard copy becomes a histogram of the experimental results.

### RS-232-C Break-Out Box

Aside from the a bit-error-rate tester, the most powerful everyday diagnostic tool for modem testing is the break-out box. Staring at the modem and cables for a long time or incantations won't help much. BOB — An RS-232-C Break-Out Box in Chapter 29 is one you can build for a reasonable price. Once you use a BOB, you will never want to be without one. Even if you don't have anything to troubleshoot, watching its blinking LEDs can be fine entertainment when the bands are dead.

In addition to modem testing, a break-out box is useful for checking any RS-232-C interfacing problem. Sooner or later you will run into an interfacing situation that you can't seem to figure out by flipping lines 2 and 3 and performing

(A)

(B)

(C)

Fig. 40 — K9NG photographs of eye patterns using his 9600-bit/s modem. Upper trace on each of the above represents the digital base-band signal before modulation. The lower trace on each photo is the received data after demodulation. Data rates were 9.6, 12 and 16 kbit/s at A, B and C, respectively.

gender-change operations on connectors. Sometimes the control lines, particularly pins 8 and 20, need to be reversed. Or, signals may not be appearing on various RS-232-C lines at the right times. A break-out box can also help you monitor what the modem is doing or not doing at various times. It helps to listen to transmitter and receiver audio at the same time.

### Eye Patterns

An essential diagnostic technique for modem design and testing is the *eye pattern* or *eye diagram* display on an oscilloscope. It gets its name from the shape of the display. The eye-pattern display is a comparison of transmitted data and received data signals. Some eye patterns photographed by K9NG appear in Fig. 40.

To produce an eye pattern, connect the

Fig. 41 — Oscilloscope connections for eye patterns. A single-trace 'scope is shown. If available, a dual-trace 'scope can be used to display eye patterns prior to modulation and subsequent to demodulation.

transmitted data to the horizontal trigger input of the 'scope. The 'scope is then set up to begin a trace when triggered, and the horizontal sweep period is set to an integral multiple of the bit period. If you have only a single-trace 'scope then connect the signal you wish to display to the 'scope vertical input as shown in Fig. 41.

In the case of the K9NG eye patterns a dual-trace 'scope was used. The upper trace in each photograph displays the digital baseband signal prior to modulation. Note that the top trace in the photo at A has smooth transitions between the upper and lower rails but that there is some flat-topping on the rails. As the bit rate is increased, the data looks less like a square wave and becomes sinusoidal in the top trace at C. The lower traces were produced by feeding the received data out of the demodulator into the second vertical channel input of the 'scope. In the lower trace at A, the eye pattern looks good with only minor amplitude and phase jitter. Amplitude jitter is seen by thickening or separation of the trace(s) in the vertical direction, while phase jitter appears as thickening or separation of the line(s) horizontally. Note how both amplitude and phase jitter increase as the data rate through the modem is increased.

## BINARY BASEBAND CODING

With so many experts working on things nothing remains simple. You didn't really think that 1s and 0s got translated directly to marks and spaces and that would be that, did you? Well, that's the way things were done in the early days of digital signaling. Experience with wire lines, missile telemetry and digital magnetic recording spawned the development of a number of different binary baseband encoding techniques, also called line coding, transmission coding, channel coding, baseband data format and pulse-code modulation (PCM).

A number of popular baseband codes are described below and illustrated in Fig. 42.

### NRZ-L (Nonreturn-to-zero — level)

NRZ-L is often called simply NRZ. It is also known as NRZ (change). A 1 is represented by one level, a 0 by the other level. Baudot and AMTOR RTTY normally use

Fig. 42 — Pulses produced by various binary baseband codes.

NRZ-L coding. This type of coding is not suitable for transmission or recording systems incapable of handling dc levels. Without transitions, there is a tendency for the baseline to shift and cause signal-detection errors.

### NRZ-S (Nonreturn-to-zero — space)

The familiar term in packet-radio circles is NRZI (nonreturn-to-zero — inverted). A 0 produces a change in level. A 1 causes no change. It does not matter whether a keying sequence is started on one tone or the other (usually called mark and space); only the transitions between the two tones are important. In NRZ-S, long sequences of 1 bits will cause no transitions, giving this code a strong dc component. However, in packet radio, *bit stuffing* or zero insertion after 5 continuous 1 bits limits the dc component to some extent. This is the predominant binary baseband code used for packet radio at this time. It is supported by

numerous protocol-controller chips including the Intel 8273, Zilog 8530 and Western Digital 1933.

### NRZ-M (Nonreturn-to-zero — mark)

This is also sometimes called NRZI, chiefly in digital recording, but it is just the opposite of NRZ-S. A 1 produces a change in level. A 0 causes no change. NRZ-M has a strong dc component whenever there are long sequences of 0 bits.

### RZ (Return-to-zero)

A 1 produces a half-bit-period pulse. A 0 produces no pulse. RZ has a strong dc component since no pulses are produced for 0 bits. The half-bit-period pulses require twice the bandwidth of codes that transmit only full-bit-period pulses.

### PPM (Pulse-position modulation)

A 1 produces a pulse in the middle of the symbol period. A 0 produces a pulse at the

beginning of the symbol period. PPM has eliminated the dc component but requires greater bandwidth than codes that transmit only full-bit-period pulses.

### **PDM (Pulse-duration modulation)**

A 1 causes a long pulse, a 0 a shorter pulse. PDM has no dc component but requires greater bandwidth than codes that transmit only full-bit-period pulses.

### **Biφ-L (Biphase — Level)**

Biφ-L is often called "Manchester." More precisely, it is "Manchester II," as it is the second code developed at Manchester, England. It is also referred to as "split phase." A 1 produces a half-bit-period 1 pulse followed by a half-bit-period 0 pulse during the symbol period. A 0 produces a half-bit-period pulse sequence of 01. Biφ-L has eliminated the dc component but requires twice the bandwidth of codes that transmit only full-bit-period pulses. Biφ-L has been used for AMSAT data links and by a few packet-radio experimenters.

### **Biφ-M (Biphase-Mark)**

Biφ-M is also called Manchester I, PE-M (phase encoding-mark), diphase and DF (double-frequency) and FM (frequency modulation) recording. There is a transition at the start of every bit period. A 1 causes a second transition halfway through the bit period. A 0 does not cause a second transition. Biφ-M has no dc component but requires twice the bandwidth of codes that transmit only full-bit-period pulses.

### **Biφ-S (Biphase-Space)**

Biφ-S is also called phase encoding. There is a transition at the beginning of every bit period. A 0 causes a second transition halfway through the bit period. A 1 does not cause a second transition. Biφ-S has no dc component but requires twice the bandwidth of codes that transmit only full-bit-period pulses.

### **DM (Delay Modulation)**

DM is often called *Miller Code*, also MFM (modified frequency modulation). A 1 causes a transition halfway through the bit period. A 0 causes no transition unless another 0 immediately follows, in which case a transition occurs at the end of the first bit period. DM is dc free and does not send pulses of less than one bit period.

### **PRZ (Polar return-to-zero)**

PRZ is a pseudoternary or multilevel-binary (MLB) code. A 1 produces a half-bit-period pulse of one polarity. A 0 produces a half-bit-period pulse of the opposite polarity. PRZ has no dc component.

### **AMI (Alternate-mark-inversion)**

AMI is also known as BP (bipolar). It is in the pseudoternary or multilevel-binary (MLB) class of codes. A 1 causes a positive pulse for the first half of the bit period and a 0 for the second half. A 0 produces a

0-level output. AMI has no dc component but lacks clocking information during long sequences of zeros.

### **HDB<sub>n</sub> (High-density bipolar codes)**

To overcome timing problems associated with AMI, HDB<sub>n</sub> limits the maximum number of 0s to  $n$ . If  $n + 1$  consecutive 0s occur in the data, the  $n + 1$ th 0 is replaced by a pulse of the same polarity as the pulse produced by the most-recent 1 bit. HDB3 (where  $n = 3$ ) is the most popular form.

### **Other Codes**

There are numerous other binary baseband codes, each having a peculiar combination of spectral and timing-recovery characteristics.

## **CIRCUIT TURNAROUND TIME**

The circuit turnaround time is the interval needed between the last bit transmitted by one station and first bit the station receiver can properly process. It is comprised of two parts: (1) transceiver switching delays and (2) propagation delay.

### **Transceiver Switching Delay**

Transceiver switching delay is the time it takes a transceiver to change from receive to transmit or vice versa and stabilize at full performance in the new condition. For design purposes, it is necessary to analyze the transceiver switching delay in terms of its four components: (1) transmitter ON time, (2) transmitter OFF time, (3) receiver ON time and (4) receiver OFF time. Worst-case measurements to date have been in the vicinity of 400 ms. Most HF and VHF radios can be modified to reduce the switching time to the 10- to 20-ms range. The requirements for HF/VHF packet radio are essentially the same as for AMTOR. All transceivers tested in the ARRL lab for the QST Product Review column will include switching times. For higher-speed packet radio (above 1200 bauds), a better design goal would be on the order of 1 ms.

### **HF Skywave Propagation Delay**

The worst-case propagation delay for a skywave path to the other side of the earth (12,000 miles) is about 70 ms. The approximate delay in ms can be computed by dividing the distance in statute miles by 186 (in km by 300). Some additional delay needs to be added to account for the distance traveled by the wave from earth to the ionosphere and back to earth again. That distance is more significant than the distance along the ground for near vertical-incidence skywave paths and can amount to as much as 260 mi (1.4-ms delay).

### **VHF/UHF Terrestrial Propagation Delay**

The VHF/UHF delay in ms can be calculated by dividing the distance in miles by 186. For example, a 32-mile path has a

propagation delay of 0.17 ms, which is usually insignificant compared to the equipment switching delay.

### **Meteor-Scatter Propagation Delay**

Meteor-scatter paths are limited to around 1200 miles as a result of the curvature of the earth. Meteor trails range from about 50 to 80 miles above the earth. Propagation delays run from around 0.3 to 6.7 ms, depending on path length.

### **Satellite Propagation Delay**

OSCAR 10 is in a highly elliptical orbit. The maximum round-trip delay at apogee is around 240 ms, or 33 ms at perigee.

## **CHANNEL ACCESS**

ALOHA, named after early packet-radio experiments at the University of Hawaii, is a channel-access method wherein a station transmits without first checking to see whether the channel is free. When a *collision* occurs, the TNC waits for a random time interval and retries until it gets the frame through and an acknowledgment from the other station. Because of collisions, the maximal channel loading is about 18%, which is acceptable as long as traffic on a frequency is light.

There are more sophisticated access arbitration schemes that involve listening before transmitting. Current packet-radio TNCs look for the carrier-detect signal from the modem before transmitting. This isn't absolute insurance against collisions because two stations could decide to transmit at exactly the same moment. Also, propagation delay makes it impossible to tell if a distant station is transmitting until some milliseconds after transmission began.

## **THE LINK LAYER**

The link layer defines the protocol for error-free transmission and reception between two points that are at two ends of a communications medium. In packet radio, that means two stations that work each other directly (not through a network). We have seen that the job of the physical layer is to get *bits* from one place through modems, radio transceivers and the propagation medium as reliably as possible. The function of the link layer is to move frames from one place to another through the physical layer and communications medium. In case the physical layer gets some bits wrong, the link layer will detect these errors and keep trying until a correct frame gets to the other station.

### **AX.25 LEVEL 2 PROTOCOL**

On October 26, 1984, the ARRL Board of Directors approved the AX.25 Amateur Packet-Radio Link-Layer Protocol (Version 2.0). The AX.25 level 2 protocol follows, in principle, CCITT Recommendation X.25. Exceptions are that the address field has been extended to accom-

modate Amateur Radio call signs and that an Unnumbered Information (UI) frame feature has been added. It also follows the principles of CCITT Rec. Q.921 (LAPD) in the use of multiple links, distinguished by the address field, on a single shared channel. With the exception of an extended address, it could be considered a subset of the ANSI Advanced Data Communications Control Protocol (ADDCP), balanced mode. It also follows the frame structure of High-Level Data Link Control Procedures (HDLC) per ISO 3309.

The AX.25 link-layer protocol formally specifies the format of a packet-radio frame and the actions a packet-radio station must taken when it transmits or receives such a frame.

At the link layer, data is sent in transmission blocks called *frames*. In addition to carrying data, each frame contains addressing, error-checking and control information. The addressing information tells what amateur station sent the frame, what station the frame is to be received by and, optionally, what stations should relay the frame. This addressing technique allows many packet-radio stations to share the same frequency. A station can monitor and display all the activity on a channel, regardless of to whom the frames are addressed. Or, a station may accept only the frames intended for it and ignore the rest. The error-checking information in the frame allows the receiving station to determine whether the frame contains any errors. If the frame is error-free, the receiving station accepts it and sends an acknowledgement to the transmitting station, if the two stations have established a *connection*. If the frame contains errors, the receiving station ignores it and waits for it to be retransmitted by the sending station.

### AX.25 Link-Layer Format

Link-layer packet-radio transmissions are sent in *frames*. Each frame is divided into *fields*. Fig. 43 shows the frame format. Transmission of the frame is normally preceded by 16 bit reversals for synchronizing. The frame consists of the beginning flag, address field, control field, a network protocol identifier (PID), information field, frame-check sequence (FCS) and an ending flag.

#### Flag Field

Each frame starts and ends with a *flag*. The flag has a peculiar bit pattern: 01111110. The pattern appears only at the beginning and end of frames. If five 1 bits show up somewhere else in the frame, a 0 bit is inserted by the sending station and removed by the receiving station. This is called *zero insertion* or *bit stuffing*, and is illustrated in Fig. 44.

#### Address Field

The *address field* consists of 2 to 10 specially encoded Amateur Radio call signs. The first address is that of the sta-

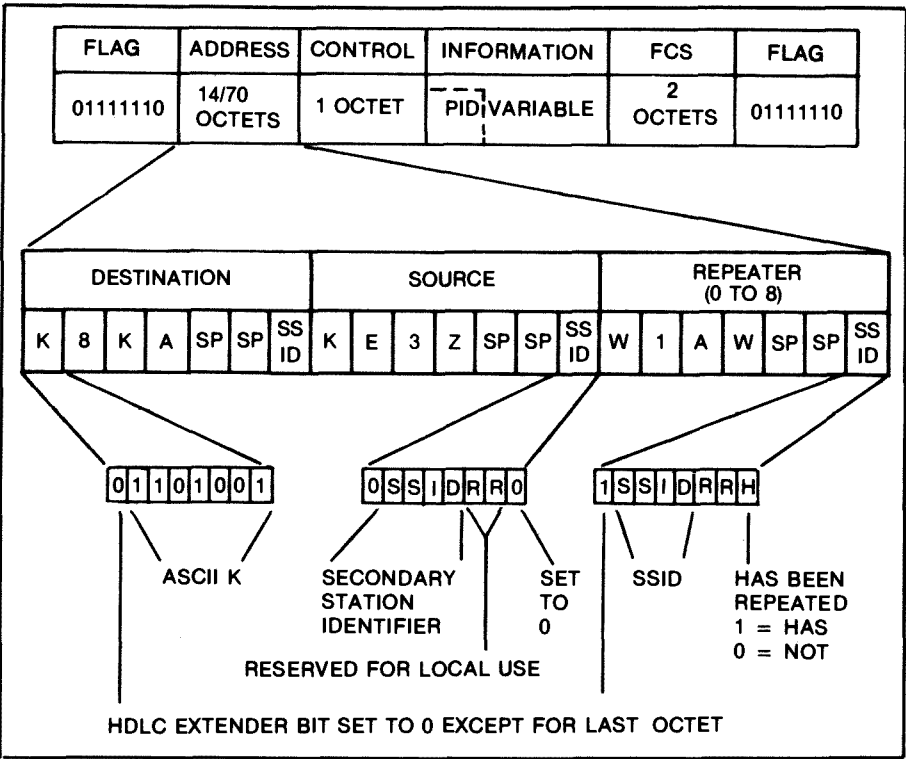

Fig. 43 — AX.25 frame format. The repeater address field is optional and may contain as many as eight repeater call signs.

Fig. 44 — The HDLC controller chip uses zero-insertion or bit-stuffing to eliminate the possibility of flags appearing within a frame. The transmitter examines the content between flags and inserts a 0 bit after all sequences of contiguous 1 bits to ensure that a flag sequence is not simulated. The receiver discards any 0 bit that directly follows 5 contiguous 1 bits that occur between the flag sequences.

tion for which the frame is intended. The second is the source or station originating the frame. If the two stations are in direct contact, that's all there is to the address field. If not, the call signs of 1 to 8 *digi-peeters* may appear.

Each call sign takes up six character spaces. Call signs are made up of upper-case alpha and numeric ASCII characters only; shorter call signs are left padded with ASCII spaces. A seventh character, called a *Secondary Station Identifier* (SSID), is added to permit up to 16 different packet-radio stations to operate under one radio call sign. For example, WIAW 5 is a digipeater, while WIAW 4 is a bulletin board station. The SSID also keeps track of which digipeaters have repeated, and which have yet to repeat, the frame. In Fig. 43, the two bits marked "R" are reserved and may be used in an agreed-upon manner in individual networks. When not implemented, they are set to 1.

The SSID *octet* (8 bits) in the repeater address, when used, differs from the others in that its last bit, "H" is used to indicate whether a frame has been repeated. This

is necessary to prevent the reception of identical frames, one direct and one from the repeater.

#### Control Field

The *control field* contains a bit pattern that tells what kind of frame it is (*information* or *supervisory*) and a frame number (0 to 7) for acknowledgments. It is used to signal a connection request, ready/not-ready conditions, frame numbering and the specific mode of operation.

#### Protocol Identifier Field

Strictly speaking, the *Protocol Identifier Field* (PID) is part of the information field and is shown as such in Fig. 43. It appears in information (I) and unnumbered information (UI) frames only. It identifies what kind of network-layer protocol, if any, is in use.

#### Information Field

The *information field* (I field) contains the data to be transmitted. This field can have any integral number of octets, up to 256, of information. As the network and

higher protocol levels are implemented, some of the octets at the beginning of the I field will be used for addressing and control for those levels.

### Frame Check Sequence Field

The *frame-check sequence* (FCS) is a 16-bit number calculated by both the sender and receiver of a frame. It follows an algorithm published in ISO 3309 (HDLC). Upon receipt of a frame, the receiver calculates the FCS on the basis of the received data then compares the answer with the FCS calculated by the sender. If the two match, that frame is acknowledged. The FCS is followed by the ending flag.

### AX.25 Procedure

Packet-radio protocols are generally executed in a microprocessor-based device called a *packet assembler/disassembler* (PAD), also called a *terminal-node controller* (TNC). Protocols can also be implemented in software written for a microcomputer. In any event, the procedures are automatic and operate without the need for operator intervention. The frame format and procedures for handling the frame are link-layer matters. What you see on your computer screen may or may not be a close approximation of what goes on at the link layer, since the screen display is a presentation-layer matter.

### Disconnected State

When power is applied, packet-radio TNCs are normally in the disconnected state or monitor mode. This permits displaying all activities on the channel. The TNC also looks for any connection requests from other stations and will respond by establishing the connection or ignoring the connection request, depending on circumstances.

### Connection Establishment

When one station wishes to connect with another, it sends a command frame to the other station and starts a time-out timer. If the other station is on the air and able to connect, it sends an acknowledgment frame. If the called station doesn't respond before the timer runs out, the calling station will reinitiate the request a number of times.

### Information Transfer

After the link connection is established, the TNCs will enter the information-transfer state. In this state, the two stations may exchange information and supervisory frames.

### Disconnection

While in the information-transfer state, either station may send a request to disconnect. The disconnection occurs after a response from the other station or if no response is heard after several disconnect attempts.

### Connectionless Operation

This is a procedure that permits round tables and bulletin transmissions via packet radio. The normal method of connection between two amateur stations is not practical when multiple stations are involved. The protocols allows this type of operation by using unnumbered information (UI) frames. Without frames being numbered, however, the TNCs do not automatically request retransmissions of bad frames as they do when connected.

### Frame Acknowledgments

The control field of each frame sent includes the number (0 to 7) of the last frame correctly received from the other station. If the sending station had sent frame

number 5 but received acknowledgment for frame number 4, it knows to repeat frame number 5.

### AX.25 Details

The protocol specification, "AX.25 Amateur Packet-Radio Link-Layer Protocol," is available from ARRL Hq. A tutorial based on an earlier version of the protocol appears in the proceedings of the Second ARRL Amateur Radio Computer Networking Conference, also available from ARRL Hq. See the end of this chapter for a bibliography.

## PACKET ASSEMBLER/DISASSEMBLERS

The assembly and disassembly of frames (or packets) is performed automatically by a computer. Special-purpose computers, called terminal-node controllers (TNCs) or packet assembler/disassemblers (PADs) have been designed for Amateur Radio use.

The TNC was introduced to Amateur Radio by the Vancouver Amateur Digital Communications Group (VADCG). The Tucson Amateur Packet Radio Corporation (TAPR) produced several TNCs that made a great contribution to the growth of Amateur packet radio. The TAPR TNC 1 and TNC 2 have been widely "cloned" by U.S. and foreign manufacturers. In addition, a number of manufacturers have introduced their own innovative TNC designs. Packet-radio manufacturers are listed near the end of this chapter. Refer to *QST* for articles and advertisements on packet-radio products. *Gateway*, the ARRL Packet-radio Newsletter carries the latest news on new packet equipment and software.

## DIGIPEATERS

A *digipeater* is a packet-radio station

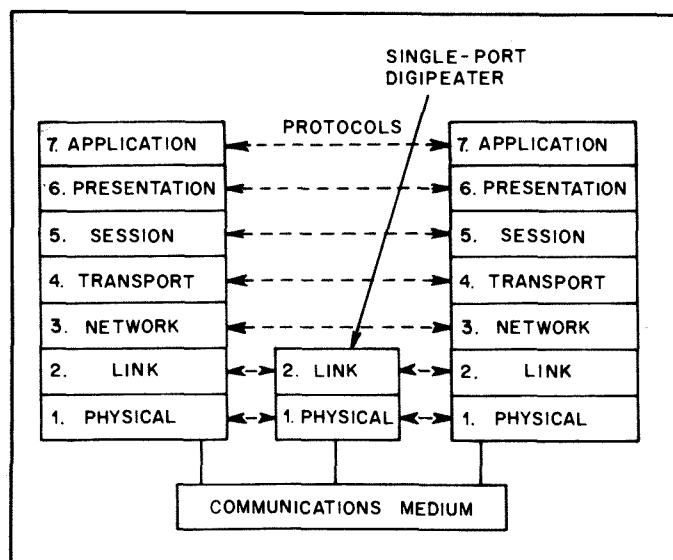

Fig. 45 — Open Systems Interconnection model of two packet-radio stations communicating through a single-port digipeater. The dashed lines represent logical communications between peer layers.

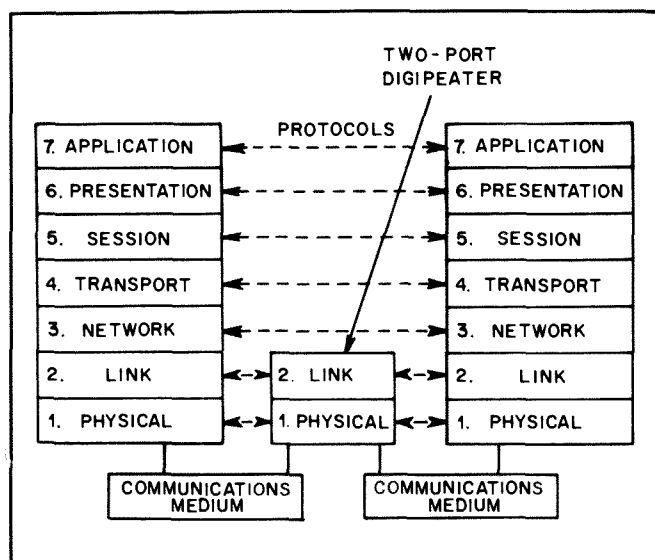

Fig. 46 — Open Systems Interconnection model of two packet-radio stations communicating through a two-port digipeater. The dashed lines represent logical communications between peer layers.

capable of recognizing and selectively repeating frames. An equivalent term used in industry is *bridge*. A digipeater can be either a single-port or multiport station. Virtually any TNC can be used as a single-port digipeater, provided that it has supporting software. TAPR TNCs and their commercial equivalents have software that includes a digipeating mode. Unmodified VADCG TNCs require a change of EPROMs for digipeater operation.

A multiport digipeater is necessary when one port operates at one set of Level 1 parameters (say 1200 bauds, Bell 202, on 2 meters) and a second port uses another set (say 9600 bauds, FSK, on 220 MHz).

The Xerox 820, without disk drives, monitor or keyboard, can be used as a multiport digipeater using software developed by KE3Z. The software can be used to link packet-radio stations operating on different frequencies, or can be used for a single-port digipeater. It uses the on-board SIO and two state machines of the type mentioned earlier in this chapter. To receive a copy of the software, send an 8-inch disk to ARRL Hq. with sufficient return postage.

An "apartment-house" diagram of how two packet-radio stations connect through a single-port or multiport digipeater is shown in Fig. 45.

## TELEPORTS

A *teleport* capable of real-time relaying of packets between packet-radio stations on the ground and a satellite is a special form of a two-port digipeater. What goes in the terrestrial port immediately goes out the port to the satellite and vice versa.

Real-time operation is not the ultimate in teleports, since when the users want to operate and when the satellite is in view may not coincide. Future teleports will include message buffering and will operate on a store-and-forward basis. Store-and-forward teleports are expected to greatly increase the utility of satellites for the average packet radio station.

Automatically operated teleports presently require a special temporary authority (STA) from the FCC. However, the rules may be changed to permit automatic operation by the time you read this.

## THE NETWORK LAYER

The purpose of the network layer is to get packets to their destination through a network. No networking standard exists as this edition of the *Handbook* is being finalized. Nor is there agreement among packet-radio experimenters on what form the network layer should take — virtual connections or datagrams, both of which are discussed below.

Fig. 47A illustrates the classical Open Systems Interconnection model of how two computers communicate through a network. Note the peer-to-peer (for example transport-to-transport) protocol relationships between the two end points and how

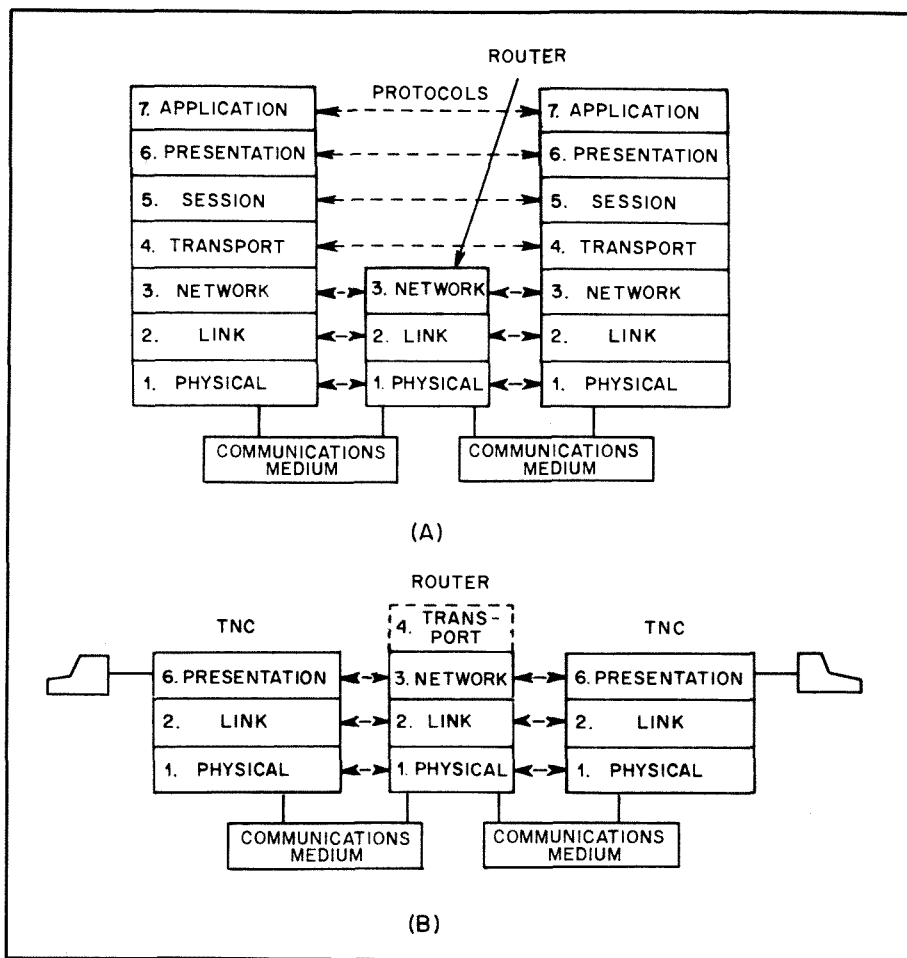

Fig. 47 — Possible packet-radio networking models. A shows the classical OSI model of two stations communicating through one or more network routers. This model will likely apply only to hosts that provide a service to the network. B represents a more modest idea of how users with present TNCs may communicate through a network. Dotted lines around the transport-layer box indicate that a transport-layer protocol may be required at the router if a datagram networking protocol is adopted. Dashed lines show logical communications between peer levels of protocol.

the physical, link and network-layer protocols involve the relay station, called a *router*. The idea is that both end points have computers with software for each of the protocol layers. The full 7-story apartment-house protocol structure may indeed become the pattern for *hosts* — those stations that will provide substantial computer services to the network.

At the moment, however, most packet-radio stations are equipped with TNCs that have only a modest capability. They implement the physical layer (modem) and the link layer (frame assembly and disassembly), and have a rather basic presentation layer. The presentation-layer code takes care of the commands and responses between the terminal and the TNC. The network, transport and application layers are skipped — often called *null layers*. Some of the future TNCs (communications processors, or whatever they will be called) may eventually implement all protocol levels. But for the moment, none do.

There is general agreement that however elaborate the network may become, net-

work designers should take care not to disenfranchise the user with a present-day TNC. Furthermore, such users should be able to enjoy the full capabilities of the worldwide packet-radio network. Just how this will be accomplished is a matter of speculation. Yet, it stands to reason that if all the fancy protocols are not in the user's TNC or personal computer, then they are likely to be in some super station nearby.

Fig. 47B may be closer to reality for amateur packet radio — certainly for the near future. The dashed lines forming the network- and transport-layer boxes in the router indicate some uncertainty of whether only the network layer or both the network and transport layers will be implemented. That depends largely on the outcome of the controversy between virtual connection and datagram approaches described below. If virtual connection is the approach chosen, only the network layer need be implemented. If datagram, then both need be included.

The data-communications industry uses

the term *local-area network* (LAN). That term, while perhaps okay when describing a 2-meter packet network, is inappropriate for packet-radio nets that might span half the globe, as they can on HF or via satellite. So, we have coined the term *intranet* to mean a (level 3) network with one net controller (router) and a bunch of user stations. The term *internet*, on the other hand, is widely used to denote communication between (intra)nets. If the network goes the virtual-connection route, there will be both intranets and internets. If it goes datagram, there may or may not be intranets. Regardless of the outcome, it is hoped that we will end up with one worldwide standard. To do otherwise would mean that high-level *gateways* have to be established between networks using different protocols. Unfortunately, when this is done, the unique advantages and enhancements in one network cannot be translated to networks not having the protocols to support them. In other words, communication between dissimilar networks becomes a matter of the least common denominator — something to avoid like grid current.

## NETWORK PROTOCOL

The protocol(s) for the network layer are now in the process of development. Two approaches are being studied by the ARRL Ad Hoc Committee on Amateur Radio Digital Communication: virtual circuit and datagram. This is a subject of considerable controversy both within amateur packet-radio circles and in the data communications industry. The Committee agreed to a period of parallel experimentation with the two approaches prior to settling on one or the other.

Operating prototypes of both virtual-circuit and datagram network protocols were unveiled at the Fifth ARRL Amateur Radio Computer Networking Conference in Orlando on March 9, 1986. Field trials in several locations across the U.S. were planned throughout 1986.

### Virtual-Circuit Protocol Proposal

A proposal based on CCITT Recommendation X.25 packet-layer protocol (PLP) was presented by Terry Fox, WB4JFI, at the Third ARRL Amateur Computer Networking Conference and elaborated upon in the Fourth Conference. Software written by Howie Goldstein, N2WX, was demonstrated at the Fifth Conference.

The virtual-circuit (VC) approach has the advantage of less overhead in the packet header and making the network (not the end user) responsible for acknowledgement of packets. In a virtual circuit, only the first packet establishing a virtual connection has the complete information needed by the network to route packets in the network header. Subsequent packets have an abbreviated network header.

### Datagram Protocol Proposal

Phil Karn, KA9Q, has proposed use of

a datagram type of network protocol based on the IP (Interned Protocol) developed by the Defense Advanced Research Projects Agency (DARPA). In a datagram protocol, each packet contains complete network addressing/routing information. There is more overhead per packet, but the advantage is that packets will reach the destination via any route still open even in an unreliable network.

Arguments in favor of a DARPA IP-based datagram protocol were given in a paper by KA9Q in the proceedings of the Fourth ARRL Amateur Radio Computer Networking Conference. Software written by KA9Q was demonstrated at the Fifth Conference.

## THE TRANSPORT LAYER

The transport layer makes sure that the data passed to and from higher layers is all there and put in the right order. In datagram protocols, it is possible that one packet sent before another one could beat the other to the destination. The transport layer has to be able to buffer incoming packets and reassemble them in the correct sequence. The transport header adds some overhead to the packet to carry out the necessary transport layer functions.

### Transport Protocol Proposals

The transport and network layers are closely associated. If a CCITT X.25 PLP-based virtual-circuit protocol is adopted, it is likely that a subset of the ISO TP-4 transport protocol now in the form of a draft international standard (DIS) will be used. On the other hand, if a DARPA IP-based network protocol adopted, it is likely that the DARPA TCP-based transport control protocol will be used.

## THE SESSION LAYER

The session layer is responsible for connection establishment and termination. In fact, it can set up multiple connections to the same or several different places. This protocol is not yet under active study.

## THE PRESENTATION LAYER

The presentation layer comes close to a

three-ring circus. It talks to the session layer to send and receive messages from distant computers. It deals with data files, code conversion and text strings, and is the traffic cop for computer peripherals. This layer also serves all the programs that might be running at the application layer.

### Standardizing TNC Commands and Responses

In 1979, the VADCG TNC original TIP (terminal interface program) had only two commands: CONTROL-X followed by a call sign meant "connect" and CONTROL-Y meant "disconnect." Commands were changed and added in other versions of the TIP. The software used in the TAPR TNC included a more-elaborate set of commands and responses. Commercial variants of the TAPR TNC used the TAPR commands and responses with only slight deviation.

In 1984, the ARRL Ad Hoc Committee on Amateur Radio Digital Communication circulated information on the latest versions of the following CCITT Recommendations:

- X.3 Packet assembly/disassembly facility (PAD) in a public data network.
- X.28 DTE/DCE interface for a start/stop mode data terminal equipment accessing the packet assembly/disassembly facility (PAD) in a public data network situated in the same country.

In simplified terms, X.3 specifies what a PAD (TNC) is supposed to do, and X.28 standardizes the commands and responses between the DTE (terminal) and the PAD (TNC). They are presentation-level protocols.

Doug Lockhart, VE7APU, studied the latest X.3 and X.28 documents for the Committee, and presented a paper on his findings at the Fourth ARRL Amateur Radio Computer Networking Conference. He proposed that an amateur version of these protocols should be adopted to standardize TNC commands and responses. A draft protocol proposal will be considered by the Committee.

### Videotex

Another presentation-level protocol can-

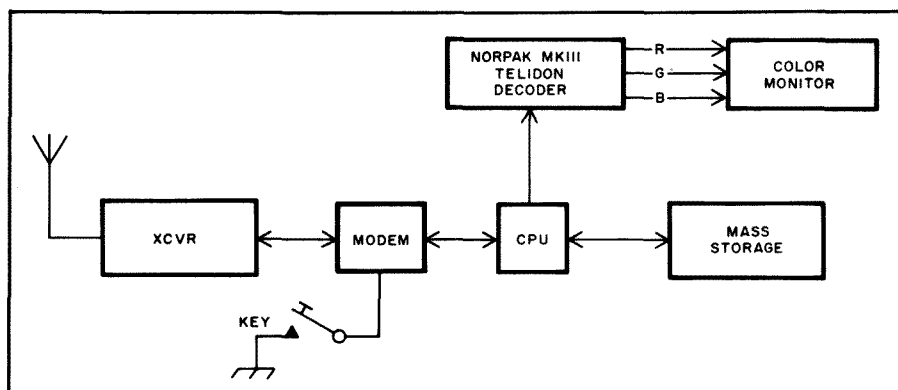

Fig. 48 — Block diagram of the station set up used for the Telidon tests.

Fig. 49 — Photograph of one trial picture, as received by VE3FTT. The picture was received error free

didate is videotex. An article in the September 1983 issue of *QST* documented some early experiments with videotex using Telidon picture-transmission techniques. A block diagram of the test setup used by VE3FTT is shown in Fig. 48. A photograph of a test picture received by VE3FTT is reproduced in Fig. 49.

Two major videotex standards exist: ANSI X3.110-1983/CSA T500-1983, Videotex/Teletext Presentation Level Protocol Syntax CCITT S.100, International Information Exchange for Interactive Videotex.

Both of these standards have a rich repertoire of graphic options, such as: alphanumeric characters, alphamosaic option, alphageometric option, alphaphotographic option and dynamically redefinable character sets (DRCS) option. Amateur experimentation with videotex will be extremely interesting in the years ahead.

## THE APPLICATION LAYER

This is the layer that runs one or more application programs — the real work of a computer in the user's view. Some computers will be set up to run one program that will offer a service to the packet-radio network. Others will be user oriented and will use the network to communicate needed information to and from other computers in the network.

### Message Protocols

Computer-based message systems (CBMSs) are high-interest applications for Amateur Radio. Probably, every metropolitan area within the network will have a CBMS to serve local amateurs. A number of packet-radio CBMSs are already in operation. Message systems help to sustain interest in packet radio by providing a reason to check in every day. They are also helpful in keeping users well informed.

It is unfortunate that the protocols used in various CBMSs are different and incompatible. Message formats used for CBMSs differ from those of the ARRL National Traffic System (NTS), the Military Affiliate Radio System (MARS) and electronic mail services. This may be of little immediate concern to many amateurs at the moment but causes a great deal of work for amateur stations that refile messages between net-

works. Lip service has been given to standardizing message formats. It seems that everyone has been willing to standardize if the rest of the world will make the first move. That may have happened. After years of discussion, the CCITT has completed work on message-handling standards and has published their recommendations in documents in the X.400 series. They will be studied closely for application to Amateur Radio.

### Host Protocols

A number of packet stations have set up host computers to provide a general or specific service to packet-radio users. The general-purpose type have included RCPM systems that allow *remote* use of a computer running CP/M®.

Except for brief demonstrations, permanent data-base hosts have not yet emerged. This is expected to be an important application for packet radio. Imagine that you're at your word processor one evening and need to have the title and author's name of an article on solar batteries. You don't know which Amateur Radio magazine it was in but think it was published in the fall of 1982 (or was it early 1983?). If an individual or club has gone to the trouble of building such a data base, you could log on the network and get the information you need within a few minutes. Or, you want to get ready for a DX contest and would like an up-to-date propagation prediction for East Asia. Again, how about signing on the network and asking for the latest word on MUFs and LUFs for the path.

Unlike message protocols, host protocols for other purposes may not need to be standardized for quite some time to come. For the present, this would be an area for wide-ranging experimentation to learn different ways of better serving the Amateur Radio community.

### Weather Applications

Packet radio is expected to make a great contribution to transmission of weather data via Amateur Radio. A paper entitled "Packet Radio and the National Hurricane Center" by Joel Kandel, K14T, is available in the proceedings of the Fourth ARRL Amateur Radio Computer Networking Conference.

A weather-reporting network around the Minneapolis-St. Paul area is being developed. A contact for this activity is Dr. Noel Petit, WBØVGI, Suite 220-B, 511 11th Ave. S, Minneapolis, MN 55415.

## ADVANCES IN PACKET-RADIO NETWORKING

As this edition of *The ARRL Handbook* is being prepared, several network-layer schemes are under consideration and are being tested in the field. (The network layer handles routing for the user.) Each of the network-layer protocols under considera-

tion is described briefly in the following section.

The ARRL Ad Hoc Committee on Amateur Radio Digital Communication has decided that networking protocols must compete in field trials until such time as one demonstrates its superiority over the others. Once the facts are in, the Digital Committee will make a recommendation to the ARRL Board of Directors on a networking standard.

### NET/ROM

The W6AMT network of digipeaters in California is testing a new firmware program for the TNC 2. Called "NET/ROM," the new firmware supports networking capabilities (commonly referred to in packet-radio circles as "layer three" and "layer four").

Developed by Ron Raikes, WA8DED, and Mike Busch, W6IXU, of Software 2000, Inc, NET/ROM runs on a standard TAPR TNC 2 terminal node controller, or on any of the commercially available TNC 2 "clones." NET/ROM is distributed in the form of a 27C256 EPROM which simply plugs into the ROM socket of the TNC 2 in place of the standard TAPR firmware ROM. NET/ROM is intended for use primarily at wide-coverage digipeater sites. It is not appropriate for end-user or mailbox stations.

A NET/ROM node provides the normal functions of an ordinary AX.25 digipeater, plus a set of sophisticated higher-level networking capabilities. A NET/ROM node user may display a list of other known network nodes; establish a transport-level circuit to a distant node; and connect to another end-user or mailbox in the vicinity of the distant node. Compared with conventional AX.25 multihop digipeating, NET/ROM's true store-and-forward packet switching technology can provide an order-of-magnitude improvement in throughput, especially over long paths. Routing from the local node to the distant node is handled automatically, and even includes alternate routing to circumvent network outages.

### NET.EXE

Another approach to the implementation of higher-level protocols is that taken by Phil Karn, KA9Q, in his NET.EXE program for the IBM PC. Essentially, Phil argues that there is no need to tie ourselves down to the AX.25 link layer protocol when a layer-four (transport) protocol is operating to ensure end-to-end data integrity. Phil's approach, as embodied in his NET.EXE program, allows several possible link-layer protocols (including AX.25).

NET.EXE executes the Defense Advanced Research Projects Agency (DARPA) suite of protocols. Included in these are IP, the Internet Protocol; TCP, the Transmission Control Protocol; ARP, the Address Resolution Protocol; FTP, the

File Transfer Protocol and SMTP, the Simple Mail Transfer Protocol. All of these are above the link layer in the hierarchy of protocols. At the link layer, NET.EXE supports simple serial data transfer via SLIP, the Serial Line Interface Protocol, and non-protocol serial I/O.

One of the most interesting aspects of the NET.EXE system is that it can do more than one job concurrently. TCP, which is used to provide end-to-end data integrity, can support multiple connections. NET.EXE also supports multiple applications processes. Using the multi-connect protocols, you could, for example, initiate a file transfer to another computer using FTP, and while that transfer is taking place you can chat with the operator of the remote computer using TELNET (the terminal-to-terminal "chat" protocol). Or perhaps chat with the operator of a *different* remote computer. Or receive forwarded mail. Or receive a file. Or... (You get the idea.)

### TEXNET

This networking protocol uses datagrams with node-to-node acknowledgments. User selection of node resources is performed on the basis of SSIDs. For example, connecting to the node with the node's call sign and an SSID of 1 will attach the user to the National Weather Service interface. Connecting to SSID 4 will let the user access the network, at which point the user can command the network node to list the other known network nodes, establish a circuit through the network, display node-activity statistics or access the message system.

The TEXNET network nodes under construction are two-port devices, with a 2-meter port for user access and a 70-cm port for node-to-node linking. The nodes will be operated from a battery and charger, providing emergency communication capabilities. Linking between nodes will be performed at 9600 bit/s.

The TPRS development team includes George Baker, W5YR, Tom McDermott, N5EG, and Tom Aschenbrenner, WB5PUC. TPRS expects to make printed-circuit boards and software available.

### Virtual Circuit Networking

A virtual circuit (VC) networking proposal based on CCITT X.25 was introduced by Terry Fox, WB4JFI, at the Third ARRL Amateur Radio Computer Networking Conference in 1984. Other early VC supporters were Gordon Beattie, N2DSY, Tom Moulton, W2VY, and Howard Goldstein, N2WX. Advocates of this approach point out that X.25 is an international standard in widespread use in commercial and government-owned packet-switched networks. Furthermore, unlike a datagram network, the network (not the endpoint) takes responsibility for delivering all packets where they are addressed and in the right order. One

advantage of VC is that once a virtual circuit is established through a network, subsequent packets have less overhead in the packet headers, whereas datagrams contain the full address every transmission.

It was Howie who wrote the code for an X.25-based VC network protocol resident in a TAPR TNC 2 that was demonstrated at the Fifth Networking Conference at Orlando in 1986. A number of groups are experimenting with this networking protocol, but a final, field-tested package has yet to be released. Howie has written dual-port networking code for the PAC-COMM dual-port TNC, which will be released soon.

### MORE INFORMATION ON PACKET RADIO

There are numerous sources of additional information on packet radio. The International Telegraph and Telephone Consultative Committee (CCITT), books and trade magazines are the best sources for packet switching in industry. The Amateur Radio literature on packet radio is rapidly growing. The bibliography that follows includes many useful articles and papers, which, in turn, will lead you to other material. Packet-radio clubs and their newsletters are also sources of new information.

### PACKET-RADIO SOURCES

There are numerous sources of packet-radio products and information. The sources listed below, while not exhaustive, are representative of what is available and will, in turn, lead you to other material.

### BIBLIOGRAPHY

## Glossary of Digital Communications Terminology

**ACK** — Acknowledgment, the control signal sent to indicate the correct receipt of a transmission block.

**Address** — A character or group of characters that identifies a source or destination.

**AFSK** — Audio frequency-shift keying.

**ALOHA** — A channel-access technique wherein each packet-radio station transmits without first checking to see if the channel is free; named after early packet-radio experiments at the University of Hawaii.

**AMICON** — AMSAT International Computer Network — Packet-radio operation on SSC L1 of AMSAT-OSCAR 10 to provide networking of ground stations acting as gateways to terrestrial packet-radio networks.

**AMRAD** — Amateur Radio Research and Development Corporation, a nonprofit organization involved in packet-radio development (P.O. Drawer 6148, McLean, VA 22106).

**AMTOR** — Amateur Teleprinting Over Radio, an amateur radioteletype transmission technique employing error correction as specified in CCIR 476-2 or 476-3. CCIR Rec. 476-3 is reprinted in the proceedings of the Third ARRL Amateur Radio Computer Networking Conference, available from ARRL Hq.

**ANSI** — American National Standards Institute (1430 Broadway, New York, NY 10018.)

**Answer** — The station intended to receive a call. In modem usage, the *called* station or modem tones associated therewith.

**ARQ** — Automatic Repeat Request, an error-control technique in which a sending station, after transmitting a data block, awaits a reply (ACK or NAK) to determine whether to repeat the last block or proceed to the next.

**ASCII** — American National Standard Code for Information Interchange, a code consisting of seven information bits.

**ASR** — An Automatic Send-Receive teletypewriter.

**Autostart** — A device that automatically senses presence of a signal and turns on a printer motor.

**AX.25<sup>SM</sup> pend.** — Amateur packet-radio link-layer protocol approved by ARRL Board of Directors in October 1984. Copies of protocol specification are available from ARRL Hq for \$8 U.S., \$9 Canada and elsewhere.

**Backwave** — An unwanted signal emitted between the pulses of an on/off-keyed signal.

**Balanced** — A relationship in which two stations communicate with one another as equals; that is, neither is a primary (master) or secondary (slave).

**Baud** — A unit of signaling speed equal to the number of discrete conditions or events per second. (If the duration of a pulse is 20 ms, the signaling rate is 50 bauds or the reciprocal of 0.02.) (abbreviated Bd)

**Baudot code** — A coded character set in which five bits represent one character. Used in the U.S. to refer to ITA2.

**Bell 103** — A 300-baud full-duplex modem using 200-Hz-shift FSK of tones centered at 1170 and 2125 Hz.

**Bell 202** — A 1200-baud modem standard with 1200-Hz mark, 2200-Hz space, used for VHF FM packet radio.

**BERT** — Bit-error-rate test.

**BER** — Bit error rate.

**Bit** — Binary digit, a single symbol, in binary terms either a one or zero.

**Bit stuffing** — Insertion and deletion of 0s in a frame to preclude accidental occurrences of flags other than at the beginning and end of frames.

**BLER** — Block error rate.

**BLERT** — Block-error-rate test.

**Break-in** — The ability to hear between elements or words of a keyed signal.

**Byte** — A group of bits, usually eight.

**Carrier Detect** — Formally, Received Line Signal Detector, a physical-level interface signal that indicates that the receiver section of the modem is receiving tones from the distant modem.

**CCIR** — International Radio Consultative Committee, an International telecommunication Union agency.

**CCIR Rec. 476-3** — The CCIR Recommendation used as the basis of AMTOR and incorporated by reference into the FCC rules.

**CCITT** — International Telegraph and Telephone Consultative Committee, an ITU agency. CCIR and CCITT recommendations are available from the U.N. Bookstore, United Nations Building, New York, NY 10017.

**Chirp** — Incidental frequency modulation of a carrier as a result of oscillator instability during keying.

**Clear to Send** — A physical-level interface circuit generated by the DCE that when ON indicates the signals presented on the Transmitted Data circuit can be transmitted.

**Collision** — A condition that occurs when two or more transmissions occur at the same time and cause interference to the intended receivers.

**Connection** — A logical communication channel established between peer levels of two packet-radio stations.

**Contention** — A condition on a communications channel that occurs when two or more stations try to transmit at the same time.

**Control field** — An 8-bit pattern in an HDLC frame containing commands or responses, and sequence numbers.

**CRC** — Cyclic Redundancy Check, a mathematical operation in which the results are sent with a transmission block to enable the receiving station to check the integrity of the data.

**CSMA** — Carrier Sense Multiple Access, a channel access arbitration scheme in which packet-radio stations listen on a channel for the presence of a carrier before transmitting a frame.

**Cut numbers** — In Morse code, shortening of codes sent for numerals.

**DARPA** — Defense Advanced Research Projects Agency; formerly ARPA, sponsors of ARPANET.

**Datagram** — A mode of packet networking in which each packet contains complete addressing and control information. (compare Virtual Circuit)

**Data Set** — Modem.

**Destination** — In packet radio, the station that is the intended receiver of the frame sent over a radio link either directly or via a repeater.

**DCE** — Data Circuit-Terminating Equipment, the equipment (for example, a modem) that provides communication between the DTE and the line radio equipment.

**Digipeater** — A link-level gateway station capable of repeating frames. The term "bridge" is used in industry.

**Domain** — In packet radio, the combination of a frequency and a geographical service area.

**DTE** — Data Terminal Equipment, for example a VDU or teleprinter.

**DXE** — In AX.25, Data Switching Equipment, a peer (neither master nor slave) station in balanced mode at the link layer.

**EASTNET** — A series of digipeaters along the U.S. East Coast.

**EIA** — Electronic Industries Association. (2001 Eye St., N.W., Washington, DC 20006.)

**Envelope-delay distortion** — In a complex waveform, unequal propagation delay for different frequency components.

**Equalization** — Correction for amplitude-frequency and/or phase-frequency distortion.

**Eye pattern** — An oscilloscope display in the shape of one or more eyes for observing the shape of a serial digital stream and any impairments.

**FADCA** — Florida Amateur Digital Communications Association, c/o Gwyn Reedy, W1BEL, 812 Childers Loop, Brandon, FL 33511.

**FCS** — Frame Check Sequence. (See CRC.)

**FEC** — Forward Error Correction, an error-control technique in which the transmitted data is sufficiently redundant to permit the receiving station to correct some errors.

**Field** — In packet radio, at the link layer, a subdivision of a frame, consisting of one or more octets.

**Flag** — In packet switching, a link-level octet (01111110) used to initiate and terminate a frame.

**Frame** — In packet radio, a transmission block consisting of opening flag, address, control, information, frame-check-sequence and ending flag fields.

**FSK** — Frequency-Shift Keying.

**Gateway** — In packet radio, an interchange point.

**HDLC** — High-level Data Link Control Procedures as specified in ISO 3309.

**Host** — As used in packet radio, a computer with applications programs accessible by remote stations.

**IA5** — International Alphabet Number 5, a 7-bit coded character set, CCITT version of ASCII.

**Information field** — Any sequence of bits containing the intelligence to be conveyed.

**ISI** — Intersymbol interference; slurring of one symbol into the next as a result of multipath propagation.

**ISO** — International Organization for Standardization.

**ITA2** — International Telegraph Alphabet Number 2, a CCITT 5-bit coded character set commonly called the Baudot or Murray code.

**JAS-1** — JAMSAT/JARL amateur satellite having packet-radio capability.

**Jitter** — Unwanted variations in amplitude or phase in a digital signal.

**Key clicks** — Unwanted transients beyond the necessary bandwidth of a keyed radio signal.

**KSR** — Keyboard Send-Receive teletypewriter.

**LAP** — Link Access Procedure, CCITT X.25 unbalanced-mode communications.

**LAPB** — Link Access Procedure, Balanced, CCITT X.25 balanced-mode communications.

**Layer** — In communications protocols, one of the strata or levels in a reference model.

**Level 1** — Physical layer of the OSI reference model.

**Level 2** — Link layer of the OSI reference model.

**Level 3** — Network layer of the OSI reference model.

**Level 4** — Transport layer of the OSI reference model.

**Level 5** — Session layer of the OSI reference model.

**Level 6** — Presentation layer of the OSI reference model.

**Level 7** — Application layer of the OSI reference model.

**Loopback** — A test performed by connecting the output of a modulator to the input of a demodulator.

**LSB** — Least-significant bit.

**Mode A** — In AMTOR, an Automatic Repeat Request transmission method.

**Mode B** — In AMTOR, a Forward Error Correction transmission method.

**Modem** — Modulator-Demodulator, a device that connects between a data terminal and communication line (or radio). Also called Data Set.

**MSB** — Most-significant bit.

- MSK** — Frequency-shift keying where the shift in Hertz is equal to half the signaling rate in bits per second.
- NAK** — Negative Acknowledge. (opposite of ACK)
- NAPLPS** — ANSI X3.110-1983 Videotex/Teletext Presentation Level Protocol Syntax.
- NBDP** — Narrow-band direct-printing telegraphy.
- NEPRA** — New England Packet Radio Association, P.O. Box 15, Bedford, MA 01730.
- Node** — A point within a network, usually where two or more links come together, performing switching, routine and concentrating functions.
- NRZI** — Nonreturn to zero. A binary baseband code in which output transitions result from data 0s but not from 1s. Formal designation is NRZ-S (nonreturn-to-zero — space).
- Null modem** — A device to interconnect two devices both wired as DCEs or DTEs; in EIA RS-232-C interfacing, back-to-back DB25 connectors with pin-for-pin connections except that Received Data (pin 3) on one connector is wired to Transmitted Data (pin 3) on the other.
- Octet** — A group of eight bits.
- OOK** — On-off keying.
- Originate** — The station initiating a call. In modem usage, the *calling* station or modem tones associated therewith.
- OSI-RM** — Open Systems Interconnection Reference Model specified in ISO 7498 and CCITT Rec. X.200.
- Packet Radio** — A digital communications technique involving radio transmission of short bursts (frames) of data containing addressing, control and error-checking information in each transmission.
- PACSAT** — Proposed AMSAT packet-radio satellite with store-and-forward capability.
- PAD** — Packet Assembler/Disassembler, a device that assembles and disassembles packets (frames). It is connected between a data terminal (or computer) and a modem in a packet-radio station. (see also TNC)
- Parity Check** — Addition of noninformation bits to data, making the number of ones in a group of bits always either even or odd.
- PID** — Protocol identifier. Used in AX.25 to specify the network-layer protocol used.
- PPRS** — Pacific Packet Radio Society, P.O. Box 51562, Palo Alto, CA 94303.
- Primary** — The master station in a master-slave relationship; the master maintains control and is able to perform actions that the slave cannot. (Compare secondary.)
- Protocol** — A formal set of rules and procedures for the exchange of information within a network.
- PSK** — Phase-Shift Keying.
- RAM** — Random Access Memory.
- Received Data** — Physical-level signals generated by the DCE are sent to the DTE on this circuit. (abbreviated RxD)
- Request to Send** — Physical-level signal used to control the direction of data transmission of the local DCE. (abbreviated RTS)
- RO** — Receive-Only teletypewriter.
- ROM** — Read-Only Memory.
- ROTR** — Receive-Only Typing Reperforator Set.
- Router** — A network packet switch. In packet radio, a network-level relay station capable of routing packets.
- RS-232-C** — An EIA standard physical-level interface between DTE (terminal) and DCE (modem), using 25-pin connectors.
- RTTY** — Radioteletype.
- Secondary** — The slave in a master-slave relationship. Compare primary.
- SOFTNET** — An experimental packet-radio network at the University of Linköping, Sweden.
- Source** — In packet radio, the station transmitting the frame over a direct radio link or via a repeater.
- SSID** — Secondary Station Identifier. In AX.25 link-layer protocol, a multipurpose octet to identify several packet-radio stations operating under the same call sign.
- SOUTHNET** — A series of digipeaters along the U.S. Southeast Coast.
- TAPR** — Tucson Amateur Packet Radio Corporation, a nonprofit organization involved in packet-radio development (P.O. Box 22888, Tucson, AZ 85734).
- TD** — Tape Transmitter-Distributor Set, a paper tape reader.
- Teleport** — A radio station that acts as a relay between terrestrial radio stations and a communications satellite.
- Teleprinter** — Trademark of ITT/Creed. A printing teletypewriter.
- Teletype** — Trademark of the Teletype Corporation, usually used to refer to teletypewriters.
- Teletypewriter** — Generic term for printing telegraph equipment. (For specific types see ASR, KSR, RO, ROTR and TD.) (abbreviated TTY)
- TNC** — Terminal Node Controller, a device that assembles and disassembles packets (frames). (used interchangeably with PAD)
- TR switch** — Transmit-receive switch to allow automatic selection between receive and transmitter for one antenna.
- Transmitted Data** — Physical-level data signals transferred on a circuit from the DTE to the DCE. (abbreviated TxD)
- TTY** — Teletypewriter.
- TU** — Terminal Unit, a radioteletype modem or demodulator.
- Turnaround time** — The time required to reverse the direction of a half-duplex circuit, required by propagation, modem reversal and transmit-receive switching time of a transceiver.
- UI** — Unnumbered Information frame.
- VADCG** — Vancouver Amateur Digital Communications Group. (c/o Doug Lockhart, VE7APU, 9531 Odlin Rd., Richmond, BC V6X 1E1, Canada.)
- VDT** — Video-display terminal.
- VDU** — Video Display Unit, a device used to display data, usually provided with a keyboard for data entry.
- Videotex** — A presentation-layer protocol for two-way transmission of graphics.
- Virtual Circuit** — A mode of packet networking in which a logical connection that emulates a point-to-point circuit is established. (compare datagram)
- V.24** — A CCITT standard defining physical-level interface circuits between a DTE (terminal) and DCE (modem), equivalent to EIA RS-232-C.
- V.28** — A CCITT standard defining electrical characteristics for V.24 interface.
- WESTNET** — A series of digipeaters along the U.S. West Coast.
- Window** — In packet radio at the link layer, the range of frame numbers within the control field used to set the maximum number of frames that the sender may transmit before it receives an acknowledgment from the receiver.
- X.25** — CCITT packet-switching protocol.

# Image Communications

Judging by the upsurge of amateur interest in systems that can send and receive pictures, many hams must be taking to heart the old Chinese proverb, "one picture is worth a thousand words." This, along with the availability of inexpensive video components, may explain why so many hams are motivated to use and experiment actively with systems capable of exchanging pictures.

There are three basic image communications systems in popular use by the amateur community. Each approach has unique fea-

tures, capabilities and applications:

- *Fast-scan television (FSTV)*: Moving pictures are displayed on a standard TV set; includes sound. Its performance is similar to commercial broadcast TV pictures. It is used predominately in the UHF bands (70 and 23 cm) to provide local area coverage.

- *Slow-scan television (SSTV)*: Low-resolution still pictures are displayed on a standard TV set. Used in the HF bands, it provides worldwide coverage.

- *Facsimile (FAX)*: High-resolution still picture produced on paper or photographic film. It is used for weather-satellite recep-

tion and in the HF bands to provide worldwide coverage.

The recent amateur interest in image communications essentially reflects the current video orientation of our society. This is evidenced by the huge sales of home consumer items such as color TV sets, video cassette recorders, TV cameras, video games and computer graphics displays. Many of these consumer devices can be used in your shack as a foundation for building a complete amateur image communications system.

## Fast-Scan Amateur Television

Fast-scan TV (FSTV), also referred to simply as amateur television (ATV), uses a transmission format fully compatible with video equipment designed for the home consumer market. The video is amplitude modulated; the audio is frequency modulated. Each video frame consists of 525 horizontal lines with 30 frames transmitted each second. (See Chapter 7 for more details on the scanning process.) Translated into simple terms, this means that an FSTV picture displays full motion, has a simultaneous sound channel, can be in color and has excellent detail just like commercial TV pictures.

Amateur television offers a major advantage over broadcast TV, though, and that is rooted in our ability to communicate interactively or two ways. Amateur television people have been communicating in round table nets for many years — long before industry discovered the benefits of interactive video or, as it's called, "teleconferencing."

Because the signals occupy several megahertz of bandwidth, the FCC does not permit FSTV on bands below 420 MHz. Most ATV is performed in the 420- to 440-MHz and 1240- to 1294-MHz segments of the 70- and 23-cm bands. Some ATV activity can be found in the 902-928 MHz band. These frequencies generally limit FSTV range to line of sight with extended

Fig. 1 — Fast-scan ATV station assembled using circuits described in this chapter plus a home-video camera and standard TV set.

coverage possible when ducting conditions exist or repeaters are used.

A Technician class or higher license is required to transmit FSTV below 1240 MHz. Novices may operate ATV in the 1270-1295 MHz portion of the 23-cm band. All you need is a home-video type camera, microphone, ATV transmitter and antenna. Depending on your application, a personal computer terminal or video tape recorder can be used instead of a camera. You don't even have to provide external synchronization. Sync pulses are part of the composite video signal from the camera, video cassette recorder or computer. No

modification to these devices is necessary.

To receive, all you need is an antenna, RF converter (also called a downconverter, it shifts the received signal to a standard VHF TV channel) and an unmodified home TV set. No scan converters are required. The basic elements of a fast-scan ATV station are shown in Fig. 1.

In keeping with the ham tradition for both public service and inventiveness in communications, ATVers have been using their live action video systems in many exciting applications. For example, the Southern California ATVers annually help coordinate and monitor the Tournament of Roses Parade and local marathons. During the Christmas season, amateurs have taken their systems into hospitals to permit children to see and talk with Santa Claus over live TV. Warren Weldon, W5DFU, uses his ATV cameras on a tall tower to search the Oklahoma skies for "killer tornadoes" while transmitting the pictures directly to the Weather Service to provide a valuable early-warning capability. Amateurs have transmitted ATV from Civil Air Patrol airplanes and even hot-air balloons. ATV has also been used in radio-controlled model airplanes and robots to provide the necessary feedback to aid the operator. Most recently, the FCC has permitted ATVers to retransmit the spectacular Space Shuttle video provided on

Fig. 2 — Aft end of STS-9 Shuttle cargo bay as seen via fast-scan ATV.

NASA's public information channel on Satcom 1R (Fig. 2).

On a day-to-day basis, there are many down-to-earth uses for ATV. You can show off your shack, your family, home movies, video tapes and travel slides. You do run the risk of putting fellow ATV watchers to sleep! Some amateurs exchange video tape copies of their contacts with hams in other countries.

Your home computer system and ATV station make an ideal marriage. By simply taking the video output of your home computer into the video input of your ATV transmitter, the computer may be used to show still and animated graphics, teach computer programming and debugging, repeat WIAW RTTY bulletins and display bulletin-board messages. Serial data can also be placed on the TV sound subcarrier for exchanging computer programs.

Since ATVers share the bands with other types of emissions and amateur interests, frequencies have evolved through formal frequency-coordination organizations that minimize mutual interference to all band users in any given area. Before you start transmitting, check with local ATVers and the *ARRL Repeater Directory*. The *Repeater Directory* also lists your area frequency-coordination committee.

### TV Waveforms

Thanks to the availability of off-the-shelf cameras, and receiving converters that preclude the need to perform surgery on your home TV set, it is not necessary to understand the inner workings of a camera or TV set. It is only necessary for you to know what the waveform at the output of a camera, computer or video tape recorder will look like to help you adjust your ATV station properly.

Fig. 3 shows what a single horizontal line of video looks like at the camera and transmitter output. Two basic elements can be seen in the waveform: the synchronization pulses and the video.

- **Synchronization pulses** — These are used in the TV receiver to synchronize the CRT electron beam scan with that of the camera (see Chapter 7). Although only "horizontal" pulses are shown in the figure, there are also "vertical" pulses,

Fig. 3 — TV Waveform. Camera and corresponding transmitter RF output power levels during one horizontal line scan for black-and-white TV. (A color camera would generate a "burst" of 8 cycles at 3.58 MHz on the back porch of the blanking pedestal.) Note that "black" corresponds to a higher transmitter output power than "white."

which occur 60 times a second to ensure that the top of the received picture lines up properly with the top of image as seen by the camera. It is only important for you to know that the proper amplitude of these synchronization pulses must be maintained in the transmission process. The transmitter and linear amplifier must be adjusted properly to ensure that the sync is not overly compressed or clipped.

- **Video** — Between the synchronization pulses lies the video information that controls the intensity of the beam as it scans across the receiver picture tube. The signal level determines whether an individual picture element (pixel) shall be white, black or a given shade of gray. This concept is shown in Figs. 4 and 5.

Color TV is more complicated than black-and-white TV. The transmitting and receiving equipment is the same for black and white transmission, except that a color camera and TV receiver are required. The corresponding frequency spectrum of the color TV signal is shown in Fig. 6.

A brief discussion of color TV can be found in Chapter 7. An excellent source of more complete information on the basics of both monochrome and color television techniques may be found in the book *Television Handbook for the Amateur* by Biagio Presti. See the bibliography at the end of this section.

### FSTV System Elements

As previously emphasized, standard, unmodified, off-the-shelf video components are used to generate and display the ATV pictures. A block diagram of a typical FSTV station is shown in Fig. 7. The most important part of the system is the antenna and coax. Since vegetation greatly attenuates UHF signals, mounting the antenna above tree tops is highly desirable. DX

Fig. 4 — The video signal resulting from viewing a gray-scale pattern ranging from black to white level.

Fig. 5 — A single line of the TV picture at A has its voltage waveform shown at B.

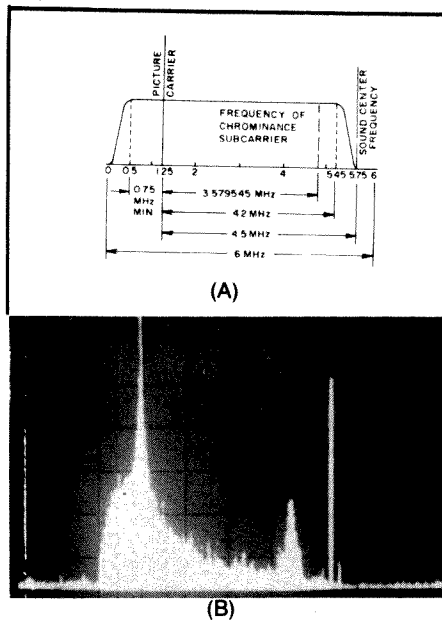

Fig. 6 — Frequency spectrum of a color TV signal shown in diagram at (A) and on a spectrum analyzer at (B). Each vertical division represents 10 dB; horizontal divisions are 1 MHz. Spectrum power density will vary with picture content, but typically 90% of sideband power is within the first megahertz.

will vary with terrain, trees and temperature inversion characteristics (ducting). Because the bandwidth of an FSTV system is considerably wider than a narrow-band voice circuit operating on the same frequency at the same power level, it is necessary to compensate for the accompanying decrease in received signal-to-noise by using relatively high-gain antennas, low-loss transmission lines and low-noise preamplifiers. One should not compare ATV performance with UHF broadcast TV reception. Commercial and public stations transmit a million, or more, watts of effective radiated power. Amateurs use considerably lower power levels, of course.

#### Antennas

The antenna must have both high gain and broad bandwidth. For the home-brew enthusiast, the 15-element quagi is popular (see Chapter 33). The MBM48/70 J Beam and several KLM models are good, high-gain, commercially constructed beams that are specially designed for broadband work. For portable applications, a small Yagi antenna, or omnidirectional antennas such as the AEA Isopole are used.

Polarization used by ATVers varies throughout the country. In general, most DX operations use horizontal, while most repeaters use vertical polarization. Check with local ATVers to determine the polarization used in your area before setting up an antenna.

#### Transmission Line

At 420 MHz, cable loss can be quite

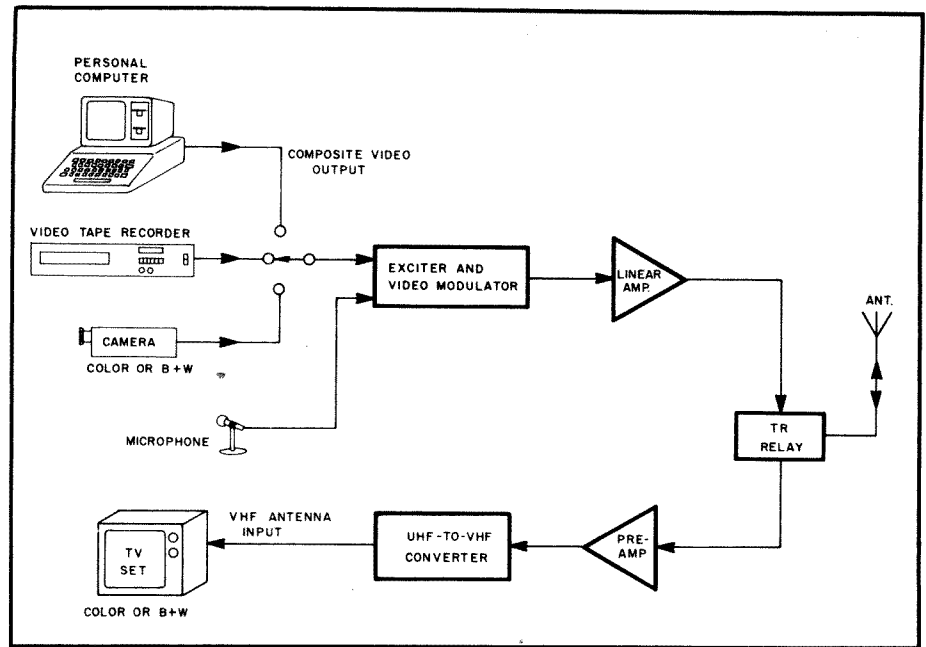

Fig. 7 — Fast-scan ATV station.

high, especially for long cable runs. Types such as RG-58 are very lossy at UHF (15-dB loss/100 feet at 420 MHz) and are not used for ATV work except for short equipment interconnects in the shack. Up to 50 feet, RG-8, -213 or -214 (5 dB/100 ft) are acceptable, but for longer runs, 1/2-inch Hardline such as Phelps-Dodge PD-FX 12-50H (2.1 dB/100 ft) or low-loss coax such as Belden 8214, Belden 9913, Belden 9914, or Saxton 8285 (3.8 dB/100 ft) is recommended. The exception to this is when the receive preamp can be mast-mounted at the antenna. The type of connector used (UHF or N) is not as important as proper installation and weather-proofing.

#### Receiver

The purpose of the receive converter is to shift the UHF signal to a frequency that is tunable on a standard TV set. The output is fed into the VHF antenna terminals on the set. No modification to the TV is required.

A preamplifier may be included as part of the converter or as a separate mast-mounted unit. The use of GaAsFET front ends for preamps, by virtue of their wide dynamic input range and related immunity from self-generated intermodulation components, has reduced the requirements for filtering ahead of the preamp. A popular commercial preamp for ATV use is Advanced Receiver Research model P432VDG.

#### Video Transmitter

A video transmitter is very similar in design to a UHF FM voice transmitter except that the constant dc voltage on the final RF amplifier stage is replaced with the amplitude-varying output of a video modu-

lator to produce amplitude modulation. The principle is identical to plate (or collector) modulation prevalent in the pre-SSB era.

The transmitter is modulated with the video and synchronization signals provided by a camera. The modulator gain must be adjusted to provide the proper modulation level. Too little gain will produce a picture lacking contrast; too much gain may cause the picture to "white out" or clip off sync. Proper set-up of modulation level is just as important as transmitter power level. A strong received signal exhibiting poor contrast may look worse than a weak signal with excellent contrast. The modulator must have the bandwidth to pass the 3.58-MHz color-burst signal provided by the camera and for a 4.5-MHz sound subcarrier. Most solid-state UHF transmitters have output matching circuits that pass the wide-bandwidth ATV signals.

#### Power Amplification

To increase the power output from the video transmitter, a linear amplifier is used. Tube amplifiers generally provide better linearity than solid-state units, while solid-state amplifiers tend to have broader bandwidths.

Proper sync-to-video ratio and picture linearity are the main concerns when using a high-power transistor amplifier. A sync stretcher in the video modulator is used to compensate for gain compression (nonlinearity at high power levels) typically found in solid-state amplifiers. By exaggerating the sync level at the amplifier input, the proper sync-to-video relationship will result at the amplifier output as shown in Fig. 8.

Transistor amplifiers, by virtue of their low loaded Qs, have sufficient bandwidth for ATV. This is generally not the case with

Fig. 8 — Oscilloscope used to observe the video waveform. The lower trace is the video signal as it comes out of the sync stretcher. The upper trace is the signal from the Mirage D1010-N amplifier.

tube amplifiers. At UHF, many tetrode high-power amps using 4CX250-type tubes have too high a loaded Q at the grid and plate to pass the color and sound subcarriers without significant attenuation. This can be overcome by control-grid modulation of the final stage and increased loading of the plate circuit. Grounded-grid triodes like the 7289 are less bandwidth restrictive in the linear mode because of the lower impedances associated with cathode drive. However, direct cathode modulation is usually preferred and much simpler. Sync stretching is normally not necessary with tube amplifiers, as their linearity is excellent.

For more discussion on the special considerations for linear amplifiers used in a television role, see "The Care and Feeding of Linear Amplifiers for ATV," *QST*, August 1982, p. 24.

### Audio Transmission Techniques

Sound can be transmitted on FSTV using two main approaches. One method is to FM audio modulate the AM video carrier frequency. This permits a rather simple transmitter design, but the penalty is paid at the receiving end since a standard TV will not be able to pick up the audio. A separate FM receiver, tuned to the video frequency, must be used to recover the audio.

A more popular approach is to provide FM audio at a frequency 4.5 MHz above the video carrier using a separate transmitter or using a subcarrier generator that feeds the input of the video modulator. The advantage of this approach is that no separate receiver is required since a conventional TV set includes the circuitry to demodulate the 4.5-MHz subcarrier.

In addition to either technique, a separate 2-meter circuit has proven highly beneficial for talk back and coordination. By using 2 meters to establish a full-duplex audio link, the receiving station can provide valuable picture-quality reports to the TV transmitting station. Also, a casual 2-meter listener is intrigued when hearing the comments about a picture that cannot be seen on 2 meters, and is surprised to even

find out that there is ATV activity in the area. Many 2-meter enthusiasts have been drawn into ATV in this manner.

### ATV Repeaters

There are two types of ATV repeaters on the air. Most are in-band machines with input and output in the 70-cm band. The other type of repeater is cross band. The input is in the 70-cm band and the output is in the 23-cm band. Exact frequencies are listed in the *ARRL Repeater Directory*. Cross band has an advantage of full-duplex monitoring of the received repeater video since receive system desense, a normal problem with in-band repeaters, is virtually eliminated. This allows an operator to make picture adjustments without relying on descriptions from other station operators.

Vertical polarization is predominant for repeater antennas because it is much easier to build or purchase commercial high-gain omnidirectional vertical antennas than horizontal types. Also it is easier for communication with mobile units which almost exclusively use vertical whip antennas.

To conserve transmitted signal bandwidth and prevent receiver desense, ATV repeaters use vestigial sideband, which is also used in commercial broadcasting. A filter at the output of the transmitter is used to suppress the lower sideband beyond 1.25 MHz while allowing up to 4.75 MHz on the upper sideband. This creates an ATV signal with 6-MHz bandwidth. Filtering can be accomplished using an interdigital filter of the type described by Fisher, "Interdigital Bandpass Filters for Amateur VHF/UHF Applications," *QST*, March 1968. (A commercially built interdigital filter is available from Spectrum International, model PSF-ATV.) Filtering can also be performed using a group of cavities tuned to provide a flat low-loss response over several megahertz but having very sharp skirts to perform the necessary out-of-band attenuation. (Such a multicavity filter is commercially available from TX-RX Systems Inc., model 19-66-79154-2.)

Amateur TV repeater design is described in more detail in Brown, "The WR4AAG ATV Repeater," *QST*, October 1975, p. 98; also Pasternak/Morris, *The Practical Handbook of Amateur Radio FM and Repeaters*, Tab Books, 1980; and *Everything You Always Wanted To Know About Amateur Television*, QCD Publications.

### Constructing a Basic ATV System

An ATV station can be assembled using four basic circuit boards. (These boards may be purchased built and tested from PC Electronics, 2522 S. Paxson La., Arcadia, CA 91006.) This approach will enable the transmission and reception of full-color television with sound.

Shown in Figs. 9 through 12, all boards run from a common 13.8-V dc, 3 A regulated power source. The complete system can be mounted in a 12 × 8 × 3 inch

chassis. At the builder's option, the receive converter and TR relay can be mounted at the antenna in an outside weatherproof electrical box and controlled from the transmitter location.

Shielded connections between modules are made with the small RG-174 50-ohm coax. At UHF, the center conductor of the coax should not be more than ¼ inch past the shield for all board connections to minimize SWR and radiation. Power and signal connections are made with no. 24 vinyl-covered wire except to the 10-watt power module, which is no. 18.

### RECEIVING PREAMP AND CONVERTER

The converter, shown in Fig. 10, tunes the 420- to 450-MHz band and shifts the received signal to TV Channel 3 (video carrier at 61.25 MHz) or Channel 2 or 4 if Channel 3 is used in your area. Trimmer capacitor, C3, which sets the varactor-diode-controlled oscillator range, sets the received frequency. The lead length from the board to the 10-kΩ frequency-tuning pot is not critical. This allows remote tuning if desired. The board, however, must be in a shielded enclosure to minimize stray pickup of unwanted adjacent TV channels.

A Mini-Circuits Lab SBL-1 doubly balanced mixer module is followed by an 80-MHz low-pass filter to reduce intermodulation from other strong signals. Ahead of the mixer is a low-noise MRF901 or NE64535 preamp stage. The MRF901 has a typical noise figure of 1.7 dB with 15-dB gain, while the NE64535 exhibits a 0.9-dB NF and 18-dB gain.

Coaxial cable with an impedance of 75 ohms is recommended to connect the unit to the TV-set VHF antenna input. Twin lead can act as an antenna bringing in strong adjacent-channel interference.

To align the converter, preset the three trimmer capacitors and the 10-kΩ VCO pot to their center positions. Set the 5-kΩ preamp transistor bias pot for 0.5-volt drop across the 100-Ω collector resistor if the MRF901 is used, or 0.8 volt with the NE64535. Have a nearby ATV station transmit a picture to you or use a signal generator. Use an insulated tuning tool to carefully adjust C3 for best reception of the signal. Watch your TV set as you adjust C3. You may find reception possible in two positions — one on the high side of the local oscillator injection frequency, the other on the low side. You want the low side. To do this, select the position with the most capacity on C3 (plates meshed). Next, fine tune with the 10-kΩ pot for best picture and finally peak C1 and C2.

### TRANSMITTING CIRCUITS

Three circuit boards are used to transmit video and sound at approximately 12-watts PEP output. The exciter/modulator generates 80 milliwatts of AM, which drives a sealed broad-band power module.

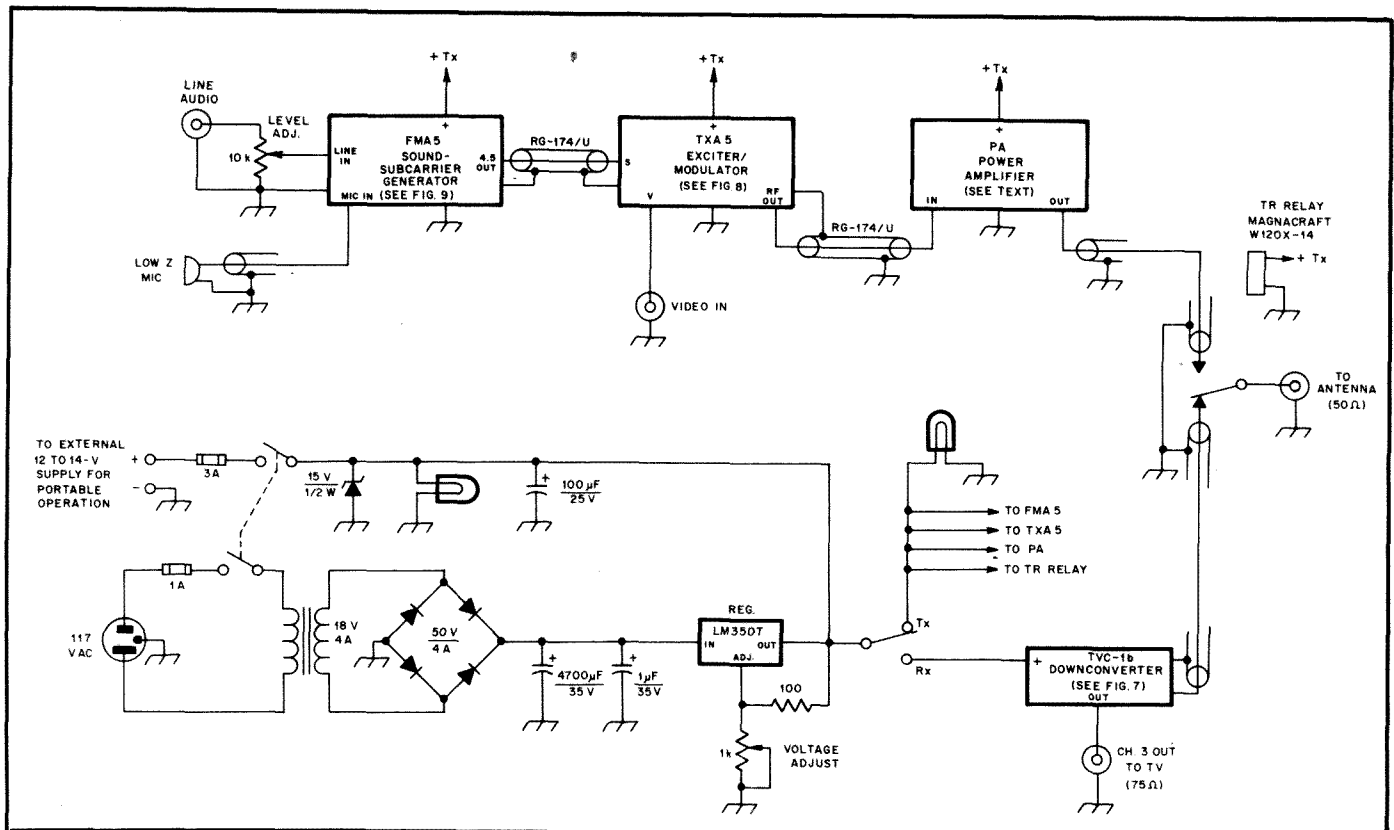

Fig. 9 — ATV system-interconnection and power-supply schematic diagram using circuit board designs described in the text. See also Figs. 10, 11 and 12. The boards are also available fully built from P. C. Electronics. Output from the converter connects to a standard TV set. Video input is from a standard 1-volt peak-to-peak, 75-ohm source such as camera, video tape recorder or computer.

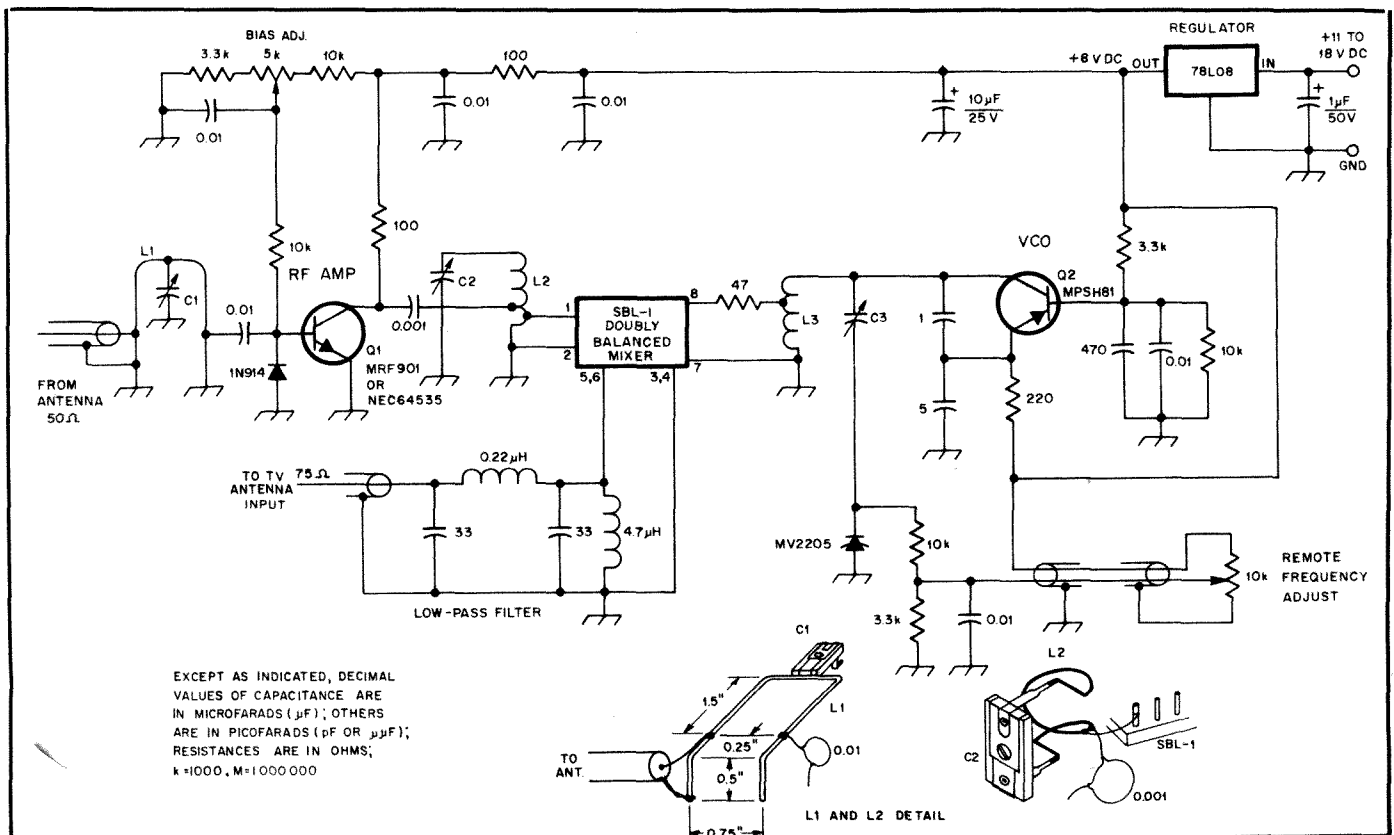

Fig. 10 — The circuit of the ATV receiving converter (TVC-1b) consists of a low-noise, high-gain RF amplifier, a doubly balanced mixer and a varicap-tuned VCO. Remote tuning of the converter permits it to be mounted at the antenna if desired. Variable capacitors are Arco 400, 1-10 pF, or equiv. L1 consists of a horseshoe-shaped loop of no. 18 wire, 4.5-inches long and 0.75 inch wide. Loop ends are soldered to a ground plane; a right-angle bend 0.5 inch from the grounded ends causes the rest of the loop to be parallel to the ground plane. Taps are made 0.75 inch from the ends. L2 consists of 1½ turns of no. 18 wire, 0.375-inch diameter, tapped at 0.5 inch from the lower end. L3 is a hairpin loop, 0.5 inch across the bottom and 0.625 inch high. It is made with no. 18 bus wire.

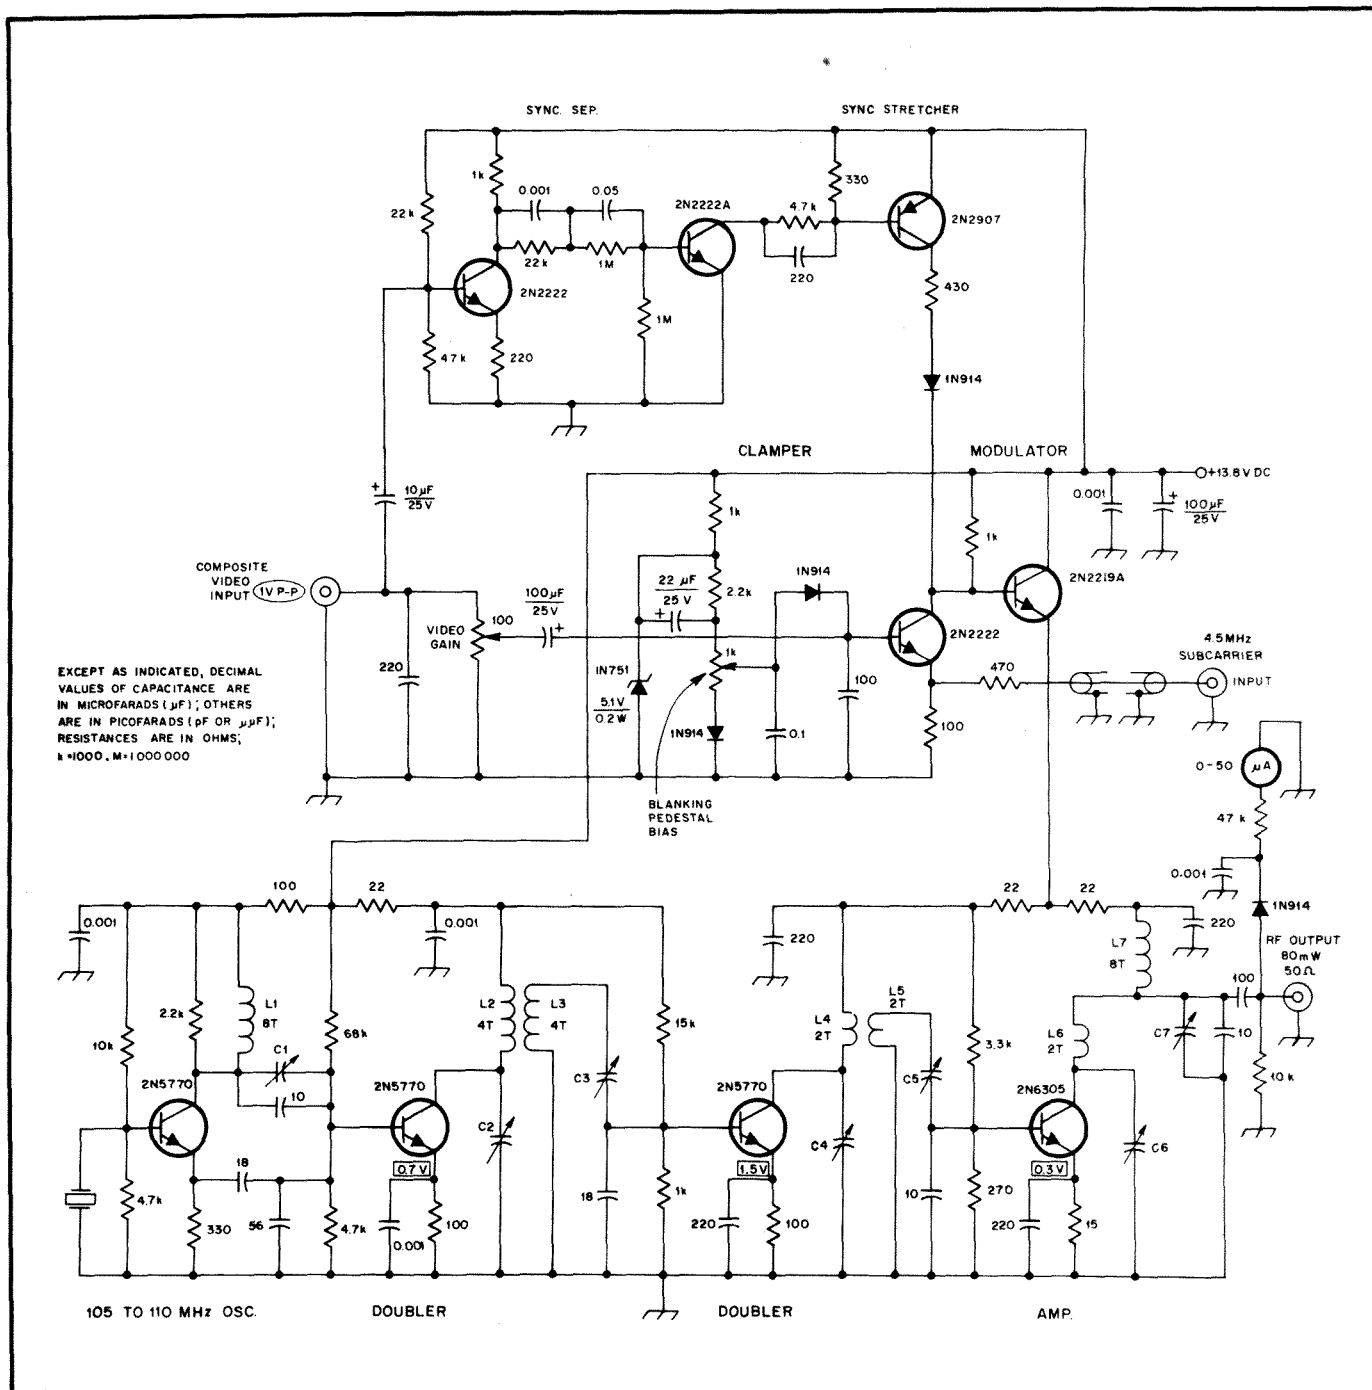

Fig. 11 — Diagram of the ATV exciter (TXA5). Variable capacitors are Arco 400, 1- to 10-pF, or equiv. All coils are wound from no. 24 bus wire, using a 10-24 screw for a winding form. Coupled coil pairs are placed 1/16 inch apart. Each stage is tuned with a voltmeter monitoring and peaking the next stage's emitter voltage. If peaked correctly, the voltages should be at or above those noted at each emitter. The 1-k $\Omega$  blanking pedestal bias pot is backed down to give 75% of the maximum unmodulated RF power output for proper video to sync ratio setup.

Another module generates the 4.5-MHz sound subcarrier.

The exciter/modulator, shown in Fig. 11, contains a fifth overtone crystal oscillator in the 100-MHz range. Following the oscillator are two doublers, the last of which is collector modulated along with the final. The bypass capacitors are chosen to remove 400-MHz energy but not attenuate the video below 8 MHz. This gives high-resolution and color even for 64-character-per-line computer video. The pedestal bias pot controls the blanking clamp level and

sets the proper video-to-sync ratio. A sync stretcher in the modulator circuit is used to compensate for nonlinearities in the final amplifier module. The stretcher circuit pulls the applied voltage on the modulated stages up to almost full  $V_{cc}$  during sync times. This is necessary since the input-vs.-output characteristic curves of UHF transistor amplifiers generally show gain compression in their upper power range. Typically, the last 3-dB increase in power output takes 6 dB of input power increase. Without sync stretching to compensate,

power output would have to be set to less than half the rated capability to maintain sync level and picture stability at the receiver.

The power amplifier consists of an MHW 710-2 or Amprex BGY41B power module with a heat sink and printed-circuit board for the line filtering parts (Fig. 9). Filtering of  $V_{cc}$  at the RF amplifier module under video modulation is critical. The supply impedance must be very low at video frequencies up to 5 MHz where the resistance and inductance of the supply

# Frequency-Modulated Amateur Television (FMTV)

In the previous section, we described the use of amplitude modulation for fast-scan television. Another method just beginning to make inroads into the amateur community is frequency-modulated (fast-scan) television (FMTV). There are performance advantages possible with FMTV.

In the U.S., FMTV is used above 420 MHz, with the majority of activity found in the 1240-1260 MHz segment of the 24-cm band. Despite the additional path losses encountered at these higher frequencies, excellent performance can be achieved because of (1) the overall processing gain advantages afforded by FM; (2) the ability to use relatively compact high-gain antennas; and (3) the availability of interference-free channels.

Frequency-modulated television offers several exciting opportunities for amateurs to experiment with new modulation enhancement techniques, and also motivates fresh exploration into the relatively untouched microwave regions. In this section, the primary focus will be on 24-cm operation; however, the FMTV principles can be readily transferred to the higher-frequency bands.

## History

The concept of transmitting fast-scan television pictures via FM is not exactly new. In fact, the possibilities of using FM for television were suggested as early as 1929.<sup>1</sup> The first quantitative analysis was reported in 1940 and was immediately followed by hardware development focused on using FM to relay commercial broadcast television between cities.<sup>2,3,4</sup> During World War II, the military sponsored research into FMTV and in the late 40s

FCC investigated FMTV for possible application in commercial UHF broadcasting.<sup>5</sup> During the 1950s and 60s research continued into various techniques such as pre-emphasis and de-emphasis, improved limiter and discriminator designs, and extensive investigations into bandwidth requirements. In the late 60s and early 70s interest in FMTV heightened as it became the primary mode for transmitting television through communications satellites and also in terrestrial communication applications for sending pictures from commercial news-gathering remote units back to their TV stations.<sup>6</sup>

In the amateur world, European hams have been at the forefront of FMTV experimentation and equipment development. Virtually all commercially-built amateur FMTV equipment is produced in Europe, with patches of FMTV just beginning to sprout in the United States.

## 24-cm FMTV Transmitters

The two basic techniques for generating a 24-cm FMTV signal are shown in Fig. 13. One method is to use a varactor to triple the amplified signal from a voltage-controlled 416-433 MHz oscillator that has been video modulated. The other approach is to simply amplify the output from a video-modulated 24-cm VCO. In either case, a standard composite video signal provided from a TV camera, video tape machine or computer is processed through a pre-emphasis filter which accentuates the high video frequencies to improve the overall system signal-to-noise ratio. The video signal is then combined with an audio subcarrier signal, typically at 5.8 or

6.0 MHz. With AM FSTV, the audio subcarrier is at 4.5 MHz. Experimentation has shown that a higher subcarrier frequency is required for good FMTV per-

(A)

(B)

Fig. 14 — FMTV transmitter components using a varactor tripler technique. At A, a Wood & Douglas 416-MHz voltage-controlled oscillator (UFM01) is used to drive a 10-W UHF amplifier (70L1N10). At B, a varactor tripler is used to produce approximately 3 W at 24 cm. This technique requires an external audio subcarrier generator and video pre-emphasis circuit. The boards are available fully assembled but require mounting and heat sinking.

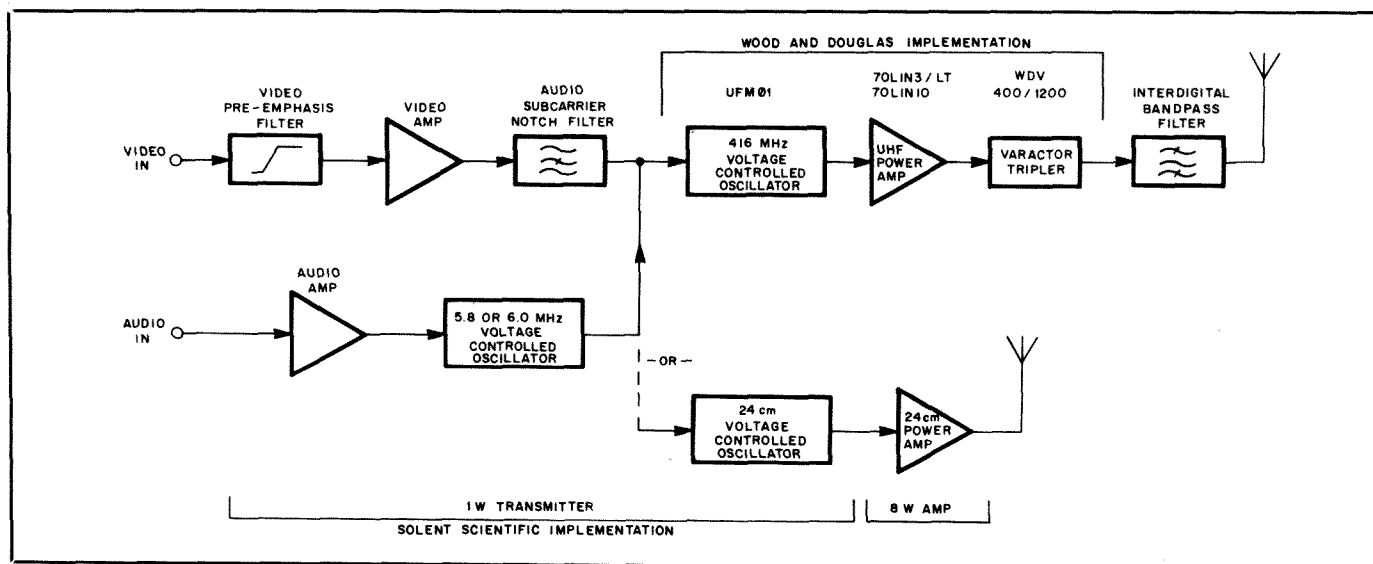

Fig. 13 — Two methods of generating a 24-cm FMTV signal.

Fig. 15 — This 1-W FMTV transmitter kit from Solent Scientific employs a 24-cm VCO and amplifier. The design includes an on-board audio subcarrier generator and video pre-emphasis filter. The output may be amplified to 8 W using an optional power amplifier kit.

Fig. 16 — This experimental 24-cm transmitter from Wood and Douglas uses a phase-locked loop and reference crystal oscillator for precise frequency stability. The unit which produces a 20-mW output, has a built-in audio subcarrier generator but does not use video pre-emphasis.

formance. The audio subcarrier design shown in Fig. 13 can be easily set on 5.8 or 6.0 MHz for this purpose. The amplitude-varying signal, consisting of the FM audio riding the video envelope, controls the frequency of a voltage-controlled oscillator to generate the video FM signal. The signal is amplified (and tripled, if it was originally generated in the lower portion of the 400-MHz band) and then transmitted. Figs. 14, 15 and 16 show FMTV hardware using both transmission techniques.

### 24-cm FMTV Receivers

While a 24-cm FM transmitter is really not much more complicated than an AM transmitter, this is not the case with the receiver. The additional complexity in the receiver design is readily apparent in the block diagram in Fig. 17. For AM FSTV, it was only necessary to employ a converter which could produce a signal in the frequency range that could be tuned by a standard TV set. The TV possessed all of the necessary circuitry to demodulate the video and audio. With FM, much of this circuitry must be provided external to the TV set.

A converter, like the one shown in Fig. 18, is used to translate the signal to an intermediate frequency. Depending on the receiver design, the IF may be anywhere from 45 to 70 MHz. Typically, a phase-locked loop or doubly-balanced mixer is used as a discriminator to demodulate the signal to baseband video where the audio subcarrier is removed and further demodulated to baseband audio. This function is usually contained on an IF/video demodulator board, as shown in Fig. 19. The video portion is de-emphasized (high noise component attenuated) and made available for display on a video

Fig. 18 — This Wood and Douglas 24-cm to VHF converter (1250DC50) is fully built and packaged.

Fig. 19 — This Wood and Douglas video IF board (VIDIF) is used to demodulate the signal at the IF to baseband video. An external subcarrier demodulator and de-emphasis unit is required, and the board requires mounting in a suitable enclosure, as shown.

monitor. A Channel 3 or 4 RF modulator may be used to upconvert the baseband audio and video signals into a format viewable on a standard TV set.

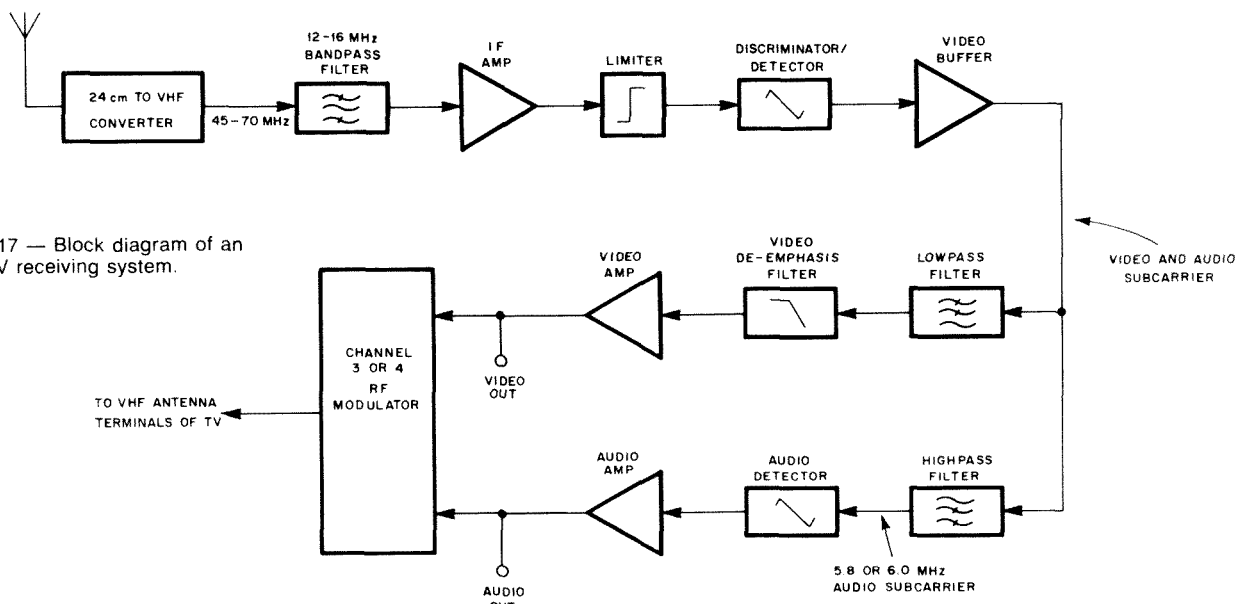

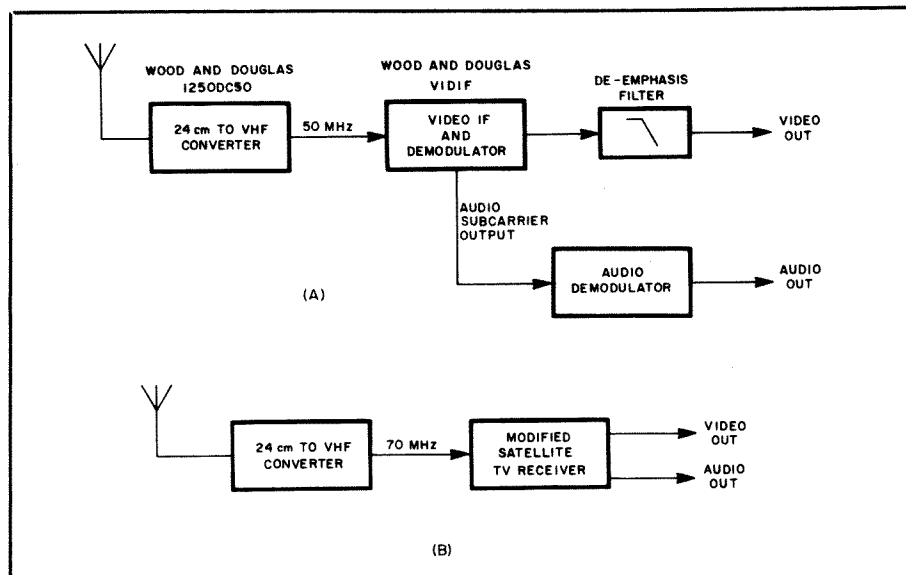

Fig. 17 — Block diagram of an FMTV receiving system.

adapted for amateur use. If the strip is to be used on 24 cm to receive a nominal 4-MHz peak deviation signal, there are two basic modifications that are required. First, the surface acoustic wave (SAW) bandpass filter in the IF, typically exhibiting a 28 MHz bandpass, must be changed to one 12 to 16 MHz wide to better match the lower bandwidth occupied by amateur signals. This will improve sensitivity and reduce interference. Secondly, the overall gain of the discriminator and/or video amplifier circuits must be increased to compensate for the substantially lower amateur deviation levels to maintain the 1 V peak to peak video output needed for driving a standard TV monitor. If the strip is to be used to receive a signal exhibiting an 8-12 MHz deviation, which may be more common with 10-GHz operation, no modification will be required.

Two possible receiver configurations based on commercially-available equipment are shown in Fig. 20. A complete 24-cm FMTV receiver corresponding to the Fig. 20A design is shown in Fig. 21. The schematic for the sound- subcarrier demodulator is shown in Fig. 22 while the circuit for the de-emphasis network will be described later in the text.

It is of interest to note that the operation of the FMTV receiver is almost identical to that used for home satellite TV reception except for the lower microwave carrier frequency and lower FM deviation levels typically used by amateurs operating in the 24-cm band. The 70-MHz satellite TV IF strips that are just beginning to become available on the surplus market can be

### 24-cm Antennas and Transmission Line

Generally, the main requirement for an antenna system is that it must possess sufficient bandwidth to support FMTV. Most commercial and homebrew designs are adequate as long as they are cut for

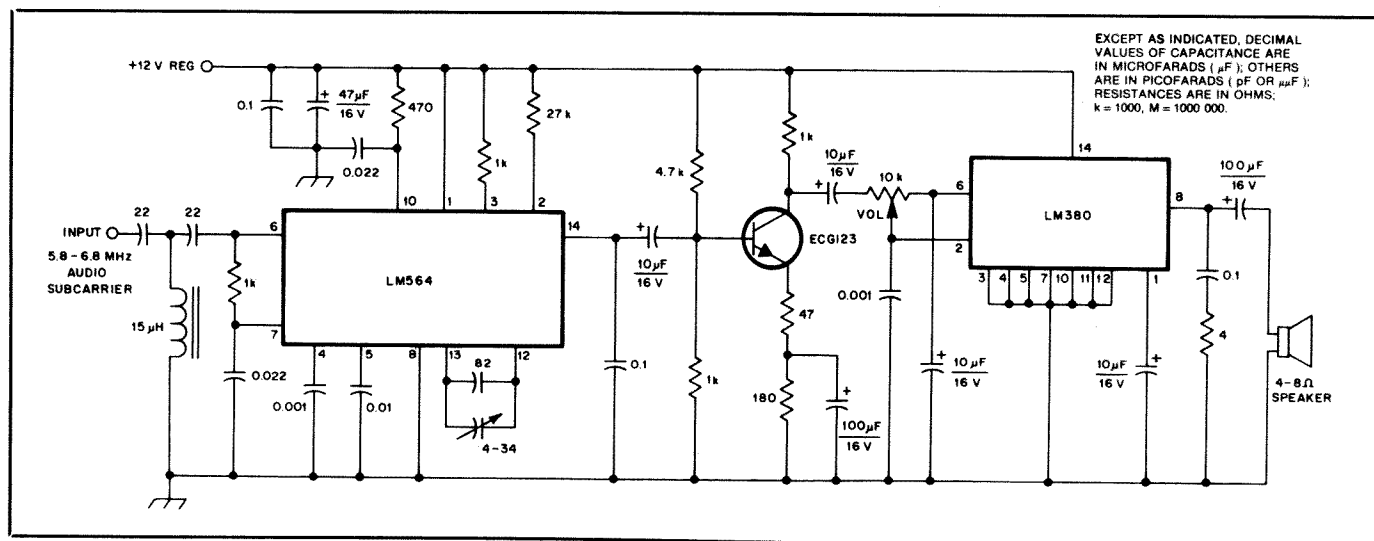

Fig. 22 — Schematic diagram of an audio subcarrier demodulator circuit that converts 5.8-6.8 MHz audio subcarrier to baseband audio.

resonance at the transmit carrier frequency. A very popular antenna for ATV use world-wide is the French-built F9FT or TONNA antenna shown in Fig. 23. It is available built for three different frequencies: 1296, 1269 and 1248 MHz. Another possibility is the loop Yagi described in Chapter 32.

Transmission line losses at 24 cm can be quite formidable. If it is not possible to mount the receiver preamplifier, transmitter power amp or varactor tripler directly at the antenna mast, very low-loss transmission line must be used. For long runs, 7/8-inch Hardline (2.1 dB attenuation per 100 feet for foam dielectric and 1.5 dB/100 feet for air dielectric) should be used. For shorter lengths, 1/2-inch Hardline (3.5 dB attenuation per 100 feet for foam dielectric and 2.9 dB for air) or Belden 9913 (4.6 dB/100 feet) can be used. For very short hookups between equipment in the shack, 1/4-inch foam dielectric, flexible Hardline (7 dB/100 feet) is ideal, but RG-8/-214 (12 dB/100 ft) or RG-58 (22 dB/100 feet) can be used as a more practical, cost-effective alternative.

### Test Equipment

Good low-cost test equipment for 24 cm is generally scarce. One exception is the availability of 24-cm test generators that produce a video-modulated signal in the 10-80 mW range. Fig. 24 shows some commercially available units. These devices are not only invaluable in checking out FMTV receivers, but are also small enough to be built into a camera or installed in model airplanes to provide a compact mobile transmit capability over short ranges. For measuring frequencies in the 24-cm band, the Ramsey PS-10B prescaler has proven to be a highly cost-effective adjunct to a low-frequency counter.

### Comparison of 24-cm FM-ATV with 70-cm FSTV

Given some of the apparent complexities of FM and some of the drawbacks of transmission on frequencies above 1 GHz, why use FMTV rather than stick with the venerable AM FSTV using readily available 70-cm gear? To fully examine the pros and cons of these systems, it is useful to first examine the relative merits of FM versus AM video and then compare 24-versus 70-cm propagation. Finally, we will look at the combined picture.

#### FM versus AM TV

A comparison between these two modulation modes has been the subject of university research and numerous studies in industry and the military. The specific advantages of FM television include:

- Better linearity and greater average transmitted power. Amplifiers can be operated in class-C mode and operated at full power using FM. Thus it is possible to obtain two to three times greater average output from a solid state amplifier oper-

Fig. 23 — The F9FT TONNA antenna is popular worldwide for FMTV work. Versions are available for 1248, 1269 and 1296 MHz.

(A)

(B)

Fig. 24 — 24-cm video test generators are helpful for checking out receivers. The 10-mW transmitter shown at A is fully built and packaged by Solent Scientific. The 80-mW transmitter board from PC Electronics, shown at B, requires an additional video inverter board to obtain the proper transmitted signal polarity.

ating in FM rather than AM. Another advantage is that sync compression, which is a common malady with improperly adjusted AM systems, is not a major problem when communicating with FMTV. These systems are therefore very easy to initially set up and operate.

- Signal-to-noise ratio improvement at demodulator output. With amplitude-modulated systems, the resulting video output signal-to-noise ratio will generally be the same as the receiver input carrier-to-noise ratio. In the case of FM, the video output signal-to-noise ratio will be significantly greater than the input carrier-to-noise ratio. The actual level depends on the input carrier-to-noise ratio being above a

“threshold level,” typically 7-12 dB, and also on the value of the deviation index (the ratio of the peak deviation to the highest modulating frequency). Several studies have specifically examined the gain advantages that FM can provide over AM television.<sup>7-10</sup> Additional studies have examined tradeoffs of various parameters such as bandwidth and deviation to further optimize system performance.<sup>11-16</sup>

- Increased signal-to-noise performance through pre-emphasis and de-emphasis. As is shown in Fig. 6B, the high-frequency components of a video signal are considerably lower in amplitude than the low-frequency components. These higher frequencies, therefore, contribute very little to the overall transmitted bandwidth. Studies and analyses have demonstrated that it is useful to emphasize these higher-frequency components prior to transmission and then de-emphasize them at the receiver to restore the signal to its original composition.<sup>17-20</sup> While performing this de-emphasis, the higher-frequency components of the noise are attenuated, which effectively increases signal-to-noise ratio. (A good discussion of the overall concept of pre-emphasis and de-emphasis can be found in Reference 21.)
- Improved co-channel interference immunity. Studies have clearly demonstrated that FM television is more resistant than AM to a wide variety of interference sources.<sup>22-24</sup>
- Immunity from fading. Because the FM receiver uses hard limiting, any amplitude variations in the received signal caused by flutter normally associated with ATV mobile operations are reduced. This greater immunity from fast fading provides more solidly locked pictures.

Of course, with every set of advantages, you can always expect some disadvantages. The specific disadvantages of FMTV are:

- Equipment complexity. As previously described, the receiving equipment is more complex and expensive than that required to receive AM.
- Greater signal bandwidth. The transmitted signal bandwidth is greater than for vestigial AM FSTV. The microwave frequencies that can accommodate this bandwidth exhibit greater propagation losses.
- Poor weak-signal performance. FMTV performance for very weak signals will be worse than AM because of the FM receiver threshold effect.
- Degradation from multi-path interference. FMTV can be more susceptible to degradation from severe multi-path effects. While an amplitude-modulated TV shows ghosting in the face of multipath, FMTV degradation manifests itself as picture distortion such as a portion of the image appearing like a photographic negative.

#### 70 cm versus 24 cm

- Although path losses are greater on 24 cm than 70 cm, these losses can be somewhat compensated by the fact that higher-gain 24-cm antennas can be constructed for the

same boom length as a 70-cm design.

- Vegetation and buildings tend to attenuate 24 cm more than 70 cm, making 24-cm antenna placement more critical.
- As 70 cm becomes more populated with narrowband voice repeaters that can put fundamentals and intermodulation products in the video receiver passband (degrading picture quality), system performance may become limited by interference more than by receiver noise figure. On the other hand, the amateur microwave frequencies are relatively free of mutual amateur interference sources. The major problem besetting the 23/24-cm amateur allocation is FAA Air Route Surveillance Radars which operate at 4 megawatts ERP and occupy an 8 MHz bandwidth in a variety of locations and center frequencies throughout the country.
- Test equipment for 24 cm is generally expensive. As amateur interest in the microwave regions begins to grow, however, new low-cost equipment should become available.

On balance, then, what does this all mean? In short, the higher path losses of 24 cm can be compensated for through higher-gain antennas, by the inherent system processing gains afforded through the use of FM and by the availability of more interference-free channels. In practical use, given paths that are at or near line-of-sight, and comparing transmitters operating at equal peak power levels, 24-cm FM-ATV will usually equal or outperform 70-cm FSTV. In cases involving large amounts of vegetation, rough terrain or man-made obstacles, or in situations normally involving very weak signal work, the 70-cm FSTV will be better.

### FMTV Operating Parameters

Amateur standards for FMTV using

Fig. 25 — Schematic diagram of a practical 525-line video pre-emphasis network for transmitter input, based on CCIR Recommendation 405-1. The capacitors should be plastic-film or mica for good stability. L1 is 56t no. 30 enam. wire on a T-50-2 core, or a Coilcraft SLOT-10-1-09.

Table 1

### Typical FMTV Amateur Operating Parameters

1. **Signal Polarity:** A black-to-white transition in the video causes an instantaneous increase in transmitted carrier frequency.
  2. **Transmit Pre-emphasis:** In accordance with CCIR Recommendation 405-1 for 525 line systems
  3. **Receiver De-emphasis:** In accordance with CCIR Recommendation 405-1 for 525 line systems
  4. **Deviation:** 4 MHz Peak (8 MHz Peak-to-Peak)
  5. **Sound subcarrier frequency:** 5.8 MHz or 6 MHz
  6. **Sound subcarrier level:** 10 dB below video

525-line systems are beginning to evolve. Table 1 shows typical operating parameters.

The purpose of developing standards is to foster interoperability between stations, to promote operation with equipment exhibiting uniformly good performance, and to aid equipment manufacturers and builders in developing equipment that can best suit the needs of the amateur community. The local nature of microwave operation permits each local amateur group to establish its own operating parameters and standards to best suit local needs. The operating parameters shown in Table 1 represent a typical system. The values were derived based on both amateur experimentation in the U.S. and research into previous industrial and military investigations.

Tradeoffs in performance, bandwidth and cost must be considered when selecting operating parameters. A major goal is to operate with the minimum bandwidth practical for good performance. Minimum bandwidth is desirable not only from the standpoint of spectrum conservation, but also from concern to avoid sideband overlap with the 8-MHz-wide FCC Air Route Surveillance Radars, the 1240-MHz band edge, 1296-MHz DX/EME stations and 1269-MHz satellite uplinks. Careful selection of operating parameters also permits the effective use (with appropriate modifications) of low-cost off-the-shelf FMTV equipment available in Europe and satellite-TV 70-MHz IF receiver strips available in the U.S.

The specific rationale for the parameters in Table 1 is as follows:

- **Signal Polarity:** A "Black-to-White/Low-to-High Frequency" polarity was selected because this is the predominant mode for commercial FMTV satellite systems and amateur FMTV systems used in Europe. No modification to the video polarity of these units is needed.
- **Transmit pre-emphasis and de-emphasis** was selected in accordance with the International Telecommunication Union (ITU) International Radio Consultative Committee (CCIR) Recommendation 405-1. Pre-emphasis and de-emphasis is very inexpensive to implement, yet is a highly effective means of substantially improving the performance of FMTV systems. The circuit shown in Fig. 25, which uses readily-available parts, is a practical and low-cost implementation of the CCIR 405-1 pre-emphasis network suitable for 525-line Amateur Radio FMTV systems. Table 2 shows the countries using a 525-line standard. The performance characteristics of the circuit are shown in Fig. 26. The actual network losses are provided for design guidance; however, it is the relative losses, i.e., curve shape, that primarily affect system performance. The

Fig. 26 — Characteristic response curve for a video pre-emphasis network.

Fig. 27 — Schematic diagram of a 525-line video de-emphasis network for receiver output. The capacitors should be plastic-film or mica for good stability. L1 is 52t no. 30 on a T-44-3 core, or a Coilcraft SLOT-10-1-12.

matching de-emphasis network for use at the receiver is shown in Fig. 27.

• A 4-MHz peak deviation is fairly standard world-wide for terrestrial (non-satellite) FMTV communications.<sup>25</sup> This deviation provides good picture quality at a lower bandwidth and deviation than is used by satellite TV systems. If a smaller deviation was used, the receiver processing gain advantages would rapidly diminish. A greater deviation, although improving system performance, would occupy excessive bandwidth; particularly for the 1240-1300 MHz (23/24-cm) amateur band. For some of the higher microwave regions

where sufficient bandwidth exists, particularly at 3.3 GHz and above, experimentation with greater deviations would be not only practical but highly desirable. Using higher deviation levels would permit the use of unmodified 70-MHz IF strips in the receiver design.

- A sound subcarrier frequency of 5.8 MHz (used by satellites) or 6.0 MHz (used by European FMTV hams) is high enough to avoid interference with the chroma signal yet low enough to minimize total transmit bandwidth.
- The -10 dB sound subcarrier level will allow good audio reception for P3.5 and better pictures. This level is referenced to the video level at the output of the pre-emphasis filter with a 1-V peak-to-peak 762-kHz sine wave applied to the transmitter video input. Increasing the subcarrier level too much can degrade picture quality while setting it too low may prevent the sound from being received under less than P5 conditions.

### Practical FMTV Measurement Techniques

To assist in setting up the FMTV transmit parameters shown in Table 1 using test equipment affordable by amateurs, the following procedures are provided.

#### Transmit Video Deviation

To properly set the deviation of a transmitter using pre-emphasis, attention must be paid to using the proper input test frequency as well as voltage level. The following procedure may be used to establish a 4-MHz peak deviation with a 1 V

Table 3

### Derivation of the Test Voltage Level for the 4 MHz Peak Deviation Adjustment:

For FM signals:

$$\text{modulation index} = \frac{\text{peak deviation}}{\text{modulating frequency}}$$

A Bessel function chart shows the relation between carrier and sideband amplitudes of the modulated signal as a function of the modulation index. At a specified value of the modulation index, the carrier and various sidebands go to zero.<sup>26, 27</sup>

By theory:

$$\text{modulation index} = 2.40 \text{ for first carrier null}$$

At the pre-emphasis crossover frequency of 762 kHz, the peak deviation of the first carrier null will be:

$$2.40 \times 0.762 \text{ MHz} = 1.8288 \text{ MHz}$$

Since the desired transmitter performance is 4 MHz peak deviation with a 1 V peak to peak input and assuming that the transmitter VCO performance is linear such that input voltage is directly proportional to transmit deviation, the results can be scaled:

$$\frac{1 \text{ V}_{P-P}}{4 \text{ MHz}} = \frac{X \text{ V}_{P-P}}{1.8288 \text{ MHz}}$$

cross multiplying:

$$1.8288 = 4X$$

and dividing:

$$\frac{1.8288}{4} = X$$

$$0.457 \text{ V} = X$$

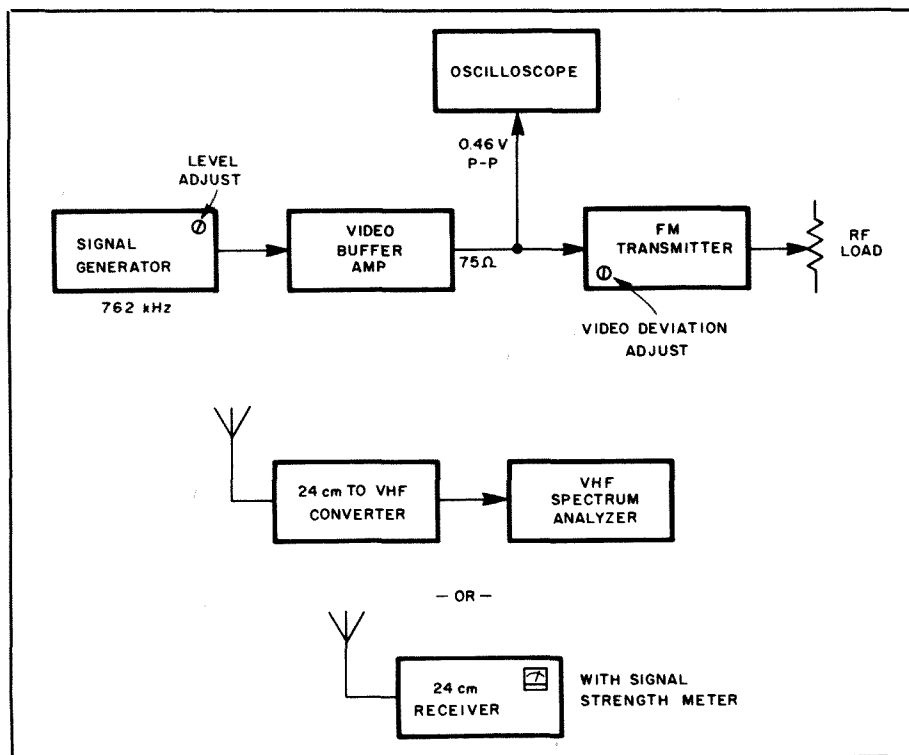

Fig. 28 — Block diagram of the test configuration for setting video deviation.

peak to peak input for transmitters employing CCIR Rec 405-1 525-line pre-emphasis. It is based on the Bessel function null measurement technique and is founded on the theory that the transmitted signal carrier for an FM signal will be nulled when the ratio of the peak deviation to the modulating frequency is equal to 2.40.<sup>26,27</sup>

Step 1 — Set the signal generator to the pre-emphasis crossover frequency of 762 kHz and the level to 0.46 V peak to peak (See Table 3) using the set-up shown in Fig. 28.

Step 2 — Set the spectrum analyzer (or a receiver with a signal strength meter) to monitor the transmitted signal. Use a resolution bandwidth of 200 kHz or less. Starting with the transmit deviation control at the lowest possible level, slowly increase the deviation. The carrier amplitude will increase and rise above the upper and lower sidebands as shown in Fig. 29A.

Step 3 — Eventually the carrier will begin to drop with increasing deviation. Set the deviation control at the point the carrier is lowest (null). See Fig. 29B. The deviation is now properly set for 4-MHz peak. You may note that if you continue increasing the deviation, there will be other settings

Fig. 29 — Spectrum pictures of transmitter output observed on the Science Workshop "Poor Man's Analyzer" while adjusting transmitter deviation. As the deviation is first increased, the carrier and sideband levels will increase in amplitude, as shown at A; just before the desired deviation is reached, however, the carrier level will begin to drop. At the proper deviation level, the carrier will be nulled, as shown at B.

that will also achieve a null. The setting that is desired is the one with the lowest deviation; i.e., the first null.

Step 4 — To set up additional transmitters with the properly adjusted unit, send a test signal with the calibrated transmitter and then note the resulting peak-to-peak-amplitude output on a receiver. For

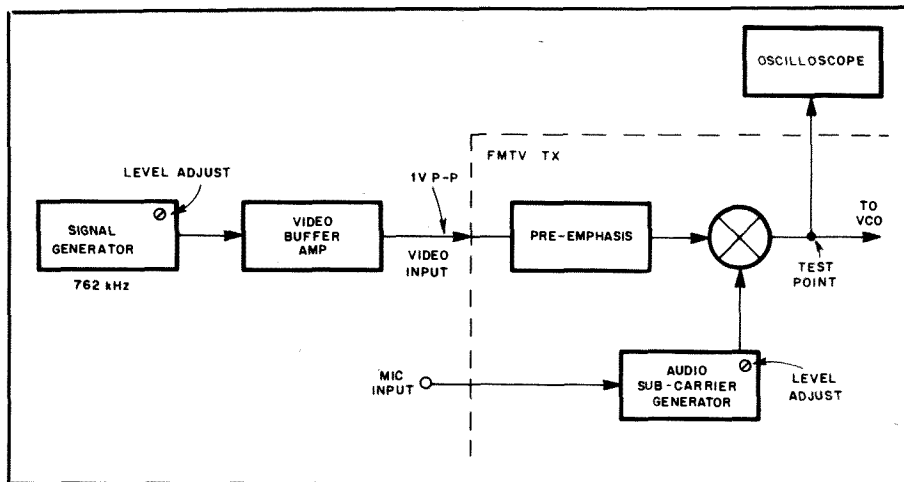

Fig. 30 — A block diagram of the test configuration for measuring audio-subcarrier level relative to the video level.

another transmitter, deviation can be rapidly set by adjusting its deviation control to produce the same receiver output levels.

When transmitting a normal camera-produced picture, if the transmitter deviation exceeds the dynamic range of the receiver demodulator, you will note the presence of undesirable "sparklies" on the screen. These are shimmering black spots which appear in the white areas of the scene. If the receiving station cannot eliminate the sparklies through careful tuning, it may be necessary for the transmitting station to slightly reduce deviation.

#### Transmit Audio Level

The test set-up for measuring the audio subcarrier level with reference to the video level is shown in Fig. 30.

Step 1 — With the audio subcarrier turned off, apply a 1-V peak-to-peak 762-kHz signal at the video input to the transmitter's pre-emphasis filter. Measure the resulting peak-to-peak voltage level at the test point where the video and audio are summed, typically at the output of the pre-emphasis filter. This establishes the video reference level.

Step 2 — Turn off the signal generator and activate the audio subcarrier generator. Measure the peak-to-peak voltage level.

Step 3 — Divide the audio subcarrier level by the video reference level. This will yield the relative audio subcarrier level. An audio level 10 dB down from video will correspond to a voltage ratio of 0.32.

## Slow-Scan Television

Slow-scan television (SSTV) started in 1958 as the effort of a small band of Amateur Radio operators led by Cophorne Macdonald, VE1BFL. The intention of the project was to send television pictures on the HF amateur bands. By virtue of HF radio design and propagation characteristics, the SSTV system design is tailored to allow operation in a 3-kHz bandwidth — considerably less than the 6-MHz width of a commercial TV channel.

To meet the objective, bandwidth was decreased by reducing the information rate. Instead of 30 pictures a second, SSTV takes 8 seconds to send one picture. Instead of 525 lines, an SSTV picture is composed of 120 lines. The video is sent as a frequency-modulated subcarrier, which varies between 1500 Hz for black elements and 2300 Hz for white elements. Vertical and horizontal synchronizing signals are sent as bursts of 1200-Hz tones. Table 5 summarizes the SSTV standards for black-and-white TV operation.

In the early years of SSTV, the picture was displayed on surplus P7 radar tubes that could hold a slowly decaying picture for about 8 seconds when viewed in a darkened room. Special shuttered vidicons or flying spot scanners were used as the video sources. By 1974, several amateurs had built digital scan converters that permitted viewing a nondecaying picture in full daylight. The digital scan converter was designed so that the SSTV image could be stored in solid-state memory, and displayed on an unmodified black-and-white TV set. Fig. 31 shows an example of SSTV picture

**Table 5**  
**SSTV Standards**

Frame Time	8 seconds
Lines per frame	120
Duration of line	67 ms
Duration of V sync	30 ms
Duration of H sync	5 ms
H or V sync frequency	1200 Hz
Black frequency	1500 Hz
White frequency	2300 Hz

quality using this technique. The converter also can be used to change the video output from a fast-scan camera into an SSTV-compatible signal. Thus, the scan converter is an interface between the slow-scan TV and fast-scan TV formats. A few years later, several commercial companies began producing these rather complex converters for amateur SSTV use.

### Station Operation

As shown in Fig. 32, a typical SSTV station uses a standard transceiver, scan converter, TV camera and TV set. The TV receiver can be used for monitoring both the received signal and image to be transmitted.

Reception of SSTV is quite simple. The SSB voice of the transmitting amateur is tuned in so it sounds "natural." When the SSTV transmission begins, the signal should be in tune. The picture can be improved by using a transceiver that has passband tuning. Under ideal conditions the audio highs can be boosted to give some-

Fig. 31 — SSTV picture as seen on a standard TV set using digital scan converter.

what higher resolution. When poorer conditions exist, the passband can be tuned to minimize interference.

A General class or higher license is required to operate SSTV. It can be used on every band. The most popular frequency band is 20 meters, especially on 14.230 MHz, where an SSTV net meets each Saturday afternoon. Operators on the lower HF bands often experience poor quality because of multipath distortion, while the VHF and UHF bands limit the operational range.

### Scan-Converter Design

The scan converter plays an integral part in both receiving and transmitting SSTV. The heart of the SSTV scan converter is the memory system. Most present systems use dynamic RAM ICs that contain enough bits

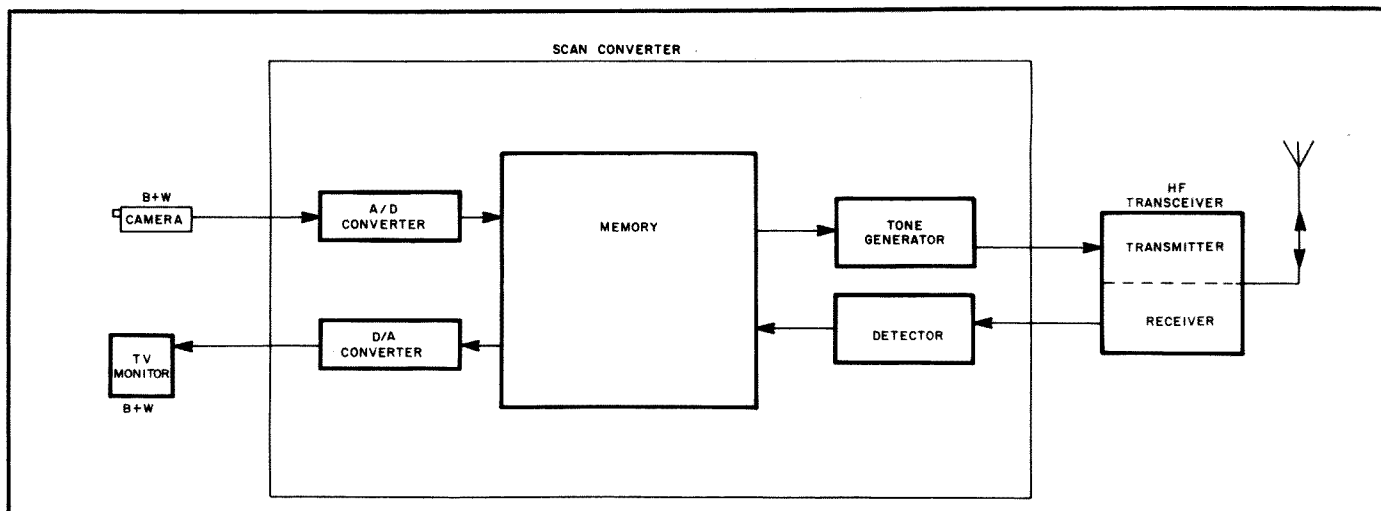

Fig. 32 — Basic SSTV station.

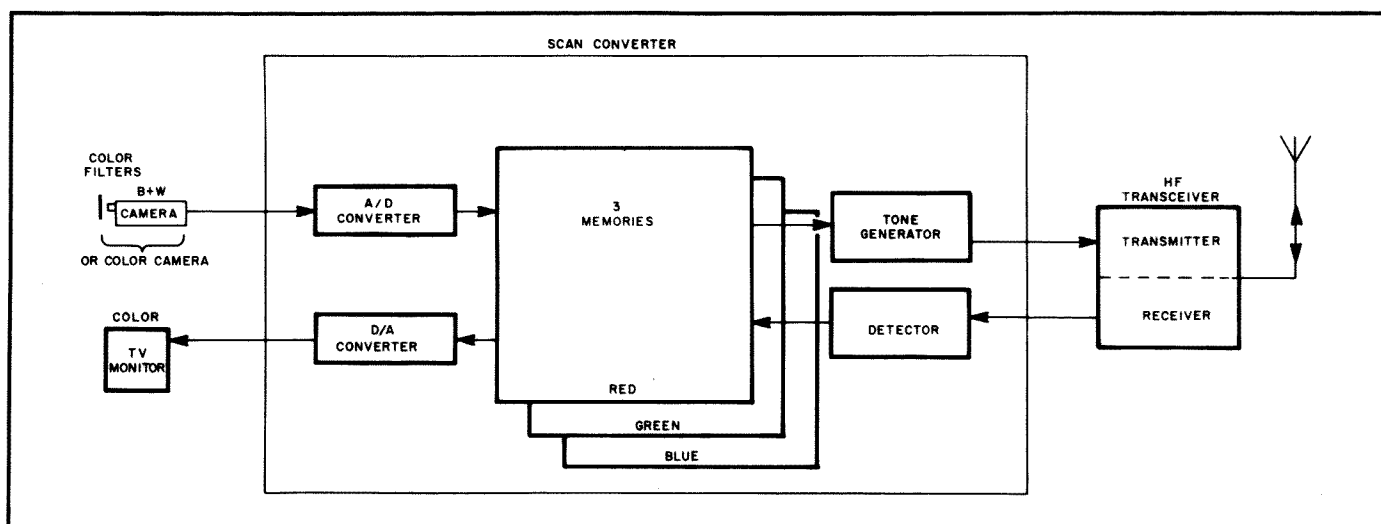

Fig. 33 — Color SSTV station.

to adequately resolve the picture elements and their gray scales. Sixty-five thousand bits (65 kbits) is the minimum considered acceptable for a single black-and-white picture.

#### Receiving

The converter has input detection circuitry to translate the SSTV audio-frequency variations from the receiver audio output into digital pulses. These contain horizontal and vertical synchronization as well as binary values representing the gray scales being sent. The pulses are stored in memory. The information is then sent to a digital-to-analog converter, which converts the stored data into an analog video signal fully compatible with a standard TV monitor to produce a nondecaying image.

#### Transmitting

Output from a black-and-white TV camera is converted into horizontal and vertical pulses along with digitized gray-scale values. The image is "snapped" in

1/60 of a second from the TV camera. The information is stored in memory. The digital output from memory goes to circuitry that produces the audio-frequency-modulated signal conforming to the SSTV standards. This SSTV output is then fed to the microphone input of the transceiver. Since the SSTV FM audio signal to the transmitter is continuous, the transceiver/linear amplifier RF power should be reduced to safe dissipation levels under this high-duty cycle operation.

#### Color SSTV

SSTVers have been experimenting with color since before the advent of the scan converters. In the initial experiments, red, green and blue filters were placed in front of the black and white TV camera and the face of the P7 monitor. The output of the filtered P7 monitor was captured on a color Polaroid® camera. The transmitting station sent a set of three 8-second SSTV frames that were received and recorded on film as a color picture, presuming the critical

photographic camera alignment was not disturbed.

The scan converter offers a vast improvement over that interesting, but error-prone, technique for color SSTV. If two more memories are added to the black and white scan converter (195 kbits total), as shown in Fig. 33, each memory can be dedicated to a color. A black and white camera with a Red no. 25 filter, a Green no. 58 filter and a Blue no. 47B filter successively placed in front of the lens then sends one or more SSTV frames of each color. (A color TV camera is often used — that avoids the filter changing, but generally at a higher cost!) The receiving SSTV station switches the output of the SSTV detector to load the appropriate "color" memory. This is referred to as multiframe color SSTV. The outputs of the three color memories are translated from their digital gray-scale values into analog voltage levels capable of directly driving the gun drivers of a color TV monitor. Other designs translate the digital gray-scale values into composite-

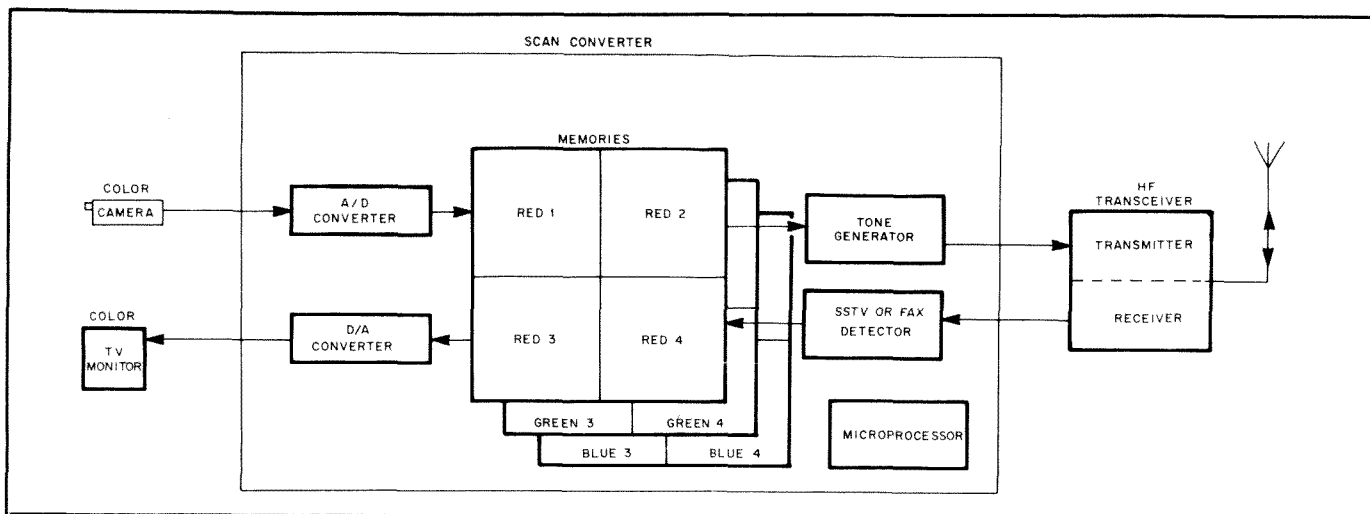

Fig. 34 — Color SSTV station capable of storing multiple images.

Fig. 35 — Microprocessor-based color SSTV station of W0LMD.

video levels and sends them to a conventional color TV set. The composite TV method simplifies the cabling and avoids TV set modification, at the cost of reduced bandwidth and resolution.

### Recent Developments

Since the advent of the microprocessor, and because of the interest in more applications of the SSTV scan converters, systems are continuing to evolve in complexity and capability.

#### Multiple Image Storage

Since memories are continually getting larger and cheaper, present scan converters are being designed to hold four or more color pictures simultaneously (Fig. 34). This means a good received picture stored in a single memory does not have to be

destroyed to make way for a new picture. If memories with 256 kbit capacity are used, the whole scan-converter memory can be built from three ICs. (A similar design 10 years ago would have required 768 of the 1-kbit memories used at that time.)

#### Increasing Resolution

The large array of memory opens up several design possibilities. The memory can be used for double vertical and double horizontal resolution if a single high-resolution picture for reception of schematics or weather satellite images is required.

#### Improved Color SSTV

In color SSTV applications, a microprocessor can be used to assign automatically the incoming SSTV color frame

(A)

(B)

Fig. 36 — Noise caused by adjacent-channel interference is shown at A. Picture improvement when noise is removed by digital noise clipping is shown at B.

to the correct memory. The microprocessor also opens the way for even better transmission schemes such as sending all of the color information required for each line before the next line is sent. This results in a single-frame color SSTV system. Several techniques have been proposed for transmitting the color information. One system is described in "8 and 12 Second Single-Frame Color SSTV," *A5 Magazine*, November 1982, p. 32; another is described

in "Robot Model 450-C Composite Single Frame Color Specification," *A5 Magazine*, February 1984, p. 28. A major objective is to maintain compatibility with existing black and white SSTV systems.

#### *FAX Compatibility*

FAX and weather satellite images can be seen on an SSTV scan converter if a format translator is attached to the input of the scan converter. Facsimile and weather satellite pictures typically use over 1000 picture elements per line and over 1000 lines per picture. Since even high-resolution SSTV converters only have  $256 \times 256$  resolution, the full quality of facsimile cannot be achieved. Nevertheless, the quality will be adequate for most experimenters.

#### *Image Processing*

The microprocessor may also be utilized for digital image processing to remove transmission noise from received pictures, and to boost the contrast of weak pictures. Since SSTV is much slower in data rate than conventional fast-scan ATV, the microprocessor has a chance to operate on the received images without resorting to very expensive high-speed digital signal-processing hardware. A highly sophisticated microprocessor-controlled color SSTV station is shown in Fig. 35.

A picture is often distorted significantly when it arrives at the receive station after HF transmission. A picture may have "buckshot noise" from adjacent-signal interference, as shown in Fig. 36A. A digital signal-processing algorithm known as a threshold noise clipper may be utilized to reduce the visibility of the noise interference. This algorithm compares the gray-scale value of each picture element (pixel) with the eight picture elements surrounding it. If the gray-scale value is significantly different from the average of the eight neighbors, then the average gray-scale value of the eight neighbors is taken instead of the original value of the center pixel. The restored picture is shown in Fig. 36B.

Another example of digital image processing is with SSTV pictures received with weak contrast as shown in Fig. 37A. This

means that the picture did not go either completely black or completely white. Often the problem is also compounded by marginal-signal conditions that inject considerable noise into the already weak picture. The restored picture in Fig. 37B shows what can be expected after a digital contrast-enhancing algorithm is used. The algorithm first derives a histogram of all the shades of gray that it finds in the received picture. Then it calculates the gray shade that represents the 10% point of the blackest picture elements, and the gray shade that represents the 10% point of all the white picture elements. Next a look-up table of expanded gray-scale values is made so that the weak shades are expanded linearly to full black and white. The microprocessor now modifies each picture element according to the expanded gray-scale values. While the effect is impressive on black-and-white pictures, it is very spectacular on color SSTV pictures. The microprocessor can also be used to electronically title an SSTV picture, as shown in the figures.

#### **Future SSTV**

The design of the scan converters is continuing to evolve. Now that image-processing techniques are becoming available in commercial SSTV scan converters, the next step will be scan-converter systems that are multitasking. This means that the scan converter can be simultaneously processing one picture, receiving a new picture and retrieving a picture from hard-disk memory for later transmission. A split-screen image could monitor all activities or concentrate on any one of them.

Another area of development will be simultaneous voice and video. This will involve sending the SSTV image during intervals of silence in the operator's voice transmission.

Standard digital silence-detecting algorithms can produce the effect of a perfect voice-control system, and instantaneously select voice or video modes along with a mode-change header.

Several amateurs in Australia and New Zealand have been experimenting with low-resolution, narrow-bandwidth motion

Fig. 37 — Weak-contrast picture (A) and the same picture after digital contrast enhancement (B).

systems. These systems are designed to operate in voice grade bandwidth, making them applicable for long-distance HF transmission. Techniques such as these may permit the visual transmission of sign language images by Amateur Radio operators with speech or hearing difficulties.

SSTV today represents a wide open field for the new breed of experimenter. Today's SSTV systems involve microprocessors and software development. For those wanting to experiment with uncharted fields, the digital imaging possibilities within SSTV offer a tremendous challenge.

## **Facsimile**

The earliest operational system for image transmission, facsimile or FAX networks date back to the late 20s and early 30s. Like any other imaging system, FAX compromises in some areas to gain advantages in others. Conventional fast-scan TV is capable of handling moving images of moderate resolution, but the rapid image repetition rate requires several megahertz of signal bandwidth, which confines it to the UHF range. SSTV sacrifices resolution

and motion to transmit relatively low resolution images in an 8-second frame within the bandwidth constraints of conventional SSB transceivers. The more advanced SSTV formats have resolution capabilities approaching fast scan but, given bandwidth restrictions, this is achieved by lengthening the transmission time for still frames to 17 or 34 seconds.

By comparison, FAX represents a high-resolution service with pictures ranging

from 800 to several thousand lines per frame. This high resolution is achieved within the constraints of audio bandwidths by using relatively long transmission times ranging from 3.3 to 15 minutes.

FAX is used widely in a number of services. Weather chart distribution is perhaps the most common, using both HF and landline links to weather service and forecast centers throughout the world. News photographs, sometimes called

"wirephotos," are also distributed throughout the world in a similar manner. A wide variety of weather satellites transmit cloud-cover pictures back to earth using FAX. Various systems are becoming increasingly common in business offices and law-enforcement agencies to facilitate the transfer of documents, signatures, fingerprints and photographs.

Amateur FAX work has been limited, primarily because of historical regulatory factors. During the post-WW II years, the 11-meter band was the only amateur HF assignment authorized for FAX operation. The subsequent loss of 11 meters left the amateur fraternity with no regular FAX operating privileges on HF. It was only with the recent authorization of FAX on all amateur bands that interest has been renewed.

### Image Transmission

A typical FAX transmitter consists of a drum driven by a synchronous motor operating from a crystal or tuning-fork frequency standard. The material to be transmitted is wrapped around the drum, which rotates at a constant speed. A small spot of light is focused on the printed material (photo, text, map, etc.), and the light reflected from the subject is picked up by a photocell, photomultiplier or phototransistor. The rotation of the drum provides the equivalent of the "horizontal scanning" of the material. A carriage, supporting the light source and pickup assembly, is moved along the drum at a constant rate providing the "vertical scanning." The carriage is usually operated by a threaded rod driven by another synchronous motor. As the carriage travels from one end of the drum to the other, the entire picture area is scanned. The voltage variations from the light pickup are amplified and used to modulate an audio subcarrier, using either amplitude or frequency modulation. For positive AM, the modulation is proportional to brightness, which typically ranges from 4% for black through 90 to 100% for white. Negative modulation reverses this relationship with minimum modulation level corresponding to white, and maximum to black.

Amplitude-modulated-subcarrier systems are typically used with VHF and microwave FM links (weather satellites using positive modulation) or weather chart and photo transmission via landline (typically negative modulation). FM-subcarrier operation uses the voltage variations from the light pickup to shift the subcarrier frequency. Black material results in a 1500 Hz frequency, rising in linear fashion to 2300 Hz for white. The FM format is used with all FAX systems that operate on HF, reducing problems caused by the fading that is inevitable on any long-distance short-wave transmission circuit.

### Image Display

The options for image display are far

more varied than those for transmission. The device that displays the picture is known as the "recorder" and is found in a wide variety of configurations. Drum-type recorders hold a single sheet of the recording medium on a drum that is quite similar to that used in the transmitter. By contrast, continuous-feed FAX recorders are designed to display pictures using material fed from a roll. Such recorders do not require that material be reloaded for each picture but are typically more complex than drum-type recorders.

Facsimile recorders also differ widely in the nature of the recording medium. Photographic systems use film or photographic paper that is exposed by a modulated-light source and lens. Such systems require a darkroom and photographic-processing chemicals and are not well suited for high-volume use. The most advanced photographic systems use a dry silver paper and modulated laser light source. These are usually continuous read-out machines in which the paper is heat processed prior to emerging from the recorder. Such systems provide superb image quality and are convenient to use. However, they are very expensive to purchase new and are not yet available on the surplus market.

Weather chart recorders are typically of the continuous-feed type and employ a damp, chemically treated paper that is "exposed" using an electrolytic process that creates a dark line when current is passed through the paper. These systems are ideal for maps and charts and can provide a reasonable gray scale for continuous-tone images.

Another medium is electrosensitive paper in which printing is accomplished by applying a high voltage to a printing wire or stylus. The paper is dry and has a black base layer with a white coating. The applied voltage will cause varying amounts of the surface material to be burned away, thus creating a trace that can be varied from white (no coating removed) to black (all the coating burned away). With the proper choice of paper and printing electronics a fine gray scale can be obtained with images approaching photographic quality.

Yet another recording medium involves the use of a combination of carbon and white paper with the printing electronics driving a mechanical system that exerts varying pressure on the carbon to produce a trace on the white paper beneath. The image quality is marginal, not to mention all of the wasted carbon paper that is discarded. Long-term availability of the specialized paper may also be a problem.

### Standards

The essential standards for a FAX unit are defined by three parameters: drum speed (helix speed in the case of continuous read-out recorders), carriage or paper feed rate, and modulation characteristics. To be suitable for use in a given class of service,

a piece of equipment must match the characteristics of the service.

### Drum Speed

Drum speed is expressed in terms of revolutions per minute (r/min) which is equivalent to the scanning line frequency (line/min). Several "standard" speeds may be found in surplus commercial equipment with some units having multiple speed options:

- 60 line/min — standard speed for old wirephoto and chart recorders. Few modern services use this line rate and it is unsuitable for amateur use because of the extended periods required for image transmission with standard frame rates.

- 100 line/min — This speed was used for a considerable period with various wirephoto services and some machines still on the surplus market. Not used by current services so conversion to 120 or 240 line/min would be required.

- 120 line/min — Standard speed for HF and landline weather charts, some wirephoto services and weather satellite use. This line rate is marginal for amateur use since transmission times will range from 7 to 15 minutes depending on the other system specifications.

- 180 line/min — Used by some office FAX systems such as the Xerox Model 400. It is acceptable for point-to-point links on VHF but for general HF use, weather charts and satellite reception, conversion to 120 or 240 line/min will be required.

- 240 line/min — Standard for weather satellite use and used by more modern wirephoto and chart transmissions. This is a good rate for amateur HF use since detailed pictures (800 lines) can be transmitted in as little as 3.3 minutes.

Other speeds can be found in specialized gear, and all will require conversion to either 120 or 240 line/min to be useful for amateur work.

### Scanning Density

Scanning density is usually expressed by the number of lines per inch (line/in). There are two different ways in which the scanning density can be used.

The first case is where the frame-time parameters of a signal format are known and you wish to obtain the appropriate scanning density for proper image display. An example might be the WEFAX weather satellite format in which the image has a 1:1 aspect ratio (square), a line rate of 240 line/min, and a frame time of 200 seconds, producing an 800-line image (4 lines/s  $\times$  200 seconds). Obviously the recorder should have a 240-r/min drum speed, but in choosing a recorder the proper scanning density must be determined. To compute the required scanning density, you need to know the width of the image format on the recorder. If you have some sample printouts, you can simply measure the width. In the case of a drum-type system, the width can be approximated by the

relationship:

$$L = 3.14 D$$

where

L = length of the scanning line (width)  
D = drum diameter

Since domestic recorders are calibrated in terms of lines/inch, your measurements should be in inches or converted to inches from the metric equivalents. In the case of a continuous readout system, the image width is usually slightly less than the width of the paper.

Another parameter is the aspect ratio of the image format (ratio of image width to image height). For the WEFAX example, the aspect ratio (A) is 1:1 or simply 1. The required scanning density can be computed from:

$$F = (tR)/(L/A)$$

where

F = scanning density in line/in  
t = frame time in minutes  
R = scanning line frequency in line/min  
L = length of scanning line in inches  
A = aspect ratio

In the case of our WEFAX example, the scanning density for an 11-inch recorder is:

$$F = (3.33 \times 240)/(11/1) = 800/11 = 72.7$$

The scanning line frequency is not a particularly critical factor. If the value is within 10% of nominal, the distortion in the aspect ratio will not be noticeable. In the case of 240-line/min recorders, a scanning density of 75 line/in is commonly available and will produce an essentially perfect picture. Many recorders to find their way onto the surplus market recently use 96 line/in. This rate will compress the image vertically — i.e., it will not be as tall as it is wide — but the picture is acceptable.

A second use for the scanning density is the computation of the transmission time using a specific format or the computation of the line/in requirement when using a recorder with a different image width. As an example, we might consider computing the transmission time for a 19-inch weather chart recorder operating with a scanning frequency of 120 r/min and a 96-line/in scanning density, which is standard for weather chart service. Since width (19 in) and scanning density (96 line/in) are given and if we specify the aspect ratio of the image (A), we can compute the transmission/reception time (t) in minutes by rearranging the previous equation as:

$$t = ((L/A) F)/R$$

where

t = transmission or reception time in minutes  
L = length of scanning line (width) in inches  
A = aspect ratio  
F = scanning density in line/min  
R = scanning line frequency in r/min

If the image is square (A = 1), then the

time can be computed from:

$$t = ((19/1) \times 96)/120 = (19 \times 96)/240 \\ = 1824/240 = 7.6 \text{ minutes}$$

If A is greater than 1 (width > height), the transmission time will be reduced. Likewise if A is less than 1 (width < height), the transmission time will be increased.

If we know the drum speed and scanning density specifications for a specific format for one recorder, we can readily compute the required scanning density (line/in) setting for other recorders. In the previous case, we noted that 96 line/in is the standard setting for 120-r/min weather charts using a 19-inch recorder. The scanning density for other recorder widths can be calculated as follows:

$$F' = (FL)/L'$$

where

F' = unknown scanning density in line/in  
F = reference scanning density in line/in  
L = reference line width  
L' = line width of new format

If we had access to an 11-inch recorder and wished to copy 120-r/min weather charts (F = 96 and L = 19), the required scanning density can be computed as follows:

$$F' = (96 \times 19)/11 = 1824/11 = 165.8$$

If you were to check the specification of the 11-inch recorder, you would find a 166-line/in scanning density switch setting. That should work fine!

### Modulation Format

The various modulation formats have already been briefly discussed. Chart recorders designed for landline use will usually have negative amplitude modulation. Weather satellite systems require positive amplitude modulation, while HF systems use FM subcarrier modulation. Some units will have several switch-selectable modulation formats. Ideally, a recorder should have complete selection for AM, FM, and positive and negative formats.

### Surplus Equipment

Surplus commercial equipment is an excellent way to acquire FAX hardware since the systems are well constructed (often to MIL specs), and the cost is low. The ideal unit will have multiple drum speeds, scanning densities and demodulation formats. In practice, some conversion will probably be needed. Before you consider conversion, factors such as documentation, circuit type and media should be considered. The modification process will require information about motor drive frequencies, control signals, circuit configurations, etc. A good technical manual containing schematics is a must! Unless you are going to use the system only for the mechanics (with a complete replacement of the electronics), you should not consider a unit for which a manual is unobtainable.

The nature of the electronic circuits is another important factor. Tube-type units are typical surplus items because they have been phased out of service in favor of solid-state equipment. Although the price may look appealing, consider carefully the present cost and availability of replacement tubes. You should not necessarily reject a tube system, but you can expect to do some circuit replacement as tubes become either too expensive or unavailable.

Finally, check out the recording medium. Electrolytic and electrostatic papers of various sorts will be around for quite some time, but some specialized media such as carbon-paper systems may be in short supply in the near future.

Given that a specific surplus unit is deemed suitable in most ways, the three primary conversion concerns are likely to be the drum speed, scanning density and modulation formats. Each of these will now be discussed.

### Drum Speed Changes

Virtually all FAX systems on the surplus market use synchronous motors for control of the drum speed. These motors are ac units that require a specific drive frequency to operate at their rated output speed. Typically, a highly stable reference signal will be derived from a crystal standard or an electrical tuning fork. This signal is amplified in a class-A or -B amplifier to a voltage and power level sufficient to operate the motor. The actual motor speed is usually quite high (several thousand r/min) with internal or external gearing used to achieve the desired drum speed. Major speed changes (such as doubling or halving the drum speed) are usually best accomplished by changing gears. Often the manufacturer has or had such gear sets available. If they can be located, conversion is simple. Occasionally, standard instrument gear sets can be made to fit in the space available.

Less drastic changes in drum speed can often be accomplished by changing the reference or drive frequency to the motor. The relationship of the original drive frequency and the new drive frequency is as follows:

$$f' = (fR')/R$$

where

f' = new drive or frequency  
f = original drive frequency  
R' = new drum speed  
R = original drum speed

For example, the vintage D-611-P wire-photo recorder operates at 100 line/min with a drive frequency of 1000 Hz. The new drive frequency that will cause the motor to operate at 120 line/min is:

$$f' = (1000 \times 120)/100 = 120,000/100 \\ = 1200 \text{ Hz}$$

The motor amplifier can be driven by a 1200-Hz signal. That signal can be derived from a 1.2-MHz oscillator with the output

divided by 1000. The motor will operate the drum at the proper 120-line/min rate.

Another example is the Xerox 400 TELECOPIER. This unit has a drum speed of 180 line/min derived from a 368.64-Hz crystal standard. The drive frequency to operate this recorder at 240 r/min is:

$$f' = (368.64 \times 240)/180 = 884,736/180 = 491.52 \text{ kHz}$$

Simply substituting a 491.52-kHz crystal for the original will complete the conversion.

Office FAX machines such as the Xerox 400 use square-wave-driven motors. Most systems, though, like the D-611-P, use true synchronous motors that employ one or more capacitors. The capacitors serve to resonate the motor inductance at the drive frequency. Any significant change in the drive frequency will require a change in the motor capacitor(s). The new capacitor value can be determined if the original capacitor value, original drive frequency and new drive frequency are known:

$$C' = C (f/f')^2$$

where

- $C'$  = new capacitor value
- $C$  = original capacitor value
- $f$  = original drive frequency
- $f'$  = new drive frequency

As an example, the Muirhead K-550 wirephoto recorder normally operates at 100 r/min with 50-Hz motor drive. From our earlier examples, you could compute the value for the new drive frequency for 120-r/min operation. The result is 60 Hz. This unit uses a pair of 320- $\mu$ F motor capacitors. The new capacitance value is:

$$\begin{aligned} f' &= 320 \times ((50 \times 50)/(60 \times 60)) \\ &= 320 \times (2500/3600) = 320 \times 0.6944 \\ &= 222.22 \mu\text{F} \end{aligned}$$

A pair of 220- $\mu$ F capacitors should do the job.

Proper drum speed is one of the most critical factors in an effective FAX recorder or transmitter. Precision frequency sources must be used! Although the K-550 machine requires a 60-Hz drive, the 60-Hz power-line frequency is not stable enough for proper sync. A suitable source would be a 6-MHz crystal oscillator, followed by five decade counters (100,000 total division).

#### Scanning-density Changes

If the surplus recorder does not have the precise scanning density (lines per inch) desired, it is possible to alter the scanning density in several ways. In the case of a drum-type system, where the print head is typically driven by a threaded lead screw, the scanning density can be altered by changing the thread pitch, gear drive (if used), or rod drive motor speed (motor substitution or drive-frequency change). In continuous-feed systems, the paper feed rate is motor-controlled to drive rollers through gears or pulleys. The drive roller size can be altered, gears or pulleys

**Table 6**

#### Standards For Various Classes of FAX Service

Service	Drum Speed (r/min or line/min)	Size (in)	Scan Density (line/in)
WEFAX			
Satellite	240	11	75
APT			
Satellite	240	11	166
Weather Charts	120	19	96
Wirephotos	90	11	96
Wirephotos	180	11	166

changed, or drive motor speed shifted. Given the considerable latitude for acceptable scanning density ranges with most image material, you can usually get by with no changes or, at least, minimal changes in the carriage or paper drive.

#### Modulation Format

Most surplus units will have amplitude-modulation capability, usually with both positive and negative formats. In some systems, shifting polarity is as simple as reversing diodes and changing the bias on a video stage. Addition of an FM capability to an AM-only unit can be achieved by using a standard SSTV demodulator with a suitable interface buffer to meet your circuit requirements.

#### Equipment Sources

Conversion requirements for surplus equipment can range from nothing to complete replacement of electronics and even mechanical changes. You should carefully study the requirements of the mode that you are interested in and evaluate the cost and conversion requirements of surplus equipment. The equipment can be found at the larger hamfests, through dealers or directly from the manufacturers. Three reliable sources of equipment are:

Alden Electronic and Impulse Recording Equipment, Inc.  
Washington St.  
Westboro, MA 01581

Muirhead Inc.  
1101 Bristol Rd.  
Mountainside, NJ 07092

Atlantic Surplus  
3730 Nautilus Ave.  
Brooklyn, NY 11224

#### Home Construction

Effective FAX systems can be built from scratch with performance equal to commercial equipment. Such projects are an interesting combination of electronics and mechanics. Reference 1 in the FAX bibli-

ography at the end of this chapter describes a complete direct-readout recorder for use with satellite imagery. This system is completely solid state and uses dry electrostatic paper. The documentation includes circuit changes for photographic printing if desired. Reference 2 describes a continuous-read-out electrolytic recorder for weather charts. Either system could be adapted for other services with the addition of different demodulators and drive motors. Anyone seriously considering building the FAX mechanical subsystem should obtain the Hurst catalog (Hurst Manufacturing Company, 1551 E. Broadway, Princeton, IN 47670). Hurst is one of the largest manufacturers of synchronous motors and carries a large line of stock and built-to-order units.

#### Services

Services of potential interest to amateurs include weather satellites, weather chart HF transmissions, HF press photos and two-way amateur operation. Table 6 summarizes the standardized recorder requirements for each service.

#### Satellites

Amateurs have been very active in this area since the inception of the satellite program in the '60s and have made many valuable contributions. Reception and display of both geostationary and polar orbiting satellite signals is entirely practical, but does involve antennas, receivers, tracking and a knowledge of the various satellite systems in addition to FAX techniques. Reference 1 in the FAX bibliography provides a complete guide to setting up a station including construction projects. Reference 3 also provides a system overview with valuable information on the conversion of surplus FAX gear. References 4 and 5 provide some additional sources of information as well as a very broad overview of amateur satellite activities.

#### Weather Charts

Weather charts are transmitted on literally dozens of HF channels throughout the day. Reception requires a stable general-coverage SSB receiver or a ham receiver with suitable frequency converter.

#### Press Photos

A very large number of press photos are sent daily on HF. The precise frequencies are not a matter of public record, although some are included in various specialized frequency guides. These pictures can be copied quite easily but are not transmitted in a broadcast service. The press agencies are covered by the nondisclosure provisions of the Communications Act of 1934. You can copy them for your enjoyment; it would be illegal to publish samples, however. Once you learn to recognize FAX signals, you can locate the stations with a little patient searching. For starters, try combing the region between 15 and

Fig. 38 — A test chart such as this can be used to check out a TV camera or an entire ATV transmitter system. It provides patterns for horizontal and vertical resolution and gray-scale testing. An 11 × 14-inch high-quality version printed on heavy paper is available from ARRL Hq. for \$3 postpaid. You can personalize the ARRL test chart by adding your call letters, location and a photograph in the white space provided.

20 MHz during daylight hours.

#### *Two-way Amateur FAX*

One of the greatest difficulties for two-way operation is locating FAX transmitters. While FAX recorders are available from surplus, FAX transmitters are much rarer. Unless a unit is found, you may have to build a transmitter that involves a simple drum and traverse system with the addition of a light source, photo transistor, an op-amp buffer and an SSTV modulator. See bibliography reference 1. Office FAX recorders, although sometimes requiring conversion, are attractive because they usually incorporate a transmitter and receiver in the same package.

For VHF operation, any kind of modulation system can be used as long as the units are compatible. Operation at HF requires the use of an FM subcarrier. At present, there are no uniform standards for HF FAX. It is anticipated that standards

can be developed within the amateur community in the not-too-distant future.

A critical element in such considerations is the transmission time. Any format requiring more than 10 minutes for a single frame transmission is illegal because of the requirement for identification. An acceptable format should be reasonably short, recognizing crowded band conditions, propagation, and avoiding excessive wear and tear on RF transmitter finals caused by extended duration, high-duty-cycle service. Recorders exhibiting 120 line/min are marginal in this respect since the transmission of quality pictures requires 6 or more minutes. As a starting point, a 240-r/min standard (75 line/in for 11-inch recorders or 42 line/in for 19-inch recorders) would seem workable. This is the essence of the WEFAX satellite format but using FM modulation. Such an approach would transmit an 800-line high-quality image in just 3.3 minutes.

With the availability of computers, we may wish to evolve our own standards as amateurs have done with SSTV. For the moment, a 240-line/min standard would appear to be a good starting point for discussion and experimentation. A national amateur FAX net is conducted every Sunday on 14.245 MHz at 2000 UTC.

#### **Computers**

Digital scan converters have revolutionized SSTV and are about to do the same with FAX. The use of home computers offers an exciting challenge for use as "intelligent" scan converters. An example of such a system is one developed by WB8DQT and K6AEP for use with the Radio Shack TRS-80C Color Computer.<sup>6</sup> The system has four elements: a FAX interface circuit, a high-resolution display board, the computer with 64-kbyte RAM and a software package. The input signals are processed by the interface board and

Fig. 39 — A typical FAX picture.

the computer, samples the image, loads it into memory and passes the picture information to a display board for presentation on a standard TV monitor. The picture is displayed in a  $256 \times 256$  format with 16 gray-scale levels.

## WEATHER SATELLITES

Since the early days of weather satellites, radio amateurs have been active in the reception of satellite imagery. Assembling a successful weather satellite receiving station can provide an exciting challenge to the interested amateur. While the technical challenges to be overcome are significant, the step-by-step improvement of the amateur's station is rewarded by continual improvements in the imagery received. There are challenges to be met in the areas of antennas and receivers, storage and processing of the signal received, image production and finally image interpretation. Some unsuspecting radio amateurs have become passably good meteorologists quite by accident! In addition there is the excitement of monitoring an operational satellite system on a day-to-day basis. In some cases radio amateurs have alerted the satellite operators to problems on board the spacecraft before the operators became aware of the problems. Amateurs are continually upgrading their imaging systems and, in some cases, the imagery received challenges that produced by commercial systems.

Modern weather satellites generate two types of images. First is the high-speed digital imagery that is designed to efficiently transfer all the data generated by the imaging instruments. These wide-band digital signals are usually transmitted at microwave frequencies and require complex receiving stations. A few amateurs with special technical skills have succeeded

in receiving and displaying this imagery, but these signals require station complexity currently beyond the reach of most amateurs.

The second type of imagery available on modern meteorological satellites is the "Automatic Picture Transmission" or APT imagery. Early in the meteorological satellite programs it became apparent that for users in remote areas to have access to the satellite imagery on a timely basis, the satellite would have to transmit directly to the remote user. The APT format was developed to meet this need. It was first carried on the US Tiros VIII spacecraft (launched Dec. 21, 1963) and has continued to be supported for the same reasons originally proposed in the early 1960s.

Construction of an APT station is much less complicated than assembly of a digital imaging station. Because of the narrower bandwidth and relatively slow rate of data transfer, standard medium bandwidth VHF receivers can be used for reception of the satellite signal and home-type audio recording equipment can be used to store the satellite signal. The VHF receivers, antennas, preamplifiers and transmission lines described elsewhere in this *Handbook* can be used on the satellite bands with appropriate modifications to change the frequency range covered.

APT image resolution is about 2-3 km for polar orbiting spacecraft and 8-12 km for the geostationary spacecraft. Clear images, completely adequate for meteorological purposes, can be obtained. APT offers higher resolution pictures than those received on commercial television broadcasts, for example. Images are much higher in resolution than those received on amateur SSTV. Under optimal lighting conditions, satellite images will show medium-sized cities, moderately large rivers and forest areas, and even, at times, interstate highways! Fortunately, the same APT format has been used by the weather satellites of the United States, the Soviet Union and the European Space Agency (ESA). Because of this international cooperation, the same equipment (with minor adjustments) can be used for reception of imagery from all of these spacecraft.

### APT Signals

The APT mode, like facsimile, allows the transmission of a relatively high-resolution image in a moderate bandwidth by using a longer time for image transmission. With APT, the detected FM signal consists of an audio-frequency subcarrier that has been amplitude modulated. The amplitude peaks on the subcarrier correspond to white areas on the image, and the low amplitude portions correspond to black areas on the image. The image is transmitted at either 120 or 240 lines per minute

(see Table 7).

The United States spacecraft and the ESA Meteosat use 2400 Hz as the subcarrier frequency. With these spacecraft the signal is always modulated at least 5%. If a noise-free signal is available, the user can employ a phase-locked loop circuit to track the subcarrier and use that information for detection or line synchronization. Soviet spacecraft do not use the 2400 Hz subcarrier frequency, although the subcarrier they use is close to that frequency (apparently about 2500 Hz). On some Soviet spacecraft, the subcarrier modulation falls below 5% during the scan line. For this reason it is not possible to "lock on" to the subcarrier of these spacecraft.

The term "WEFAX" describes a special type of APT format. This format consists of separate image frames consisting of 800 lines of imagery, with defined borders on all four sides. Data is transmitted at 240 lines per minute. In addition, clearly identified start and stop tones make it easier to automate image reception. Since the imagery is prepared at the spacecraft command station, some of the "images" may consist of text bulletins and weather charts.

There are some important differences between the APT format (including WEFAX) and the facsimile mode used for HF transmissions. It is probably more helpful to think of APT as a completely different mode. It should not be assumed that surplus facsimile equipment will automatically function in the APT mode, although many successful conversions have been made.

### Spacecraft

Currently active spacecraft can be divided into two categories. First are the polar-orbiting spacecraft. This group includes the Tiros-N series operated by the United States and the Meteor 2 and Meteor 3 series spacecraft operated by the Soviet Union. Other countries, including the People's Republic of China, have plans for launching and operating weather satellites of this type. Currently active polar-orbiting meteorological spacecraft all transmit APT imagery in the form of scanning radiometer imagery. To produce this imagery the spacecraft views the earth below through a rotating mirror which scans a narrow strip of the earth below and then transmits that one line of the image obtained. See Fig. 40. As the mirror rotates, the spacecraft moves through space; each rotation of the mirror covers a new portion of the earth. In this way the spacecraft produces a long, continuous image with clearly defined side borders, but no definite top or bottom.

The second group of meteorological satellites are the geostationary satellites. This group includes the GOES series op-

**Table 7**

retransmitted to WEFAX receiving stations, including amateur stations. In this case, although the spacecraft carries the imaging instrument it is serving as a transponder in the WEFAX mode; imagery from one spacecraft may be transmitted on a different spacecraft altogether. Spacecraft with non-functioning imaging instruments have, at times, been used to retransmit APT data from other spacecraft.

A third, somewhat unpredictable, source of APT data is APT instruments carried on experimental Soviet spacecraft. Spacecraft in the Meteor-Prirada series have carried APT instruments in the past and transmitted in the 137 MHz band. These are usually 240 line-per-minute scanning-radiometer images and have been popular among amateurs because of the high resolution offered. In addition, some of the Cosmos radar imaging spacecraft (Cosmos 1500 and 1602) have transmitted imagery in the APT format. These spacecraft seldom transmit over North America although occasionally imagery may be available. European amateurs can frequently receive APT signals from these spacecraft as they transmit data to receiving stations within the Soviet Union.

## RF Signals

The two types of weather satellites transmit imagery in different frequency ranges. The polar-orbiting meteorological spacecraft use the 137 MHz VHF band for APT data. The geostationary spacecraft have used the S-band microwave frequencies of 1691 MHz (GOES) and 1694.5 MHz (Meteosat). In both cases the signal is sent as a medium bandwidth FM signal (about 30 kHz). Conventional FM receivers can be used as long as proper system band-

erated by the United States and the Meteosat spacecraft operated by the European Space Agency. Both of these spacecraft carry APT data in the WEFAX format, which differs from the scanning-radiometer data obtained from the polar orbiters. In these spacecraft the high

resolution digital data is transmitted to a ground command station, computer processed and changed to the WEFAX format. In some cases geographical boundaries and titles are overlaid on the images. The image is then transmitted up to the spacecraft from where it is

width is maintained and good dynamic range is preserved.

#### Receiving Systems

Two frequency ranges are of interest for

tice. If crystal control of the receiver is anticipated, these five frequencies are the most active and should be included. Typical antennas for this frequency range include the turnstile antenna as described for

APT users. First is the 136-138 MHz satellite band. Weather satellites are assigned to the frequencies between 137 and 138 MHz. Commonly used frequencies are shown in Table 7. The frequencies used by the NOAA series spacecraft have not changed for many years. The three frequencies noted here in use by Meteor series spacecraft have been the primary channels for their operational Meteor 2 series spacecraft during the past 6 years. Other frequencies have been used intermittently by Soviet experimental spacecraft, but these are variable and change without notice.

OSCAR use, the multturn helical antenna, and crossed Yagi antennas with right-hand circular polarization. An antenna-mounted preamplifier is recommended, but not absolutely required. If a high performance, low noise preamplifier is available, good imagery may be obtained with an omnidirectional antenna such as a short helix or a discone antenna.

The other frequencies of interest are 1691 MHz and 1694.5 MHz in the microwave S band. These frequencies are used by the geostationary spacecraft operated by the U.S. and ESA. Interdigital or stripline downconverters can be built to convert these frequencies to the desired intermediate frequency. Several commercial units converting 1691 MHz down to 137.5 MHz are now available. A parabolic dish antenna (usually about 6 feet in diameter) is a typical antenna, although smaller dish antennas can be used if high performance, low noise preamplifiers are available.

#### Imaging Systems

Several types of instruments for displaying satellite imagery are in common use at this time. First are the "drum" type machines such as that described many years ago in *QST* by Wendell Anderson. With this type of unit a sheet of light-sensitive photographic paper is wrapped around a long cylinder or (drum) which is then spun at exactly the same rate as the satellite image line rate. If the satellite transmits data at 240 lines per minute, for example, the drum must be rotated at precisely 240 revolutions

per minute. The sensitized paper is exposed one line at a time by an intensity-modulated light source which is slowly drawn along the length of the drum. In this way the entire surface of the paper is exposed. After exposure the paper is removed from the drum and is developed using standard photo-fining techniques. The image can then be examined. A variation of this method is the use of an electrostatic paper on an office-type facsimile machine. The Xerox model 400 and the older Western Union Desk-Fax machines have been used successfully for APT after modifications.

A second widely used method of preparing satellite imagery is with the use of a dedicated CRT. With this method the CRT is controlled with a very slow sweep rate to match the line rate as transmitted by the spacecraft. The image is drawn on the face of the CRT slowly, one line at a time. Because of the length of time required to draw an entire image on the face of the CRT, a camera is needed to photograph the screen of the CRT in order to see the detail in the image.

A third approach is the modification of commercial facsimile equipment for print-out of satellite images. Some models of commercial equipment work well in this capacity. The amateur is cautioned to become familiar with the equipment and select a particular machine carefully. This equipment is still fairly expensive, even as surplus. Some units are designed to print only black and white (as for weather maps

and line drawings); these may not work well in an application (such as APT) where a good gray scale is important.

More recently, with the availability of microcomputers and digital memory, the prospect of using scan converters for APT imagery has become a practical possibility. The use of this technique has lagged behind its use in SSTV because of the concern for the loss of detail in the scan conversion process. Since the APT image has a great many more pixels than an SSTV image, more of the image will be sacrificed for a given framestore size. For example, while 256 pixels by 256 pixels may be perfectly adequate for an SSTV image it would be considered a practical minimum for APT use. Even at this level, at least half of the image detail will be lost.

There are three general approaches to the development of a scan converter (digital framestore device) for APT use. The first is to sample the APT image, store the data in the memory of a personal computer and display the image on the screen of the personal computer. This has been done with Commodore 64, Apple II, and IBM personal computers among others. The results of this approach are usually disappointing. Since the amount of memory available for data storage may be limited in a PC, a relatively low resolution image often results. The second approach involves the use of a microcomputer to control a separate block of RAM with additional hardware to send

the display to a dedicated monitor. See references 6 and 7. The third approach is the development of a dedicated hardware-controlled scan converter without the use of a microcomputer. While this approach is less flexible it does offer the option of producing imagery without the expense of a microcomputer.<sup>8</sup>

# Special Modulation Techniques

Amateur Radio is not limited to sending telegraphy, voice or images by conventional modulation systems. There are numerous uses for telecommand (remote control) and telemetry (distant reading of a sensor), both of which may use a variety of signaling techniques. In some applications, telecommand or telemetry signals are sent over a radio link dedicated to that purpose. In others, signaling is sent along with telegraph, voice or image communications in a secondary or incidental way, usually to facilitate communications. This chapter will cover some of the signaling techniques of interest to amateurs. Also, this chapter contains information about uses of experimental transmission techniques by radio amateurs.

### RADIO COMMAND AND CONTROL

Amateur Radio may be used for remotely controlling an object or another radio station. Although command and control transmissions may not be used indiscriminately on the amateur bands, FCC rules include a number of special provisions for different applications. Before designing or attempting to operate new telecommand systems, it is a good idea to check *The FCC Rule Book*, available from the ARRL.

According to §97.3(l) of the FCC rules, *radio control operation* is one-way radio communication for remotely controlling objects or apparatus other than Amateur Radio stations. Reading further in §97.3(m), *control* means techniques used for accomplishing the immediate operation of an Amateur Radio station. Control includes one or more of the following: *local control*, *remote control* and *automatic control*. Remote control is defined by §97.3(m) (2) as manual control, with the other control operator monitoring the operation on duty at a control point located elsewhere than at the station transmitter, such that the associated operating adjustment(s) are accessible through a *control link*. §97.3(n) defines a control link as apparatus for effecting remote control be-

Fig. 1 — A typical radio-controlled model airplane with its accompanying control transmitter. The operator works the joysticks, and his or her actions are translated into commands that operate servos to control the airplane.

tween a control point and a remotely controlled station.

Whether controlling objects, apparatus or other Amateur Radio stations, bear in mind that N0N (formerly A0 or F0) emission (an unmodulated carrier) is not permitted below 51 MHz. This would apply to control transmissions that send control signals only occasionally but with the carrier left on continuously.

### RADIO CONTROL OF A REMOTE MODEL AIRCRAFT OR VEHICLE

Radio control (R/C) of remote model aircraft or vehicles by hobbyists was started in the 1930s. ARRL's Ross Hull with R. B. Bourne, Clinton DeSoto, Byron Goodman, Harner Selvidge and H. M. Plummer did some early work, as did Walt and William Good. The Good brothers used a radio system to steer the free-flight type of model airplanes back to the launch point. The system was big, and not totally reliable, but it showed definite potential. A large tube-type transmitter on the ground sent a steering pulse on command to a tube-type receiver in the model airplane.

All of the early experimenting was carried on by Amateur Radio operators because amateur frequencies were the only frequencies available. Later, in the early 1950s, Citizen Band spots at 27.255 and 465 MHz were opened by the FCC for shared use by R/C hobbyists. This caused rapid growth of the R/C hobby due to the simpler license.

When the Citizens Band was formed from the old 11-meter amateur band, certain frequencies were set aside for or shared by the R/C enthusiasts. However, since many of the early receivers were wideband superregenerative types, many fliers found their airplanes crashing because of adjacent CB interference. Many became amateurs as a result, and operate to this day at the top of the 6-meter band, a territory unused by most amateurs because of its proximity to TV Channel 2.

Recent pressure by 6-meter FM repeater operators to use this upper area has resulted in the suggested R/C frequencies being moved to the bottom end of 6 meters. Some amateur R/C operators use 10 meters by obtaining new crystals and retuning the

Fig. 2 — Sample signal from an R/C transmitter.

Fig. 3 — The signal seen by each servo.

Fig. 4 — Example of a PCM-encoded signal.

older 27-MHz CB R/C equipment. The bulk of R/C operation occurs on the new license-free radio-control bands at 72-73 and 75-76 MHz.

The license-free frequencies do get overcrowded at many flying fields, so most amateurs who are R/C hobbyists purchase 6-meter R/C transmitters and receivers.

#### Uses

The majority of R/C systems are used for controlling the flight of model airplanes, as shown in Fig. 1. Other applications include R/C cars and R/C motorboats and sailboats. The airplanes vary in size from about a pound in weight with a 1-foot wingspan to gigantic multi-engine models weighing over 50 pounds with 15-foot wingspans. Many modelers fly large-wingspan gliders. R/C cars may have electric motors or be gas-engine driven.

The operator controls the model from a transmitter that has control sticks. Miniature receivers are built into the model to receive signals from the transmitter. The action of the control sticks is sent through the transmitter and receiver to servos located in the model. These translate the stick movement into some mechanical movement which produces the desired control. The operator can control movements such as ailerons, elevator, rudder or throttle in an airplane. The operator may control the steering, throttle, rudder or a sail winch in a model car or boat. Often, more sophisticated scale models have other systems controlled remotely, such as retracting wheels, "bomb dropping," flaps, battleship guns that turn and fire, anchors that raise and lower, and many other interesting actions.

Because R/C systems are widely available at low cost, amateurs can use them for many unique applications around the station that may require some kind of mechanical adjustment. The amateur TV station can have its TV cameras panned, zoomed or focused using R/C. Potentiometers or tuning knobs can be turned by R/C. Miniature antennas could be turned by some of the special high-thrust servos intended for very large model airplanes. Several amateurs active on SSTV use R/C servos to swing in color filters over their black-and-white TV cameras.

#### Design

Most current R/C designs consist of a low-power transmitter that sends out a repeating series of width-modulated pulses to the R/C receiver. Each width-modulated pulse represents a single channel, for example the rudder channel. An R/C system is rated by the number of channels it supports, based on how many of these width-modulated pulses are involved. See Fig. 2. For example, systems are called 4-channel systems, 7-channel systems, and so on. An R/C system also may be sending out more than "4 channels," but only have four servos or four control sticks included with the system, so it is still known as a "4 channel." The series of pulses repeat about 50 times a second, so that any control stick movement can quickly result in an appropriate servo movement.

Each channel's servo monitors a positive pulse that varies in duration between 1 and

2 milliseconds, centered at 1.5 ms. See Fig. 3. The servo's electronics are designed so a 1.5-ms pulse will cause the motor to move the control arm to a centered position. If the pulse width changes to 1 ms, the servo control arm will turn 45 degrees in one direction. If the pulse width had changed to 2 ms, the servo control arm would have turned 45 degrees in the other direction. The servo quickly reacts to any change in the transmitter control stick, and maintains position if no new stick movement has occurred. Depending on manufacturer and type, the precise pulse duration and amount may vary slightly.

Some servos are very small and light, with little torque. Others are larger with considerable torque. Most of the newer servos have three leads — a ground or common lead, a +4.8-volt lead, and the pulse lead. Prices vary from \$10 to \$50 per servo.

Some recent systems utilize pulse-coded modulation (PCM) instead of the traditional pulse-width modulation scheme. See Fig. 4. PCM sends the absolute position of each channel, encoded as bits (similar to ASCII), plus a check bit. The receiver is then able to reject any faulty or corrupted signal, and use the last good position setting. If no good positions arrive over a predetermined short period of time, the system can reset the servos to an assumed safe position, such as low throttle and neutral control surfaces, until the system once again obtains acceptable PCM codes.

Most of the existing R/C transmitters use discrete components to encode the pulses. Fig. 1 shows a prototype transmitter that uses a CMOS microprocessor for the encoding task. The block diagram of such a transmitter is shown in Fig. 5. This transmitter has the ability to have totally new control features and options added by simply replacing the program in EPROM. This transmitter can retain the flight trim settings of four different airplanes, or it could provide an unlimited number of channels for unique applications such as scale boats or robotics.

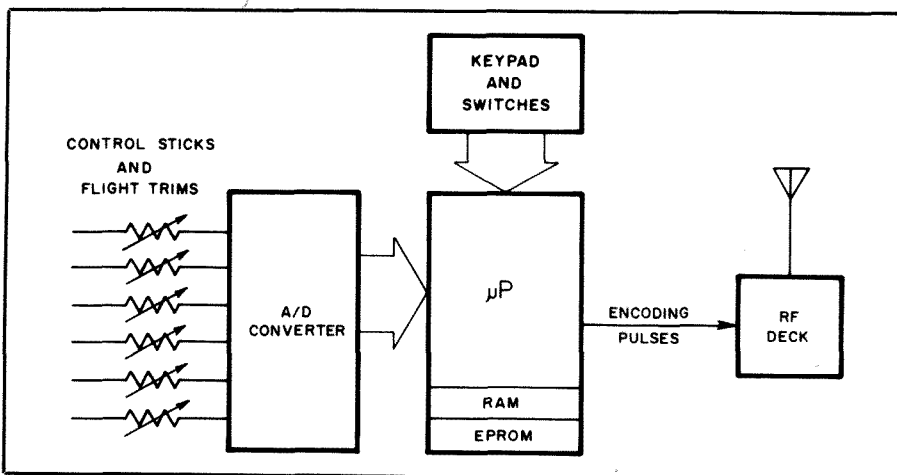

Fig. 5 — Simplified block diagram of a microprocessor-encoded R/C transmitter.

(B)

Fig. 6 — UoSAT-OSCAR command station, G3YJO, at the University of Surrey, Guildford, Surrey, England. At A is the 2-m, 70-cm and 23-cm az-el antenna array. Inside the station, at B, are the digital command and display consoles alongside the transmitting and receiving equipment.

Because of the potentially lethal nature of R/C airplanes flying often in excess of 100 mi/h, 6-meter repeater operators on 50 MHz or 53 MHz should coordinate their frequencies with the local R/C clubs. The most commonly used Amateur Radio R/C frequencies are: 53.1, 53.2, 53.3, 53.4, 53.5, 53.6, 53.7, 53.8 and 53.9 MHz. Most current Amateur Radio R/C activities occur on 53.1 to 53.5. These frequencies are expected to be vacated by 1990.

New frequencies are:

Frequency	Channel No.
50.80	00
50.82	01
50.84	02
50.86	03
50.88	04
50.90	05
50.92	06
50.94	07
50.96	08
50.98	09

Recommended practice is to use the even-numbered channels until 1990 and all channels thereafter, when the selectivity of R/C receivers is expected to improve.

## RADIO REMOTE CONTROL OF AN AMATEUR RADIO STATION

Radio communication for remotely controlling another Amateur Radio station is considered *auxiliary operation* by the FCC. All Amateur Radio bands above 220.5 MHz (excluding 431 to 433 and 435 to 438 MHz) are available for auxiliary operation. FCC rules specify that the remotely controlled station must have provisions to limit transmission to a period of no more than 3 minutes in the event of malfunction in the control link.

### Remote Control of a Repeater

When remotely controlling a station in *repeater operation*, the control link must use frequencies above 220.5 MHz and may not use the input (receiving) frequencies of the repeater, according to FCC rules. For

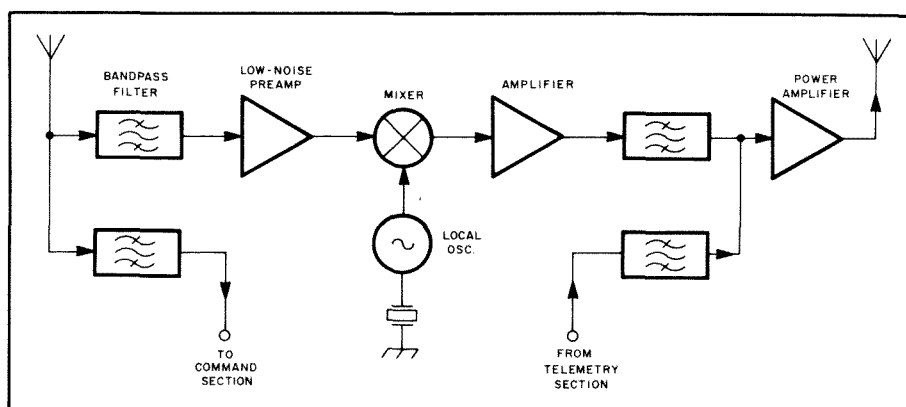

Fig. 7 — Functional block diagram of a typical satellite transponder showing telecommand and telemetry channels.

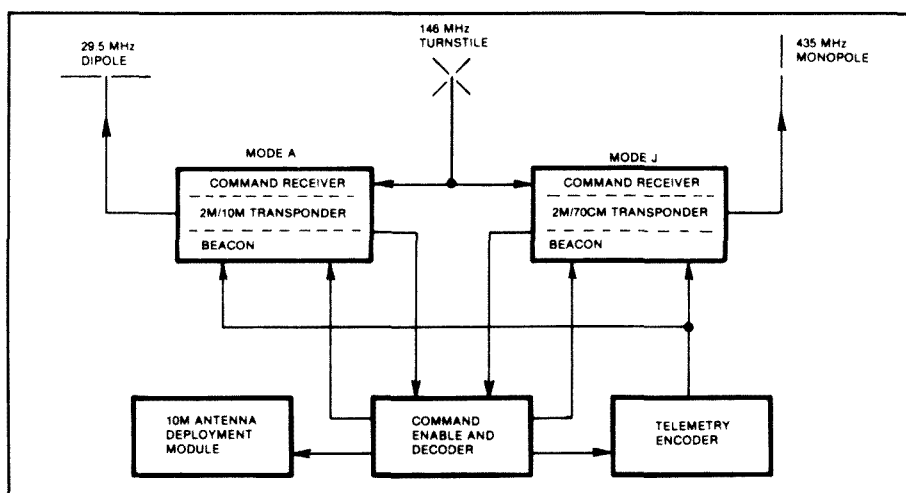

Fig. 8 — AMSAT-OSCAR 8 satellite functional block diagram. OSCAR 8 telemetry was sent using 20-WPM Morse code. A complete set of data required about 20 seconds to send.

a discussion of repeater-control methods see Chapter 14.

### Telecommand of a Satellite

The FCC defines *telecommand operation* as earth-to-space Amateur Radio communication to initiate, modify or terminate

functions of a station in space operation (that is, an Amateur Radio communications satellite).

The following frequencies are available for telecommand operation: 7.0-7.1, 14.0-14.25, 21.0-21.45, 24.89-24.99, 28.0-29.7, 144-146, 435-438 and 24,000-24,050 MHz.

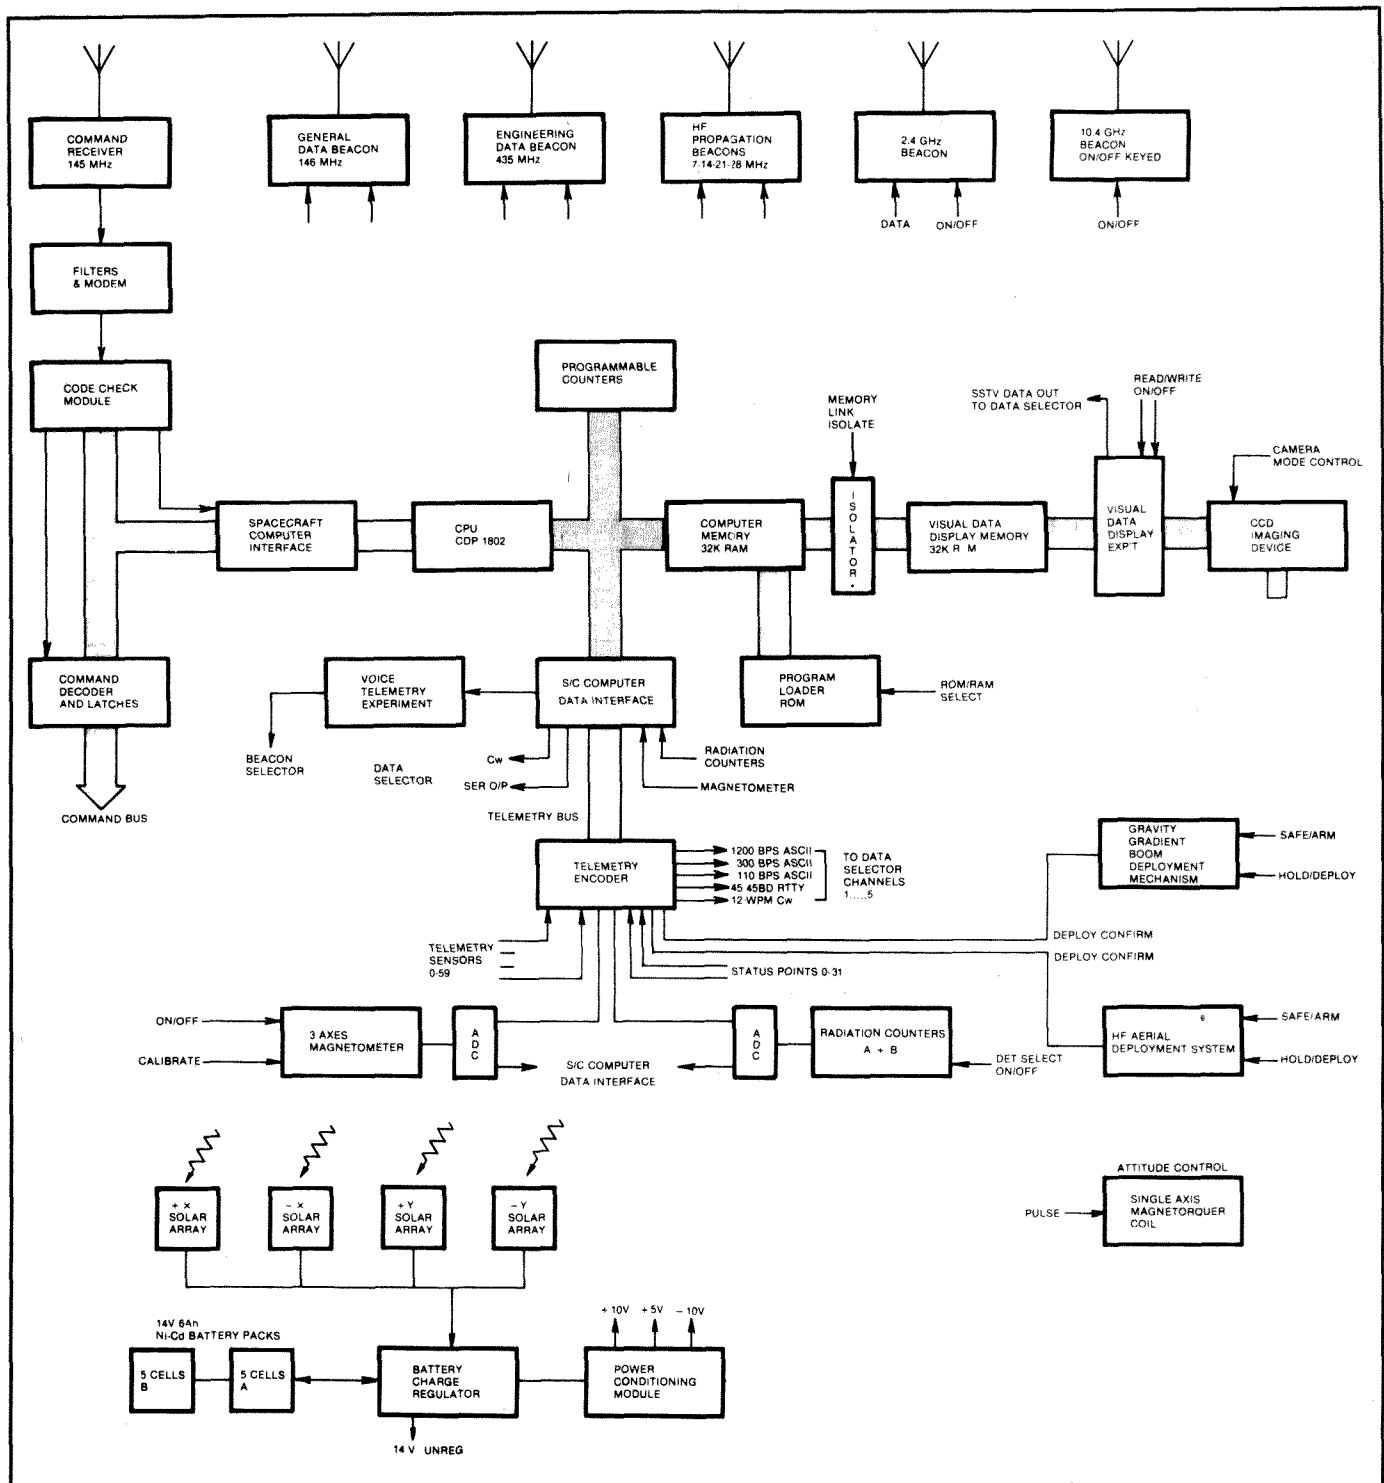

Fig. 9 — UoSAT-OSCAR 9 functional block diagram. The OSCAR 9 telemetry system has provisions for monitoring 60 analog sensor channels and 45 digital status points. Telemetry data can be sent on Morse code, RTTY (Baudot code) or ASCII.

Stations in telecommand operation are exempt from station identification requirements and may transmit special codes intended to obscure the meaning of command messages to the satellite, according to §97.421 of the FCC rules.

Telecommand links are used to switch OSCAR satellites from one operating mode to another and to turn off a malfunctioning transmitter that might cause interference. In addition, the ability to telecommand subsystems prolongs the useful life of the

satellite by turning off parts of the satellite to conserve energy. Command frequencies, codes and transmission formats are confidential and provided only to AMSAT-approved command stations.

There are volunteer command stations in more than 8 countries. Fig. 6 shows the UoSAT-OSCAR command station at the University of Surrey, England.

## TELEMETRY

*Telemetry* is the process of measuring a

quantity, transmitting the result to a distant station, and there indicating or recording the measured quantity. It is strongly associated with rocketry and satellites but has many other applications. In many instances where radio is used to telecommand or control a distant radio station, a telemetry link is needed to monitor conditions at the remote station. When a command is sent, telemetry provides the feedback necessary to see whether the command was carried out and to monitor

conditions afterwards to ensure the desired results.

## AMATEUR-SATELLITE TELEMETRY

In §97.403(d) of the FCC rules, telemetry is defined as space-to-earth transmissions, by a station in space operation, of results of measurements made in the station, including those relating to the function of the station. The FCC considers telemetry transmissions by amateur satellites to be permissible one-way communications and says that such transmissions may consist of specially coded messages intended to facilitate communications.

Telemetered information typically includes satellite temperature, solar-cell current, battery temperature and voltage, and other parameters that describe the electrical and mechanical conditions of the satellite. Telemetry data may also include the results of scientific observations in the case of amateur satellites with a research mission.

Telemetry is transmitted by means of a beacon, usually just outside the satellite's communications passband. Beacon transmitters typically have output power levels of 50 mW to 1 W depending on the altitude of the spacecraft. Telemetry encoding methods vary, but OSCAR satellites have used Morse code, Baudot radioteletype, "advanced encoding techniques" (ASCII for computer processing) and digitized speech.

## SIGNALING

Signaling systems for command, control and telemetry must be designed with high reliability in mind. Many early signaling systems used analog transmission techniques to represent continuously variable quantities by the amplitude, frequency or duration of a tone. Most new systems use some type of digital transmission technique and often include a degree of redundancy for detection and correction of errors.

### Multiplexing

Most signaling systems are capable of sending more than one piece of information in the same transmission. For example, the telemetry from a satellite might routinely include a complete system check with readings from numerous sensors. Combining two or more streams of information on one radio carrier is called *multiplexing*.

**Frequency-division multiplexing (FDM)** is a method of sending each of the information streams over separate subcarriers, each at a different frequency. The subcarriers could be modulated in various ways, according to the nature of the information. Fig. 10 illustrates the baseband of an FDM signal.

**Time-division multiplexing (TDM)** uses only one channel but assigns the different data streams to different time slots. For example, telemetry from sensor 1 could be followed in turn by that of sensors 2, 3, and

Fig. 10 — Frequency-division multiplexing (FDM). Each block represents a logical 1 being transmitted. The spaces in between are 0s. Four streams of data are being sent, each on a separate frequency.

Fig. 11 — Time-division multiplexing (TDM). Four data streams are interleaved to produce one multiplexed data stream at four times the individual data rate.

so forth, as shown in Fig. 11.

### Coding

Essentially every signaling system, whether for control or telemetry, requires some type of encoding at the sending station and decoding at the receiving station. A voltage or current reading cannot be transmitted in its original form but could be used to frequency-modulate an audio tone suitable for transmission. The signal can be demodulated by a frequency-to-voltage converter. Alternatively, the original signal could have been fed to an analog-to-digital converter to produce a digital code that, in turn, could frequency-shift key an audio tone. This signal could be received by an FSK demodulator and decoded by a digital-to-analog converter.

In general, FCC rules permit codes where they facilitate communication rather than obscure meaning. A careful reading of *The*

*FCC Rule Book* is advised before using specific coding and modulation systems.

### Error Control

When designing a signaling system, particularly one for command and control, serious attention should be given to the possibility of errors and the consequences of those errors causing undesirable results. There is no such thing as an error-free communications channel, although some approach the level of perfection. Amateur Radio channels are subject to noise, interference and fading, so some errors may be encountered from time to time. It is best to ensure that the communications channel has a basic reliability well into the 90% range before considering it for control purposes.

It is worthwhile to consider at least some type of *error detection* scheme to prevent the decoder from accepting erroneous com-

mands or falsing on no signal. To give the decoder something to work on for detecting errors, it is necessary to add some redundancy to the encoding process prior to transmission. For example, a single-bit parity check is often added to the ASCII code. There are several ways of using parity, but using the "odd parity" system, the parity bit is set to make sure that the number of 1 bits in the character is always an odd number. If, on reception, the number of 1s is even, the decoder knows that the command contains an error.

Error-detection systems are simply methods of confirming the (probable) correctness of a signal. More sophisticated techniques provide error correction, often called *forward error correction (FEC)*. It takes more than 1 bit of redundancy for a 7-bit code to implement FEC. Several additional bits will be needed to provide sufficient redundancy to determine what the correct signal should have been. The exact ratio of parity bits to original coding bits varies according to the specific type of FEC system and the percentage of errors that the system can correct on its own.

### Encryption and Authentication

*Encryption* is a technique of encoding each symbol against a changing key in order to obscure meaning or prevent someone else from knowing what command to send. The FCC has recognized its importance as a safeguard against tampering with satellites and permits its use for telecommand of amateur spacecraft. The FCC rules do not presently permit encryption to be used for other Amateur Radio purposes, such as controlling a repeater. Yet, it is undesirable to use a control system that is vulnerable to manipulation.

Where tampering is a threat, an *authentication* technique should be considered. Using this approach, you can send the same command each time but have a changing element appended to the end for authentication purposes. For example, if the command for turning on the autopatch is OA, then the first transmission of that command might be OA7, the next one OAR, the third OAM, and so forth, the third character being selected from a sequence known only to the encoder and decoder.

### SPECIFIC SIGNALING TECHNIQUES

Before settling on a specific signaling technique, it is useful to consider some of the trade-offs. Here is a suggested checklist:

- What is the original form of the data to be transmitted?
- Does it need to be converted to a transmissible format?
- Will the modulation fit within a standard voice channel, on-off or frequency-shift-key a transmitter, or does it need a special modulator?
- What type of demodulator is required?
- Does the data need to be converted after demodulation?

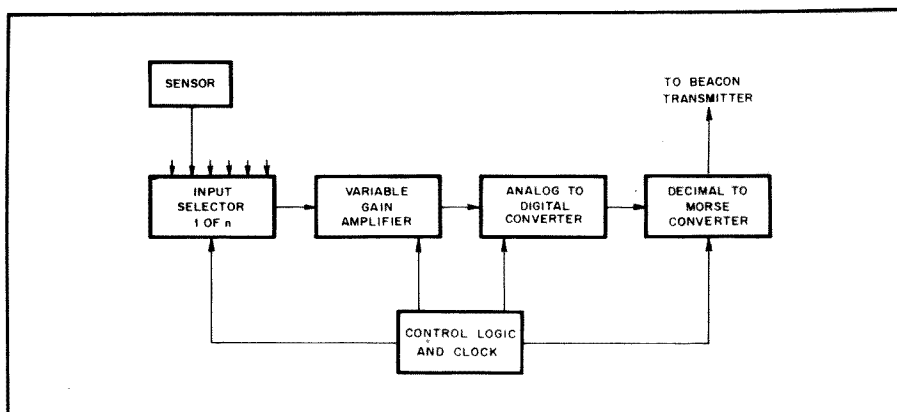

Fig. 12 — Block diagram of a typical AMSAT-OSCAR Morse code telemetry encoder.

- Is it legal within the FCC rules for the frequency purposes?
- Is frequency coordination needed?
- Will the encoding/modulating equipment be accessible to the stations transmitting the signals?
- Will the demodulating/decoding equipment be available to the stations expected to receive the signals?
- Have precautions been taken against errors, tampering or simple loss of control?

### Morse Code

Morse code has been used for transmitting telemetry from OSCAR satellites because no special decoding equipment is needed to copy the telemetry information. See Fig. 12. Speeds of 10 and 20 WPM have been used to ensure that a large number of people could copy the telemetry. The chief disadvantage of this application is that speeds that are easily copied aurally do not permit the transmission of massive data.

If sent using on-off keying, Morse-code transmission may not be reliable enough for command and control purposes. Use of frequency-shift keying would overcome that problem. Computers can be used for both the generation and decoding of Morse characters.

### Baudot Code

ITA2 (commonly called Baudot) is normally a direct-printing telegraph system. However, §97.69 of the FCC rules provides that ITA2 figures-case characters except the numerals and slant bar may be used for remote control of receiving printers and other objects. The purpose of doing so must be to facilitate communication, not to obscure meaning. The codes available for control purposes are the figures-case positions corresponding to the following letters: A, S, D, F, G, H, J, K, L, Z, C, V, B, N and M.

For telemetry purposes, the complete ITA2 character set may be used. Numerous amateurs throughout the world are equipped to receive and print these transmissions.

The complete ITA2 character set is given in Chapter 19.

### AMTOR

What was said about ITA2 applies to AMTOR, as AMTOR uses the ITA2 character set. However, AMTOR has two optional error-control modes (ARQ and FEC), which may be valuable for control or telemetry transmissions.

### ASCII

ASCII has a larger character set than ITA2. Further, it is usually sent at speeds much higher than ITA2 or AMTOR. Also, it is the native code for most microcomputers, making code conversion unnecessary. These advantages make ASCII suitable for many telemetry applications.

The same FCC rule provision for controlling printers or other objects mentioned above for Baudot applies even more so in this case. The reason is that ASCII has a much larger number of control characters already built into the code. See Chapter 19 for the complete ASCII character set.

### Digitized Speech

UoSAT-OSCAR 9 first used digitized speech for telemetry. It has the advantage that anyone who knows the (English) language can instantly decode the meaning. It is particularly useful for educational demonstrations involving students in the lower grades. Its low data rate for easy listening makes it unsuitable for most telemetry applications.

### Amateur Television

It may seem strange to consider amateur television (both slow scan and fast scan) as a signaling system, but don't overlook it as a possibility. Image communications systems are excellent for some types of telemetry. TV could be used to look at meter faces, confirm that an antenna system is still there and pointing in the right direction, or could look at the weather situation at a remote location. The camera can be remotely controlled so it can view

Fig. 13 — DTMF key pad layout. Whenever a key is pressed, the pad produces two AF tones, one from the low group and one from the high group. Twelve-button key pads are standard. Optional 16-button key pads are available on some hand-held radios.

Fig. 14 — The effect of pre-emphasis on DTMF tones.

different scenes, zoom in on items of interest, and so forth. Fast-scan ATV might also be the “eyes” for remote control of models.

### Dual-Tone Multifrequency Signaling

In the late 1940s, Bell Laboratories developed the Touch-Tone® signaling system to replace telephone pulse dialing. The dual-tone multifrequency (DTMF) signaling system, as it is known generically, became widely used in Amateur Radio with the introduction of autopatches to 2-meter FM repeaters. Repeater operators also found many control applications for DTMF. These aspects of DTMF signaling are covered in Chapter 14.

The fact that many amateurs own VHF/UHF transceivers with built-in DTMF encoders makes DTMF an attractive candidate for a variety of control purposes. However, this is simply a one-way advantage (that is, from a hand-held transceiver to a base unit) because the hand-held radios do not presently include DTMF decoders. Such decoders would be used for selective-calling purposes in order to mute the hand-held receiver until a prearranged tone sequence is received.

The standard 12-button DTMF key pad is a 2-out-of-7 tone encoder, meaning that the encoder selects one tone from the low group of 697, 770, 852 or 941 Hz and a second from the high group of 1209, 1336 or 1477 Hz. An optional 16-button DTMF key pad is also available; it is a 2-out-of-8 tone encoder. The 16-button variety uses the additional high-group frequency of 1633 Hz. The key pad layout with tones related to character assignments is shown in Fig. 13.

A number of amateurs have puzzled over how to encode the 26 Latin letters on a DTMF pad. There is an encoding scheme that was originally devised to enable the deaf to use a DTMF pad on a telephone to report a fire to the local fire department. In this system, two buttons are pressed for each letter. First, push the button with the letter printed on it — that would be the “2”

button for A, B and C. The result would be ambiguous, so press \*, 0 or # to indicate whether it is A, B or C, respectively. The only problem left is what to do with Q or Z, which do not appear anywhere on the key pad. The solution is to send \*\* for Q and ## for Z. They’re easy to remember because they fall directly below the keys (PRS) and (WYX) where they were omitted. As an example, 225 Main St. would be encoded

$\frac{2}{2} \frac{2}{2} \frac{5}{5} \frac{M}{6^*} \frac{A}{2^*} \frac{I}{4\#} \frac{N}{60} \frac{S}{7\#} \frac{T}{8^*}$

DTMF signals may be encoded with either a manual key pad or an automatic dialer. With manual keying, the duration of the tone depends on how long the key is pressed, and the length of the wait between tones is a function of how long the operator takes to press the next key. A minimum dwell time of 30 to 40 ms is necessary to ensure that most DTMF decoders will properly recognize the tones. Typical decoders need at least 10 ms delay between tones and may reset themselves if the next tones are not received within 2.5 seconds. Thus, a decoder designed for 35 ms dwell time and 15 ms of spacing could decode up to 20 digits per second. Automatic dialers are programmed to transmit one or more telephone numbers in rapid sequence. Repertory dialers are automatic dialers that store a large quantity of telephone numbers, any one of which can be recalled by a few key strokes.

*Twist* or tone differential refers to the relative amplitude difference between the low-group and high-group tones, expressed in decibels. DTMF tone encoders are usually designed to produce a twist of 3 dB, where the high group is at the higher amplitude. Some DTMF key pads have an internal adjustment that can vary the low or high group as much as  $\pm 5$  dB. DTMF decoders can tolerate a certain amount of twist, sometimes as much as 12 dB, without malfunctioning, in order to allow latitude for misadjustment of the encoder and fre-

quency distortion in the communications channel.

When DTMF tones are fed into the audio input stage of an FM transmitter, the levels of all tones should be about equal at that point. The DTMF tones should emerge from the audio-processing stage of the transmitter without clipping. Any clipping at this point will generate intermodulation products that could cause interference and may hinder proper decoding at the receiving station. In a normal FM transmitter, the modulation is pre-emphasized by 6 dB per octave. This means that a frequency of 1394 Hz would be 6 dB higher after pre-emphasis than a 697-Hz tone, assuming that both tones were of the same amplitude before pre-emphasis. Fig. 14 shows the relative amplitudes of the DTMF tones after pre-emphasis. It can be seen that the combination of the highest tone from the low group (941 Hz) and the highest from the high group (1477 Hz on a 12-button key pad and 1633 on a 16-button key pad) will produce the greatest frequency deviation. So when you set the peak deviation for DTMF signaling on an FM transmitter, it is necessary to do so at the highest tones from the low and high groups. On a 12-digit key pad use the pound sign (#) to adjust the deviation to about 3 kHz (for a transmitter designed for 5-kHz deviation on voice peaks).

At the receiving end, 6-dB-per-octave de-emphasis does the job of restoring the DTMF tones to an equal level.

### SPREAD-SPECTRUM COMMUNICATIONS

The common rule of thumb for judging the efficiency of a modulation scheme is to examine how tightly it concentrates the energy of the signal for a given rate of information. While the compactness of the signal appeals to the conventional wisdom, spread-spectrum modulation techniques take the exact opposite approach — that of spreading the signal out over a very wide bandwidth.

Communications signals can be greatly increased in bandwidth by factors of 10 to 10,000 by combining them with binary sequences using several techniques that will be described later. The result of this spreading has two beneficial effects. The first effect is dilution of the signal energy so that while occupying a very large bandwidth, the amount of power density present at any point within the spread signal is very slight. The amount of signal dilution depends on several factors such as transmitting power, distance from the transmitter and the width of the spread signal. The dilution may result in the signal being below the noise floor of a conventional receiver, and thus invisible to it, while it can be received with a spread-spectrum receiver!

The second beneficial effect of the signal spreading process is that the receiver can reject strong undesired signals—even those much stronger than the desired spread-spectrum signal power density. This is because the desired receiver has a copy of the spreading sequence and uses it to “despread” the signal. Nonspread signals are then suppressed in the processing. The effectiveness of spread spectrum’s interference-rejection property has made it a popular military antijamming technique.

Conventional signals such as narrow-band FM, SSB and CW are rejected, as are other spread-spectrum signals not bearing the desired pseudonoise (PN) coding sequence. The result is a type of private channel, one in which only the spread-spectrum signal using the same pseudonoise sequence will be accepted by the spread-spectrum receiver. A two-party conversation can take place, or if the code sequence is known to a number of people, net-type operations are possible.

The use of different binary sequences allows several spread-spectrum systems to operate independently of each other within the same band. This is a form of sharing called code-division multiple access. If the system parameters are chosen judiciously and if the right conditions exist, conventional users in the same band space will experience very little interference from spread-spectrum users. This allows more signals to be packed into a band; however, each additional signal, conventional or spread spectrum, will add some interference to all users.

### Benefits for Spectrum Managers

Effective spectrum management attempts to use a band as fully as possible while keeping interference to a minimum. A limit exists as to how many signals can be put in a band. When the allocation is used up, additional stations that use conventional modes may cause interference that degrades or blocks communications by other users. Additional spread-spectrum signals, however, may not cause severe interference; they just raise the background noise level. The limit to the number of spread-spectrum signals that can occupy a

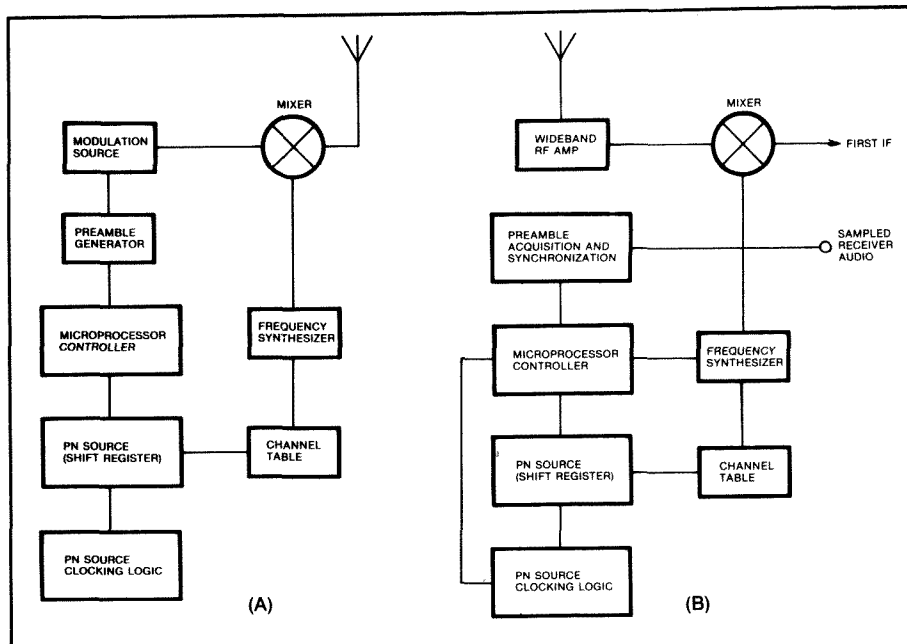

Fig. 15 — The block diagram of a frequency-hopping (FH) transmitter is shown at A. The channel table contains frequencies that the FH transmitter will visit as it hops through the band. These channels are selected to avoid interference to fixed band users (such as repeaters). The preamble employs the falling edge of an audio tone to trigger hopping. Conventional modulation, such as SSB, is employed. The block diagram at B is for an FH receiver. Preamble acquisition and synchronization trigger the beginning of the hopping mode and keep the receiver channel changes in step with the transmitter.

Fig. 16 — A graphic representation of the distribution of power as the signal bandwidth increases. The uns spread signal (A) contains most of its energy around a center frequency. As the bandwidth increases (B), the power about the center frequency falls. At C and D, more energy is being distributed in the spread signal’s wider bandwidth. At E, the energy is diluted as the spreading achieves a very wide bandwidth. Bandwidth is roughly twice the bit speed of the PN code generator.

band is sometimes called a “soft” limit because the effects of over allocation are not as severe as the rapid degradation caused by over allocation of conventional users.

Overlay is a spectrum-management concept that takes advantage of the spread-spectrum signal rarification and interference-rejection effects to share a band with conventional modulation users. In bands that are channelized and are fully allocated by assigned users such as repeaters, there are few ways to accommodate new users. Yet, viewing such a band on a spectrum analyzer reveals that much of the spectrum is only lightly used because of the intermittent use of many repeaters and the presence of numerous guard bands between fixed channels.

In the overlay concept, the spread-

spectrum signal is continuously spread over a shared band. It can exist in both the unused guard bands and on intermittently used repeater channels. It is, in effect a form of frequency diversity that takes advantage of whatever unused spectrum space is available within its spreading width.

Spread spectrum possesses a number of additional advantages. Spread spectrum provides a degree of protection against fading (a large variation in received signal strength caused by reflections, as in TV “ghosts”). Frequency-selective fading typically affects a relatively narrow band of frequencies. The spread carrier offers a form of frequency diversity that can offset the faded frequencies by those within the spread-spectrum signals that do not experience the same fading. The effects of reflec-

tive or multipath interference, which result from several parts of the same signal arriving at the spread-spectrum receiver at slightly different times, can be largely reduced. Signals that arrive late at the spread-spectrum receiver will not match the spreading code currently being used to decode the signal. Hence they are rejected as interference.

Finally, spread spectrum can be used to construct very precise ranging and radar systems. The spread carrier, modulated with the PN sequence, permits the receiver to measure very precisely the time the signal was sent; thus, spread spectrum can be used to time the distance to a transmitter for ranging, or to an object as in the case of a radar reflection. Both applications have been commonly used in the aerospace field for many years.

### Types of Spread Spectrum

There are numerous ways to cause a carrier to spread; however, all spread-spectrum systems can be viewed as two modulation processes. First, the information to be transmitted is applied. A conventional form of modulation, either analog or digital, is commonly used for this step. Second, the carrier is modulated by the spreading code, causing it to spread out over a large bandwidth. Four spreading techniques are commonly used in military and space communications, but amateurs are currently authorized to

use only two of the four techniques.

### Frequency Hopping

*Frequency hopping* (FH) is a form of spreading in which the center frequency of a conventional carrier is altered many times a second in accordance with a pseudo-random list of channels. See Fig. 15. The amount of time the signal is present on any single channel is called the dwell time. To avoid interference both to a conventional user and from conventional users, the dwell time must be very short, commonly less than 10 milliseconds.

### Direct Sequence

*Direct sequence* (DS) is a second form of spreading in which a very fast binary bit stream is used to shift the phase of an RF carrier. This binary sequence is designed to appear to be random (that is, a mix of approximately equal numbers of zeroes and ones), but is generated by a digital circuit. This binary sequence can be duplicated and synchronized at the transmitter and receiver. Such sequences are called pseudo-noise or PN. See Fig. 16. Each PN code bit is called a *chip*. The phase shifting is commonly done in a balanced mixer that typically shifts the RF carrier between 0 and 180 degrees; this is called binary phase-shift keying (BPSK). Other types of phase-shift keying are also used. For example, quadrature phase-shift keying (QPSK) shifts be-

tween four different phases.

DS spread spectrum is typically used to transmit digital information. See Figs. 17 and 18. A common practice in DS systems is to mix the digital information stream with the PN code. The result of this mixing causes the PN code to be either inverted for a number of PN chips for an information bit of one or left unchanged for an information bit of zero. This modulation process is called bit-inversion modulation for obvious reasons. The resulting PN code is mixed with the RF carrier to produce the DS signal.

### Chirp

The third spreading method employs a carrier that is swept over a range of frequencies. This method is called *chirp* spread spectrum and finds its primary application in ranging and radar systems.

### Time Hopping

The last spreading method is called *time hopping*. In a time-hopped signal, the carrier is on-off keyed by the PN sequence, resulting in a very low duty cycle. The speed of keying determines the amount of signal spreading.

A hybrid system is formed by combining two or more forms of spread spectrum into a single system. Typically, a hybrid system combines the best points of two or more spread-spectrum systems. The performance

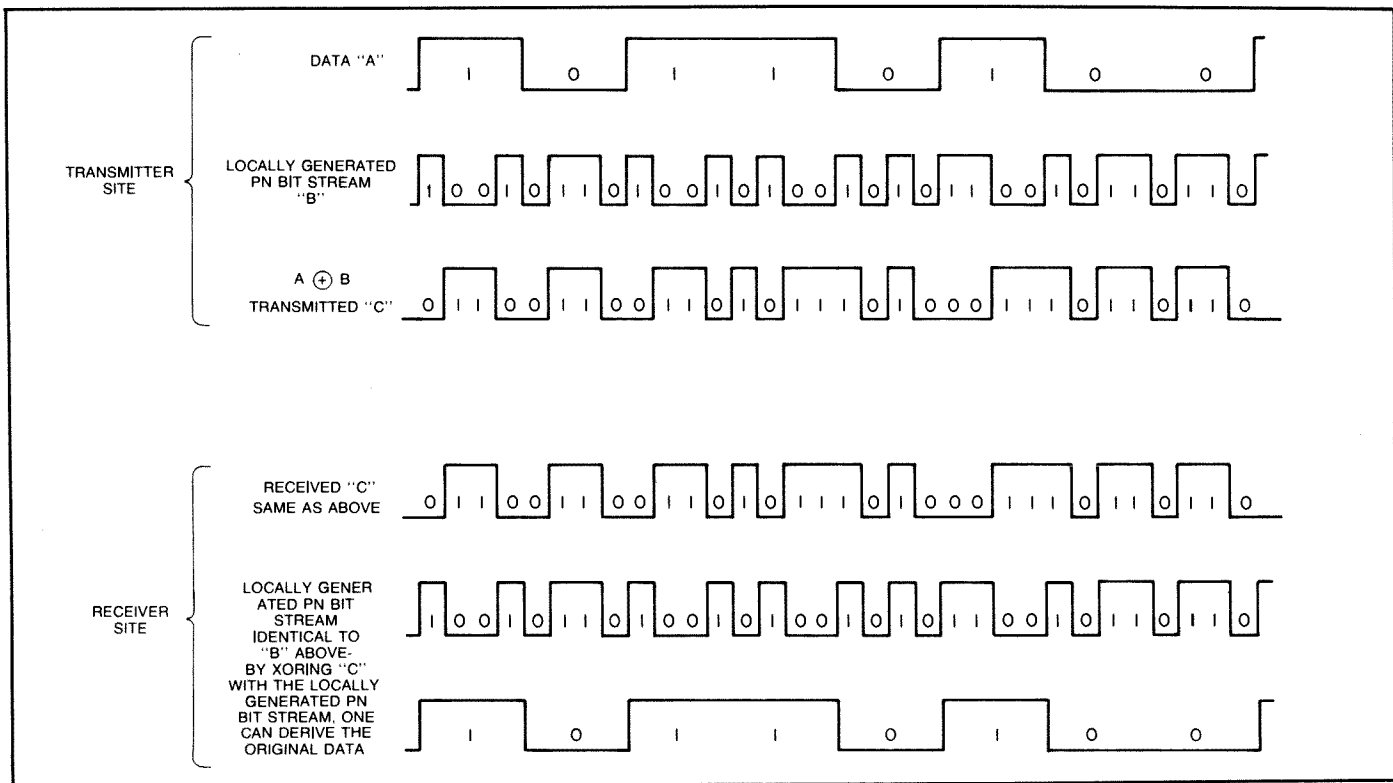

Fig. 17 — In bit-inversion modulation, a digital information stream is combined with a PN bit stream, which is clocked at four times the information rate. The combination is the exclusive-or sum of the two. Notice that an information bit of one inverts the PN bits in the combination, while an information bit of zero causes the PN bits to be transmitted without inversion. The combination bit stream has the speed characteristics of the original PN sequence, so it has a wider bandwidth than the information stream.

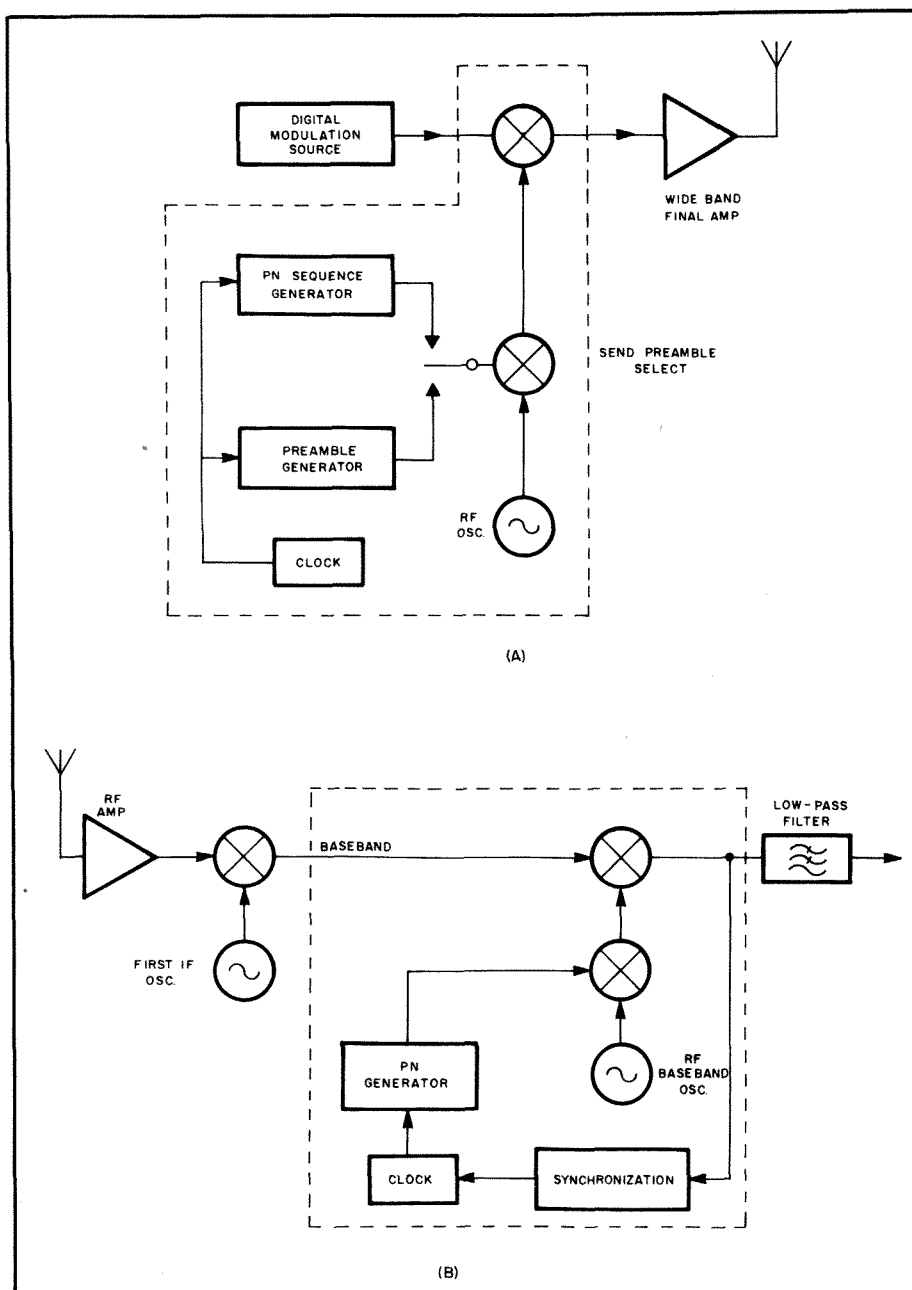

Fig. 18 — The block diagram of a direct sequence transmitter is shown at A. The digital modulation source is mixed with a combination of the PN sequence mixed with the carrier oscillator. The PN sequence is clocked at a much faster rate than the digital modulation; a very fast composite signal emerges as a result of the mixing. The preamble is selected at the start of transmission. Part B shows a direct sequence receiver. The wideband signal is translated down to a baseband (common) frequency. The processes form a correlator, mixing a baseband oscillator with the PN source and then mixing the result against the incoming baseband RF. The synchronization process keeps the PN sequence in step by varying the clock for optimal lock. After mixing, the information is contained as a digital output signal and all interference is spread to noise. The low-pass filter removes some of this noise. Notice that the transmitter and receiver employ very similar designs, one to perform spreading, the other to despread.

of a hybrid system is usually better than can be obtained with a single spread-spectrum technique for the same cost. The most common hybrids combine both frequency-hopping and direct-sequence techniques.

### Spreading Sequences

One of the most important aspects of spread spectrum is the PN sequence used to spread the RF carrier. The spreading sequence determines how well the various

properties of spread spectrum will perform.

The spreading sequence takes a form geared to the type of spread spectrum being used. For frequency hopping, the spreading code is a stream of numbers that represent the channels to which the frequency hopper will travel. In a DS system, the spreading code is a very fast bit stream generated by a digital circuit. In both cases, the PN code is generated to resemble random activity and passes many of the

tests devised to identify random sequences. Codes that have random-like properties are called pseudorandom or pseudonoise sequences.

### Correlation

Correlation is a fundamental process in a spread-spectrum system and forms a common method of receiving signals. Correlation measures how alike two signals are; that is, how similar in appearance they are to each other. The degree of likeness is often expressed as a number between zero and one. A perfect match is typically indicated by a one, while no match may be indicated by a zero. Partial matches yield values between one and zero, depending upon likeness.

In a spread-spectrum receiver, correlation is often used to identify a signal that has been coded with a desired PN sequence. Correlation is usually done with a circuit known as a correlator. A correlator is typically composed of a mixer followed by a low-pass filter that performs averaging. The mixer is where the two signals to be compared are multiplied together. A match yields a high value of output; but if the two mixed signals differ, the output will be lower depending on how different the signals are. The averaging circuit reports the average output of the mixer. This value is therefore the average likeness of the two signals.

In a DS system, the correlator is used to identify and detect signals with the desired spreading code. Signals spread with other PN codes, or signals not spread at all, will differ statistically from the desired signal and give a lower output from the correlator. The desired signal will have a strong match with locally generated PN code and yield a larger output from the correlator.

Notice that the averaging circuit of the correlator gives the average mixer value over time. If noise or interference is present, some of the received signal will be corrupted. After mixing, the interfering signals are spread and resemble noise, while the desired signal is despread and narrowband. The averaging circuit of the correlator then performs a low-pass filter function, thereby reducing the noise while passing the desired narrowband information. This is the heart of the DS interference-rejection process.

Correlation action in an FH system is implemented differently, but the concept is the same. In a frequency-hopping system, the transmitter carrier frequency is being moved about many times a second according to the spreading sequence. The receiver uses the same spreading sequence to follow the transmitter, moving from channel to channel in exact step with the signal. If the receiver is out of step with the signal, it cannot recover the information being transmitted.

FH signals that are under the control of a different PN sequence will be received only randomly, by the chance that both the

desired and undesired PN codes have a channel in common at that moment. Narrowband signals will be visited occasionally by the hopping signal and should not be a cause of interference.

### Despreading and Detection

In DS systems, collapsing the spread-spectrum signal by removing the effects of the spreading sequence is called despreading. If the DS signal is viewed as a signal with two types of modulation impressed on it (one for spreading and the other containing information) then despreading is a demodulation step aimed at the spreading sequence. What remains after the removal of the spreading sequence is the digital information stream.

The despreading process is in fact performed by a correlator containing a mixer and an averaging circuit. In the correlator, like signals produce a high value while unlike signals produce lower values. Thus signals that are the same produce high outputs because the signals reinforce each other. Signals that are unlike cannot reinforce each other and therefore form lower-valued products.

Bit-inversion modulation is detected by this correlator action since an information bit of "1" caused the PN code to be inverted, while a "0" leaves the PN code unchanged. In the correlator, a "0" information bit generates an uninverted PN code stream that closely correlates with the local PN code. Comparatively, a "1" results in a complete decorrelation since the PN code is inverted for this information bit. Through this action the correlator recovers the transmitted information.

Undesired signals in the DS receiver passband are not correlated with the local PN code. Within the correlator, the undesired signals randomly fall in and out of match on a bit-by-bit basis. Here the mixer output resembles noise that is filtered by the correlator low-pass filter. In comparison, the mixer will produce a stream of ones for an uninverted PN sequence or a stream of zeros for the inverted PN sequence.

Thus, the mixing process despreads the desired spread-spectrum signal and causes the undesired signals to spread to noise. It is mainly through the mixing process that interference is rejected within a spread-spectrum receiver.

### Spreading Sequence Generators

Generation of the PN sequence is commonly done with linear-feedback shift registers (LFSR). See Fig. 19. The shift register consists of a number of one-bit memory registers that shift their contents to the right with each clock pulse. New values are introduced at the left-most stage while output is commonly taken from the right-most stage.

The shift register can be used to generate a wide variety of sequences. Generation of a linear sequence is typically done by tapping the values of certain cells and com-

Fig. 19 — Various PN sequences. At A, a three-stage shift register with (1,3) stages tapped. There are seven unique code words, each as wide as the shift register. At B, a three-stage shift register with (2,3) stages tapped produces a somewhat different arrangement of code words. At C, two nonmaximal-length cycles result from the tap choices of (1,2) for the three-stage register. A and B are maximal-length cycles. At D is a three-stage linear feedback shift register. The stages to be combined with exclusive-or to produce feedback are selected by S1-S3.

binning the values using an exclusive-OR (one-bit addition without carry) gate. The combined output is then fed back to the input of the left-most cell.

The LFSR sequence is a repeating sequence whose maximum length is related to the number of stages (N) in the shift register by the equation: length =  $2^N - 1$ . This equation determines the maximum length; not all tap choices produce the longest sequence, however. There are two cases to consider: the maximal-length sequence or m-sequence and the nonmaximal-length or composite sequences.

The length of an m-sequence is given by the equation  $2^N - 1$  and is the longest possible for a given register length. Since the output repeats after producing  $2^N - 1$  bits, the entire sequence can be viewed as a cycle (see Fig. 19).

Initializing the register with any sequence of consecutive bits from the cycle will generate the entire cycle from that point. A cycle is commonly started by an initial value of all zeros followed by a one such as 0000001 for a seven-stage register. Other starting values still generate the same sequence but are said to be phase shifted from the zeros followed by a one initial starting point. A run of bits selected from the sequence that is the same length as the generating shift register is called a code

word of the sequence. All code words from an m-sequence are unique with no repeats, and no code word contains all zeros.

Comparatively, the length of the non-maximal sequence is always shorter than  $2^N - 1$ , and its outputs form a number of distinct short cycles. Code words are not unique for this type of sequence. The non-maximal sequences are called a composite sequence because a composite sequence can be expressed as a combination of shorter maximal-length sequences. The nonmaximal-sequence length is in fact the product of the length of the smaller m-sequences of which it is composed.

Determining whether a given tap sequence will produce a maximal or composite sequence is quite complicated. Most efforts have been carried out by computer search methods, and a number of excellent tables are available for the designer.

A maximal-length sequence seven-stage shift register can easily be built with two ICs, as shown in Fig. 20. A more complete description of this shift register appeared in October 1986 QEX.

### Orthogonality

An important consideration in choosing a sequence for a spread-spectrum system is the amount of statistical similarity a sequence has with conventional signals and

with sequences employed by other spread-spectrum systems. The greater the degree of similarity, the less able the spread-spectrum receiver will be able to reject interference.

The ideal sequence will show a very low correlation when compared with undesired sequences. Moreover, the PN sequence should also have a low correlation with shifted versions of itself. A measure of a sequence's self-correlation is measured by its autocorrelation function (ACF). The ACF measures how much interference will be received from other spread-spectrum units using the same PN sequence but with different starting points within the PN code cycle.

Two code families that have found common usage are the m-sequences and Gold codes. Gold codes are a family of spreading codes generated by exclusive-OR combining the output of two "preferred" m-sequence generators. Many other PN codes can be used with spread spectrum — Dixon lists a number of such codes.

### Synchronization

Synchronization is the most difficult issue for spread-spectrum systems. For a spread-spectrum receiver to demodulate the desired signal, it must be able to synchronize the locally generated PN code reference with the one used by the transmitter. This operation commonly takes place at very high speeds. It is usually viewed as two processes: rough synchronization which searches and acquires the receiver's PN code within one bit or channel of the transmitter's, and fine synchronization which maintains bit or channel dwell timing.

In rough synchronization, the receiver attempts to line up the local PN code as close as possible to the transmitters. There are two methods. The first is called epoch synchronization, in which the transmitter periodically sends a special synchronization sequence. Commonly, this synchronization sequence is a unique short bit sequence chosen because it is easily detected by a simple correlator known as a digital matched filter. This filter consists of a shift register that clocks the received sequence by one bit at a time and compares it against the unique sequence. The output of the matched filter is highest when the unique word is found in the input bit stream.

A second method of synchronization is known as phase synchronization. Here, the receiver attempts to determine which of the  $2^N - 1$  phases the m-sequence could be in. To determine the phase, and thereby the synchronization, at least N bits would have to be received without error. Noisy signals may require more than N bits depending on the signal-to-noise ratio.

PN codes with short cycle times will exhibit several repetitions in a short amount of time. A digital matched filter can be constructed to signal the presence of a unique code word from this short spread-

ing code sequence. This is essentially a form of epoch synchronization.

Longer sequences require more-complex synchronization methods. One method uses a sequence based on the time of day. The receiver sets up a digital matched filter with a value several seconds ahead of the current time and waits for this unique code word to appear. The procedure may be useful for net operations in which stations can enter or leave a net at will.

There are a number of specially developed sequences available for rapid synchronization; however, they fall beyond the scope of this brief discussion.

### Preamble

A preamble signal is commonly sent by the spread-spectrum transmitter immediately before the transmitter enters the spread mode. The preamble signal alerts the receiver to set up its synchronizing procedure to acquire the spread signal. The format of the preamble is different from system to system.

In slow frequency hopping, which has hop rates of less than 100 times a second, a tone appearing on a prearranged frequency or home channel can be used. The falling edge of the tone signals the beginning of hopping. At faster speeds, the precise instant the tone falls may be difficult to measure accurately; other preamble methods are typically employed. One such method calls for the frequency-hopping receiver to examine a specific set of channels continually. A frequency-hopping transmitter would hop on these channels a prearranged number of times to allow the receiver to synchronize.

In direct-sequence transmissions the preamble performs three functions. First, the RF carrier must be acquired by the receiver. This may be done by transmitting a run of all zero bits, which reveals the carrier's center frequency to the receiver. Second, local clock synchronization is established by transmitting a sequence of alternating ones and zeros. The receiver will detect these transitions and derive bit timing from them. Last, the spreading code itself must be synchronized. This can be

done by an epoch synchronization procedure.

Once rough synchronization is established, the spread-spectrum receiver must track and maintain bit timing or channel dwell timing. There are several techniques to accomplish fine synchronization; however, the underlying mechanism is a feedback loop that attempts to minimize the timing error between the transmitter and receiver PN code at the fraction of a bit time.

The feedback loop itself commonly consists of a differencing circuit that calculates the actual bit difference and a feedback path that adjusts the receiver spreading code clock. In one technique called dithering, the spreading-code clock speed is continually rocked back and forth around the synchronization point, causing the receiver to periodically move in and out of synchronization a small amount. The point at which best synchronization is achieved is used to synchronize the receiver clock. Dithering can track a spreading code whose timing may be changing, perhaps because the transmitter is mobile, or in the case of HF spread spectrum, with changes in the height of the reflecting layers of the ionosphere.

### Spectrum of Spread Spectrum

The spectrum of each type of spread-spectrum signal depends on several factors, such as the speed at which the spreading code is clocked, the type of spreading code used, whether frequency hopping or direct sequence is being used, the modulation bandwidth and the method of modulation.

Fig. 21 is the spectrum of a BPSK DS sequence. The signal is symmetric around the center frequency and contains several peaks that are called lobes. The main lobe is maximum at the center frequency but falls rapidly. The point at which the main lobe falls to its low point is called the first zero; subsequent lobes are called spectral sidelobes. The main lobe of a DS signal contains the majority of power, about 90 percent, while the remaining 10 percent is distributed over the side lobes. In many systems, the side lobes are clipped since

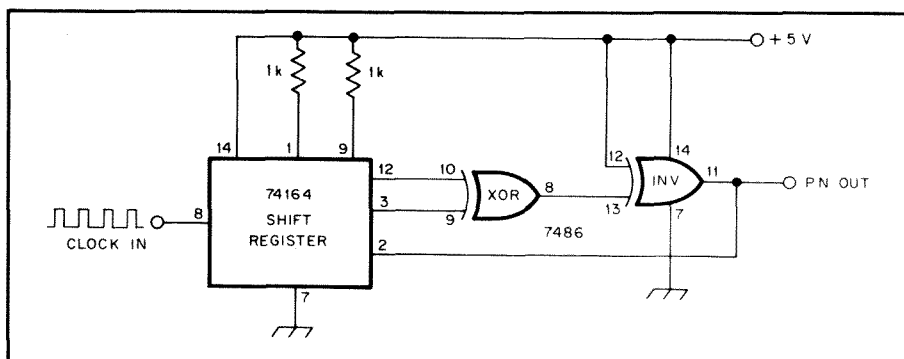

Fig. 20 — A maximal-length sequence seven-stage shift register. A complete description of this circuit appeared in October 1986 QEX.

Fig. 21 — Power vs. frequency for a direct-sequence-modulated spread-spectrum signal. The envelope assumes the shape of a  $\sin^2$  divide by  $x$  curve. With proper modulating techniques, the carrier is suppressed.

Fig. 22 — Power vs. frequency for frequency-hopping spread-spectrum signals. Emissions jump around in pseudorandom fashion to discrete frequencies.

they tend to extend out over a large span of spectrum but carry little of the DS signal's power.

The chip rate determines the overall spread of the DS signal. The overall size of the DS carrier expands as the chip rate increases, while lower chip rates collapse the signal into a nonspread conventional PSK signal. In addition, the chip rate determines the size of the DS main lobe and the location of the zeros. The main lobe is  $2/\text{chip-rate}$  wide, centered about the DS carrier's center frequency. Zeros occur at multiples of  $1/\text{chip-rate}$ , symmetrically on either side of the center frequency.

The spectrum of an FH signal is shown in Fig. 22. The spectrum structure is not as complex as in the DS signal, but depends on the spreading bandwidth and type of modulation used. The spectrum of FH signals consists of a carrier that moves pseudorandomly among many channels. As the speed of hopping increases, channels are visited more frequently with less time spent on a channel. At very fast hopping speeds, significant sidebands can be observed on the FH signal. These sidebands are generated from the pulse-like behavior that the FH signal exhibits at high speeds.

The amount of power the frequency-hopping transmitter delivers per channel is related to how often the channel is visited and the dwell time. The amount of power per channel is greater with fewer channels; conversely, a large number of channels decreases the frequency of visits, hence a lower power per channel. In sum, the larger the number of channels, the lower the signal power per channel.

Last, the method of modulation has a

marked effect on the spectrum of an FH signal. For example NBFM produces a constant-amplitude signal and generates a relatively flat spectrum. SSB, however, emits energy only when there is information to transmit, and hence less energy is emitted overall.

### Near vs. Far-Field Strength

Spread-spectrum signals exhibit some unusual but logical signal effects. Close to the transmitter, a spread-spectrum signal may be observed readily on a conventional receiver; however, at a distance (50-100 miles) the signal may be noticed only with careful measurement. This results in a property called *low probability of intercept* (LPI). Some authors dispute the notion of LPI, saying that spread-spectrum signal energy is in fact intercepted by the receiving station's antennas and receivers; however, there is a low probability that the listener will recognize the presence of spread spectrum. The term *low probability of recognition* (LPR) has been suggested in place of LPI.

This radical difference in signal strength between close-in and distant observers is quite logical. The power of a narrow-band signal is typically concentrated about a center frequency; hence, a conventional narrow-band receiver will be in a position to collect much of the original power subject to path loss. In the DS spread-spectrum case, the same power is distributed over a band of frequencies, giving less power per hertz. A narrow-band receiver can collect only as much of this distributed power as the width of its IF passband; consequently, it registers a much weaker signal. A spread-spectrum receiver's passband is quite wide, allowing it to receive the entire bandwidth containing the spread-spectrum signal. This power is concentrated by the despreading process, making the output signal-to-noise ratio at least equal to the narrow-band signal's.

In the case of FH spread spectrum, a full-power narrow-band carrier is hopped among many channels. The concentrated power of the carrier can be observed at a distance equal to that of a nonhopping narrow-band signal; however, a conventional receiver will only catch a glimpse of the FH signal as it briefly visits the currently received channel.

### FH Frequency Generation

Generation of FH frequencies is commonly done with a synthesizer that operates in one of several ways. The most popular amateur synthesizer technique uses a phase-locked loop (PLL) in which a voltage-controlled oscillator (VCO) generates the frequency of interest. The VCO is typically locked to a multiple of a reference crystal that also determines the channel spacing. The loop is established by sampling the VCO output frequency and dividing it down so its divided frequency matches the reference-oscillator frequency.

The error voltage generated by the phase comparator holds the VCO on the desired multiple of the reference oscillator.

This approach is limited because of the time required for the loop to settle. Various modifications are possible such as replacing the loop's low-pass filter with an active low-pass filter; however, the settling-time problem is difficult to overcome. One successful method has been to use two or more synthesizers, alternately allowing one to settle while using the other to control the current channel. The increase in hopping speed can be found by calculating one minus the number of synthesizers multiplied by the ratio of dwell to settling time.

Another enhancement to the basic PLL synthesizer comes by inserting a D/A converter into the PLL. The D/A takes a digital word from a computer which represents a voltage feed to the VCO. The voltage has been selected so the VCO will produce a desired frequency. The PLL and reference oscillator are used to lock the VCO output to a precise channel; however, the large settling time, attributed mainly to the loop tracking large jumps in frequency, is absent.

A different approach to FH generation can be found in the direct-synthesis approach. Here, a large number of samples are taken of a sine wave that is stored in a ROM. A signal is generated by feeding these samples into a wide-band D/A converter, producing an RF sine wave. The frequency of the RF sine wave is determined by the rate at which the samples are fed to the D/A. A synthesizer of this type is capable of hopping many thousands of times per second and commonly has a resolution of 1-hertz steps.

### Self Policing and Enforcement

Spread spectrum belongs to the general class of wideband signals that are new to many Amateur Radio operators. Traditionally, amateur experience has been with narrow-band signals that can be easily received with conventional receiving equipment. Wideband signals require larger IF bandwidths and some new ways of thinking.

Spread spectrum employs a carrier with a very wide bandwidth. In addition, the carrier is coded with a PN sequence. These two factors make conventional amateur receivers unsuitable for spread-spectrum reception. There are, however, many techniques available that recognize, locate and recover the transmitted information for amateur spread-spectrum users.

Amateur operators are interested in experiments that enhance communications; hence, system parameters are chosen to facilitate communications. Amateur systems are designed so they can be received without too much difficulty. Conversely, military users are interested in signal hiding — to prevent reception by unauthorized users — so military system parameters are

set with this objective in mind.

When a spread-spectrum signal is above the noise level, it can be received with a wideband receiver, and direction-finding techniques can be used to locate the signal source. Interference to other amateur operations or TVI complaints are resolved easily because a signal strong enough to cause interference is far enough above the noise that it can be located with conventional DF techniques. In particular, a directional antenna can be connected to the receiver that is being interfered with. Rotation of the antenna can be used to help locate the source. Moreover, the periodic identification required of all amateur signals can aid the interference-determination process.

Currently, the FCC has authorized two types of spread-spectrum communications for amateurs. The user must identify with narrow-band transmissions on one frequency in the band being used. Alternatively, the station ID may be transmitted while in spread-spectrum operation if the transmission is changed so that CW, SSB or narrow-band FM receivers can be used to identify the station. One proposed identification procedure is for the stations involved to send call signs by on-off keying of the spread-spectrum carrier. This will provide a method to readily identify an amateur spread-spectrum user.

Sometimes it is necessary to monitor the contents of an amateur spread-spectrum transmission to determine if the amateur station is being used properly. This is possible when the signal is above the noise; a wideband receiver and appropriate detector to demodulate the signal are necessary. Other signals in the passband can cause interference, so a sharp beam antenna is required to reduce the effects of the undesired signal.

In DS spread-spectrum transmissions, both the spreading PN code and the transmitted information are digital in nature and are often mixed before being used to modulate the RF carrier. The signal must be despread before the digital information can be recovered; however, the PN code must be known in advance. In the spread-spectrum rules, the FCC defines three m-sequence PN codes for amateur use. These codes are generated by three shift-register configurations: a seven-stage register tapped at stages (7,1); a 13-stage register tapped at stages (13,4,3,1); and a 19-stage register tapped at stages (19,5,2,1). These three sequences are the only ones that amateurs are allowed to use. It is not difficult to test all three sequences against a received amateur DS signal to determine which is in use. Once the sequence is identified and synchronized, the transmitted digital information can be recovered.

#### Amateur SS Experimentation

Spread-spectrum development for jam-proof military communications began in the late 1940s. John P. Costas, W2CRR, was the first person to recognize non-

military applications for SS. Costas presented a paper entitled "Poisson, Shannon, and the Radio Amateur," in the *Proceedings of the IRE* for December 1959. (Poisson and Shannon developed mathematical models for communications systems — all analytical studies in communication theory and information theory are based on their results.)

In this paper, Costas explained that congested band operation presents an interesting problem in analysis that can be solved by statistical methods. He showed that in spite of the bandwidth economy of SSB, there are definite advantages to using very broadband techniques. Costas concluded that broadband techniques would result in more efficient use of the spectrum and an increase in the number of available channels. At the time, Costas' statements were revolutionary, for they challenged the conventional theory that congestion in the radio spectrum can be relieved only by the use of smaller transmission bandwidths.

In 1980, Dr. Michael Marcus of the FCC Office of Science and Technology (OST) suggested that radio amateurs experiment with spread-spectrum modulation techniques. The rationale was that (a) the civil radio services could take advantage of the spread-spectrum pioneering of the military, (b) design of spread-spectrum systems by the private sector was slow because of the high cost of development vs. return on investment, (c) more experimentation was needed in areas such as designing for low-cost and on-the-air testing in congested frequency bands, and (d) radio amateurs could perform useful experiments without the need for either governmental or industrial research and development money.

The Amateur Radio Research and Development Corporation (AMRAD) requested, and the FCC granted, a Special Temporary Authority (STA) to permit spread-spectrum tests in the amateur bands by a small number of amateurs, for one year beginning in March 1981. Under the STA, the first Amateur Radio SS tests were conducted by W4RI in McLean, Virginia and K2SZE in Rochester, New York. Later, WA3ZXW in Annapolis, Maryland ran additional on-the-air tests with K2SZE. The equipment used was capable of hopping over a frequency range up to 100 kHz at rates of 1, 2, 5 and 10 hops per second. RF power output levels of 100 and 500 watts were used into dipole antennas.

These particular radios functioned best at 5 hops per second. This was subjectively judged on the basis of least-bothersome interference from the various signals at the different hopping frequencies. It was observed that frequency hopping was more successful in the presence of heavy CW interference than it was in the presence of heavy SSB interference. In comparison, conventional SSB usually provided better communications than frequency-hopped SSB whenever a single clear channel could be found for the conventional SSB.

However, the conventional SSB could be disrupted by strong interference on that channel. While hampered by cyclic interference when busy frequencies were revisited, the frequency-hopped link could be maintained despite band congestion.

Although the tests were announced beforehand in Amateur Radio publications and on the air from W1AW, no correspondence was received indicating that the frequency-hopping tests either interfered with, or were heard by, other Amateur Radio stations. The only exception was that several amateurs in the Northern Virginia area could recognize the presence of the frequency-hopped transmissions on conventional SSB receivers after learning what the signal sounded like. All were within five miles of W4RI and were able to hear both ends.

AMRAD member Chuck Phillips, N4EZV, built a VHF frequency-hopping radio in 1980. The design consisted of a modified VHF-Engineering scanner board capable of switching between four different crystal oscillators. By tripling the clocking speed, the transmitter was made to hop at 12 hops per second. The oscillators were arranged to operate continuously, and were switched in and out by using high-isolation solid-state switches. Sometime in 1981, the Motorola synthesizer chip showed up in a GLB add-on synthesizer board. N4EZV modified a couple of those boards and managed to reach 15 hops per second. Later that year, N4EZV tried a new synthesizer, working at lower frequencies, by modifying some Heathkit HW2031s. The synthesizer signal was then heterodyned to the desired output frequency. Both the transmitter and receiver were equipped with identical frequency "look-up tables" stored in EEPROMs. When the push-to-talk microphone switch was depressed, a short audio tone burst was transmitted and then decoded at the receiver. At the end of the burst, both transmitter and receiver started hopping to the frequencies pre-loaded in the look-up tables. The hopping rate was derived by dividing down from the reference crystal used to pilot the whole setup. When the microphone push-to-talk button was released at the end of a transmission, another tone was sent, which stopped the hoppers. If the receiver detected only noise, (caused by interference), it would automatically revert to its "home frequency" where it would wait for another transmission. This system seems to operate well up to about 100 hops per second over a 4-megahertz frequency range.

Experiments run by AMRAD in 1985 used a Commodore computer to control the frequency of an ICOM IC-2AT. Very little interference to conventional 2-meter users was created by the spread spectrum transmissions. The signals were inaudible to amateurs involved in regular QSOs, but the transmissions did cause some interference by keying some repeaters that did not have a carrier-sense activation delay.

This interference affected only a few repeaters out of many in the Northern Virginia area, and the problem was cured by removing the appropriate repeater input frequencies from the table of frequencies used in the frequency-hopping scheme.

In 1987, AMRAD member Elton Sanders, WB5MMB used the direct-synthesis oscillator described by Fred Williams in the February 1985 issue of *QST* to build a frequency hopper. The frequency of the direct-synthesis oscillator was determined by a program written by David Borden, K8MMO, to run on an IBM® PC-XT clone, and the oscillator output was limited to frequencies within the 6.15 to 6.25 MHz band. This output was then multiplied by 72, and fed to a 70-centimeter output amplifier. (Hopping rates ranging between 250 and 1000 hops per second were obtained by this method.)

Initial discussions with the FCC concerning the second STA revealed that the FCC Field Operations Bureau was interested in conducting monitoring and direction-finding exercises against amateur spread-spectrum transmissions. In February 1985, FCC personnel conducted a "fox hunt" to find an amateur spread-spectrum transmitter operating at an undisclosed site. Using the standard FCC spectrum analysis van and enforcement car, FCC personnel located the transmitter within 25 minutes, proving that they can DF amateur spread-spectrum transmissions if necessary.

On May 9, 1985, the FCC amended the rules to permit SS operation on the amateur bands above 420 MHz at power output levels no greater than 100-W PEP for domestic communications. These rules became effective in June 1986. The amateur community is working toward establishing

a set of standards for amateur SS operation. The current rules authorize three PN sequences, and both FH and DS are allowed. Hybrid spread-spectrum techniques are not permitted. Bandwidths may be as large as the amateur band of operation. Also, SS users are specifically prohibited from causing interference to other users of the band.

Under these new rules, amateurs engaging in SS operation must maintain a log with the following information.

- 1) A technical description of the transmitted signal.
- 2) Signal parameters including the frequency or frequencies of operation, the chip rate, the code, the code rate, the spreading function, the transmission protocol(s) including the method of achieving synchronization, and the modulation type.
- 3) A general description of the type of information being conveyed; for example, voice, text, memory dump, facsimile, television and so on.
- 4) The method and, if applicable, the frequencies used for station identification.
- 5) The beginning date and ending date of use of each type of transmitted signal.

Throughout 1986 and 1987, AMRAD continued to devise and run experiments designed to bring this spread-spectrum technology within the reach of the average radio amateur, by utilizing only parts and technologies readily available to everyone. In June 1986, AMRAD member Andre Kesteloot, N4ICK, demonstrated a way to derive clock signals (suitable for frequency-hopping) by using broadcast TV signals. The complete experiment is described in October 1986 *QEX*, pp 4-7. With the equipment described, the trailing edge of an audio tone burst was used to derive original

synchronization, and the two sets hopped at 15 hops per second for more than one hour without losing sync.

In September 1986, N4ICK demonstrated an experimental board allowing for the transmission of data with direct-sequence spread spectrum. Synchronization was obtained by using a sliding correlator, fully described in the December 1986 issue of *QEX*. In 1987, N4ICK developed a method for deriving precise clock signals from AM radio broadcast transmitters (see October 1987 *QEX*) which was used in an interesting experiment conducted in January 1988. This experiment (see May 1988 *QEX*) can be summarized as follows (see Fig. 23): N4ICK used two hand-held transceivers operating on 445 MHz. At both sites, PN generators were driven by clock pulses derived from the same AM radio transmitter. These two PN sequences were thus driven by synchronous clocks (it was still necessary to correlate them). At the receiver end, additional pulses were fed into the clock pulse stream, making that clock operate slightly faster than the transmitting clock. The receiver output was connected to a DTMF decoder. In the absence of a valid tone, the receiver clock would continue to operate faster than the transmitter clock. If a DTMF tone was sent at the transmitter for a certain duration of time, there would necessarily be a moment when the transmitting and the receiving PN sequences would be in phase. At that moment, the output of the receiver's doubly balanced mixer would be correlated, and a signal would reach the DTMF decoder. A valid output from the DTMF decoder would be used to slow the receiver clock-pulse generator down to its normal speed. Although the overall synchronization process was relatively slow

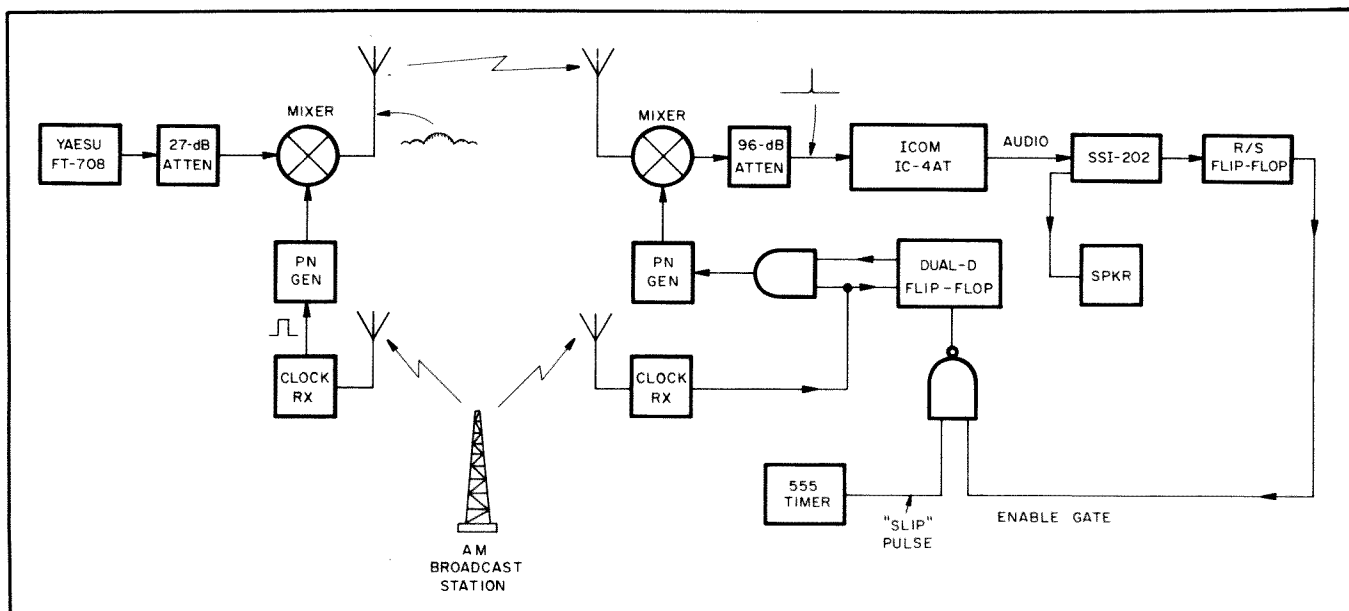

Fig. 23 — Block diagram of one of N4ICK's spread-spectrum experiments.

(it could take up to 45 seconds to reach sync) once synchronization was reached both stations would remain in lock for hours.

The above AMRAD experiments all relied on a clock derived from an external reference. Eventually circuitry will be devised so that it will be possible to derive a clock directly from the received signal. Present investigations at AMRAD are directed toward this goal, and although promising results have been obtained at 144 MHz at power levels of the order of the milliwatt, it remains a formidable challenge to translate these experiments into actual QSOs at 440 MHz. (Interested readers should write directly to AMRAD, PO Box 6148, McLean, VA 22106.)

### Selected SS Bibliography

Reading material on spread spectrum may be difficult to obtain for the average amateur. Below are references that can be mail ordered. Spread-spectrum papers have also been published in *IEEE Transactions on Communications, on Aerospace and Electronic Systems* and *on Vehicular Technology*.

### COHERENT CW

While spectrum management has received much attention in the recent Amateur Radio literature, the problems and possibilities of "more QSOs per kilohertz" were first recognized more than half a century ago. The late Frederick Emmons Terman, 6FT, presented his vision of

narrow-band communications in "Some Possibilities of Intelligence Transmission When Using a Limited Band of Frequencies," published in *Proceedings of the Institute of Radio Engineers*, January 1930.

As early as 1927, the Bell Telephone Company had reported successful experiments with 200-WPM Baudot TTY communications in a 50-Hz bandwidth over undersea cables. The bandwidth reduction resulted from synchronization of the transmitter and receiver.

Technology made giant leaps in the next 45 years. In September 1975 *QST*, Raymond Petit, W6GHM, described the experiments of some radio amateurs with a mode he called "coherent CW." Petit did not acknowledge Terman's paper, so we must conclude that he rediscovered the wheel.

In CCW, the receiver is designed to respond to characteristics that differentiate the transmitted signal from received noise. The transmitted signal has three distinguishing characteristics: precise frequency, precise pulse length and predetermined pulse sequencing (pulse phase).

Fig. 24 shows a block diagram of a CCW system. Notice that a precise frequency standard is used at both the receiver and the transmitter. These frequency standards, synchronized to WWVB (and by WWVB to each other) are the source of the "coherence" in CCW. Digital techniques are used to derive timing signals from the frequency standard; these timing signals set the precise frequency of the transmitter or receiver, determine the basic pulse length and establish the exact instant at which each pulse begins and ends. The transmitter uses these timing signals to generate a signal with pulse length and phase exactly synchronized to the master standard. The

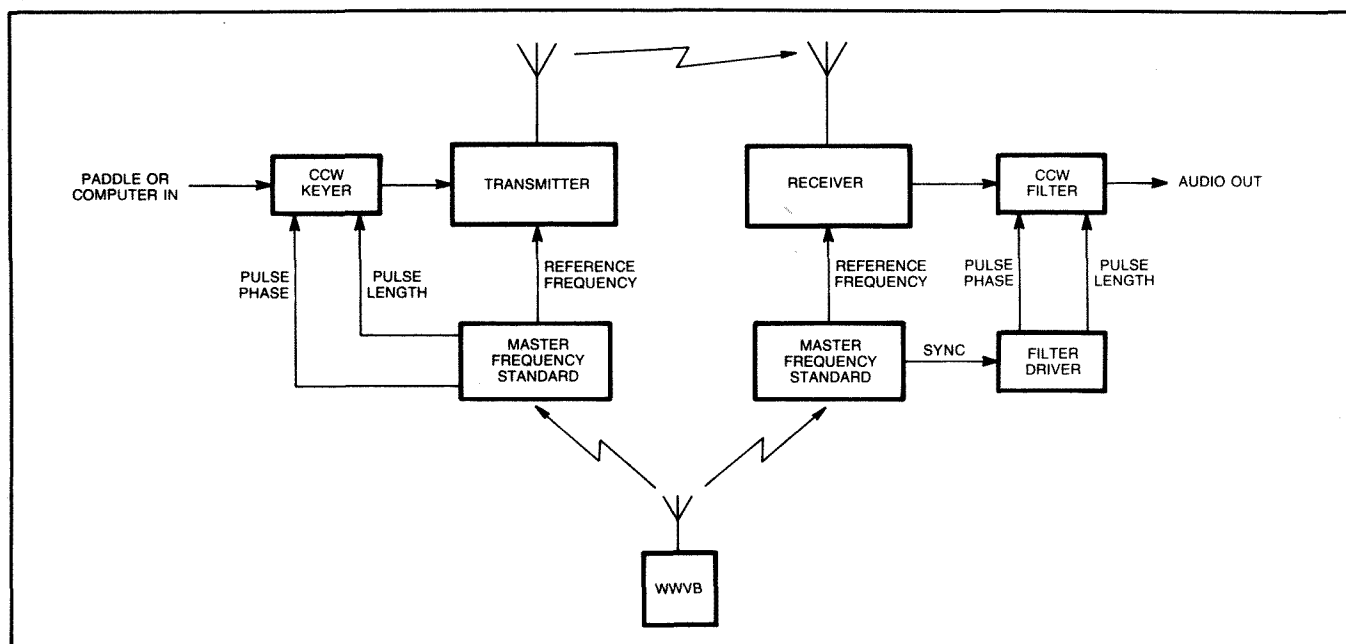

Fig. 24 — Block diagram of a coherent CW system. Precise timing signals from WWVB are used to synchronize the transmitter and receiver.

Fig. 25 — This is the first complete amateur station to be built for coherent CW operation. Assembled by Andy McCaskey, WA7ZVC, it consists of a modified Ten-Tec PM-2 transceiver and homemade modules that provide for the control and processing of signals as required for coherent CW operation.

receiver samples the received signal in pulses synchronized by its master oscillator. In this way, the receiver and transmitter are both synchronized to the same master frequency standard (WWVB) and their operation is "coherent."

Using CCW techniques allows a very narrow filter to be used at the receiver. The bandwidth required for transmitting a radiotelegraph signal is directly proportional to the keying rate. For a speed of 12 WPM the unit pulse length is 0.1 second. Since a dot and a space each require 0.1

second, a string of dots at 12 WPM is a square wave having a fundamental frequency of 5 Hz. To preserve the square-wave characteristic of the emission, an SSB transmission bandwidth of at least 15 Hz is required. Terman reported that with synchronization techniques, the receiver bandwidth could be reduced to 1.5 to 2.0 times the keying rate. In practical CCW systems, a combination of digital and analog techniques is used to produce a filter with a 3-dB bandwidth of 9 Hz, which is within the range predicted by Terman.

Noise bursts and strong adjacent-channel signals result in an occasional extra dot or an elongated dash, but are otherwise unnoticed. At the 12-WPM keying speed used by CCW experimenters, a signal-to-noise ratio improvement of about 20 dB can be realized over the bandwidths typically used for CW. Faster speeds are possible, but the bandwidth must be increased at the expense of signal-to-noise ratio.

To establish CCW contact, one station sends a preamble of dots to allow the receiving operator to synchronize his filter. Experience thus far indicates that once the filter has been synchronized, it usually won't need adjustment for several hours. Fig. 25 depicts a typical CCW station. The early experimenters built their stations around simple QRP equipment to dramatize the communications advantages

offered by the mode and to emphasize the accessibility of the necessary technology. The simple gear requires some add-on circuitry to allow oscillator stabilization.

The more modern synthesized transceivers can be outfitted for CCW more easily — replacing the internal reference oscillator with an external standard is all that's required. To send CCW, the paddle-actuated clock in the keyer must be replaced by a continuous pulse train from the frequency standard. Coordinating one's paddle movements with the "metronome" requires a different keying technique. A buffered keyboard (controlled by the standard) is the ideal CCW sending instrument.

When more stations have CCW capability, the mode may prove highly useful for emergency communications. Another possible use for CCW is in EME work.

# Radio Frequencies and Propagation

Although great advances in understanding the many modes of radio wave propagation have been made in recent years, the number of variables affecting long distance communication are very complex and not entirely predictable. Amateur attempts to schedule operating times and frequencies for optimum results may not always succeed, but familiarity with the nature of radio propagation can improve your chances for success and add greatly to your enjoyment of the pursuit of distant communications. Indeed, personal computer technology now allows the average radio amateur to more accurately assess how day-to-day propagation changes will influence his operation and provides guidelines for frequency and operating time selections.

The sun, ultimate source of life and energy on Earth, influences all radio communication beyond ground-wave or line-of-sight ranges. Conditions vary with such obvious sun-related cycles as time of day and season of the year. Since these conditions differ for appreciable changes in latitude and longitude, and everything is constantly changing as the Earth rotates, almost every communications circuit has unique features with respect to the band of frequencies that are useful and the quality of signals in portions of that band.

Historically, propagation forecasting has been somewhat of a mystery, consisting of a combination of experience, "old wives' tales" and reference manuals. Today the radio amateur has new tools to perform rational frequency management, so frequency selection need not be a hit or miss proposition. In this chapter we will look at sky wave propagation and what influences it. We will also look at some ways that radio amateurs can reduce the mystery and even use the idiosyncrasies of propagation to their advantage.

As we study the various modes and conditions that affect the propagation of radio waves, we need to be sure that we understand the terms being used. Reflection and refraction are two words that often seem to be used interchangeably, even though they describe quite different phenomena.

Fig. 1 — Because radio waves are bent in the ionosphere, they return to Earth far from their origin. Without refraction in the ionosphere, radio waves would pass into space.

Reflection occurs at any boundary between materials with different dielectric constants. Familiar examples with light are reflections from water surfaces, window glass and mirrors. Both water and glass are transparent for light, but their dielectric constants are very different from that of air. Some of the light energy that hits either material will bounce off, or be reflected. Radio waves, having much longer wavelengths than light, are practically unaffected by a thin layer of glass, but their behavior upon encountering water may vary, depending on the purity of the water. Distilled water is a good insulator; salt water is a relatively good conductor.

Depending on their wavelength (or frequency), radio waves may be reflected by buildings, trees, vehicles, the ground, water, ionized layers in the outer atmosphere, or at boundaries between air masses having different temperatures and moisture content. Some of the radio energy will be absorbed in the medium that the wave hits, and some of it may pass into (or through) the material. *Medium* is the term used to

refer to a material that a wave is traveling through.

Refraction is the bending of a wave as it passes from one medium into another. (If the wave is moving in a direction that is at a right angle to the boundary between the two materials, the wave will not be bent.) This bending occurs because the wave travels at a different speed in the new material. If you place a straight object into water at an angle, the object will appear to be bent at the water's surface. (You can try this with a pencil and a glass of water.) This is an example of refraction of light waves.

Radio waves bend when they pass from one material into another in the same way that light waves do. The degree of bending depends on the difference in speeds at which the waves move through the two materials. The amount of bending also increases at higher frequencies. As radio waves travel through different areas of the atmosphere, there may be gradual changes in the speed of the waves as the temperature, air density and levels of ionization change. This will result in a gradual

bending of the radio waves. Most amateur communication on the HF bands depends on this bending of radio waves, so it is a very important concept. Fig. 1 illustrates the refraction of a radio wave as it is returned to Earth.

## THE IONOSPHERE

On frequencies below 30 MHz, long distance communication is the result of refraction (bending) of the wave in the ionosphere. The ionosphere is a region 30 to 260 miles above the Earth's surface where free ions and electrons exist in sufficient quantity to affect the direction of wave travel. Depending on the frequency used and the time of day, the ionosphere can support communications from very short ranges of less than 60 miles (called Near Vertical Incidence Signals — NVIS) to distances of greater than 6000 miles.

Ionization of the upper atmosphere is attributed to ultraviolet radiation from the sun. The result is not a single ionized region, but several layers of varying densities at various heights surrounding the Earth. Each layer has a central region of maximum electron density, which tapers off both above and below that altitude.

### Ionospheric Layers

The ionospheric layers that most influence HF communications are the D, E, E<sub>s</sub>, F<sub>1</sub> and F<sub>2</sub> layers. Of these, the D layer acts as a large RF sponge that absorbs signals passing through it. Depending on frequency and time of day, the remaining four are useful to the communicator.

The D layer, which is between 45 and 55 miles above the Earth, is most pronounced during daylight hours with its ionization being directly proportional to how high the sun is in the sky. Because absorption is inversely proportional to frequency, wave energy in the two lowest amateur bands (1.8 and 3.5 MHz) is almost completely absorbed by this layer during daylight hours. The rise and fall of the D layer dictates the lowest usable frequency (LUF) over a given path. While the effects of the D region are reasonably well known, the exact chemistry and physics of how this layer behaves are not well known or defined.

The lowest region of the ionosphere useful for returning radio signals to the Earth is the E layer. Its average height of maximum ionization is from 65 to 75 miles. The atmosphere here is still dense enough so that ions and electrons set free by solar radiation do not have to travel far before they meet and recombine to form neutral particles. For this reason the layer can maintain its ability to bend radio waves only in the presence of sunlight. Ionization is thus greatest around local noon, and it practically disappears after sundown.

A nomadic cousin of the E region is called sporadic-E. The sporadic-E region consists of relatively dense patches of ionization that literally drift around about 70 miles above the Earth. The effects of

sporadic-E become confused with those of other types of ionization on the lower amateur frequencies, but they stand out above 21 MHz and into the VHF region. This is especially true during a solar minimum, when the bands above 21 MHz are rarely open. Sporadic-E propagation is covered in more detail in the VHF/UHF section of this chapter.

The region of ionization mainly responsible for long distance communication is the F-layer. Its altitudes of ionization range from about 90 to 250 miles. It ionizes very rapidly at sunrise, reaching peak electron density early in the afternoon at the middle of the propagation path. The ionization decays very slowly after sunset, reaching the minimum value just before sunrise. This period, called the pre-sunrise depression, is the time when the lowest MUF over the path is observed. During the day, the F region is split into two layers, the F<sub>1</sub> and the F<sub>2</sub>.

The F<sub>1</sub> layer is not an important propagation medium. Its refracting heights are between 90 and 120 miles, and it forms and decays in direct correlation to the passage of the sun. After sunset, the F<sub>1</sub> layer decays and it is replaced by a broadened F<sub>2</sub> layer.

The F<sub>2</sub> region is the primary medium supporting amateur HF communications. The thickness of this layer ranges from a relatively thin layer (50 miles) during the day to a broad layer (95 miles) centered at about 200 miles above the Earth at night. The daytime layer is very dense and has very complex combination/recombination characteristics. Because of Earth/ionospheric geometry, the maximum range of a single hop off the F<sub>2</sub> region is about 2500 miles. Fig. 2 summarizes day to night variations of the layers and shows approximate heights for them.

Traditionally, the ionospheric layers are characterized as nice, well behaved, stratified layers. Recent technologies allow very high resolution measurements of the medium to be made, and indicate that the ionospheric layers are in continual horizontal and vertical motion. You should recognize that these variations are a routine situation that must be dealt with. Periods of very high solar activity, with their disruptions, may present the opportunity for unusual propagation periods. Use the winter solar minimum periods to exploit 160 meters and use the uncertainties of HF propagation to your advantage.

Fig. 2 — The ionosphere consists of several layers of ionized particles at different heights above the Earth. At night, the D and E layers disappear and the F<sub>1</sub> and F<sub>2</sub> layers combine to form a single F layer.

## Virtual Height

An ionospheric layer is a region of considerable depth, but for practical purposes it is convenient to think of each layer as having a definite height. The height from which a simple reflection from the layer would give the same effects (observed from the ground) as the effects of the gradual bending that actually takes place is called the virtual height of that layer. Fig. 3 illustrates the virtual height of a layer in the ionosphere.

The virtual height of an ionospheric layer for various frequencies is determined with a variable-frequency sounding device (called an ionosonde) that directs energy vertically and measures the time required for the round-trip path. As frequency is increased, a point is reached where no energy will be returned from the ionosphere. The frequency where radio waves will penetrate a layer of the ionosphere instead of returning to Earth is called the critical frequency for that layer.

## TYPES OF PROPAGATION

Depending on the propagation method, radio waves can be classified as ionospheric waves (sky waves), tropospheric waves or ground waves (surface waves). The sky wave is that main portion of the total radiation leaving the antenna at angles above the horizon. Without the refracting (bending) qualities of the ionosphere, these signals would be lost in space. The tropospheric wave is that portion of the radiation kept close to the Earth's surface as a result of bending in the lower atmosphere. This normally occurs only at the higher HF or lower VHF frequencies. The ground wave is that portion of the radiation directly affected by the surface of the Earth. It has two components — an Earth-guided surface wave and the space wave. Ground wave propagation is vertically polarized and its absorption increases with frequency. At equal power levels, a surface-wave signal over water will travel tens to hundreds of miles farther than the same signal over land.

Nearly all amateur communication on frequencies below 30 MHz is by means of sky waves. After leaving the transmitting antenna, this type of wave travels from the Earth's surface at an angle that would send it out into space if its path were not bent enough to bring it back to Earth. As the radio wave travels outward from the Earth, it encounters ionized particles in the ionosphere. The ionosphere refracts (or bends) radio waves, and at some frequencies the radio waves are refracted enough so they return to Earth at a point far from the originating station.

Because most amateur operation uses the sky wave mode of propagation, let's try to visualize just what is happening over a typical HF circuit. The *propagating bandwidth* is that band of frequencies which are propagating or usable between two points. This band of frequencies is

Fig. 3 — The virtual height of a layer in the ionosphere is the height at which a simple reflection would return the wave to the same point as the gradual bending that actually takes place.

constantly changing throughout the day, as shown in Fig. 4. This day/night plot (called a diurnal plot) shows how the band of propagating frequencies changes as a function of day and night. The upper boundary is called the maximum usable frequency (MUF).

The MUF is a function of how highly ionized the F region is. During a solar maximum, the MUF can rise above 30 MHz during daylight hours. Fig. 4 was developed from data taken during a solar minimum between Cycles 20 and 21.

The low-frequency boundary on Fig. 4 is called the lowest usable frequency (LUF). The LUF is a function of absorption, signal-to-noise ratio, power and transmission mode. Note that the change in LUF directly correlates to the movement of the sun over the path, and peaks at noon at the midpoint of the path. The vertical axis in Fig. 4 shows relative signal amplitude. The irregularity is due to the various multihop

modes that can exist between the MUF and LUF.

It is important to remember that the definitions of LUF and MUF are for a specific communications path. For example, the frequencies useful for communications from your location to western Europe may be quite different from the frequencies useful for communications to Australia.

## Multihop Propagation

When an ionospherically propagated wave returns to Earth, it can be reflected upward from the ground, travel again to the ionosphere, and be refracted to Earth. This process can be repeated several times under ideal conditions, leading to very long distance communications. Ordinarily, ionospheric absorption and ground-reflection losses exact tolls in signal level and quality, so multiple-hop propagation usually yields lower signal levels and more distorted modulation than single hop

Fig. 4 — Day-Night characteristics of typical HF sky wave propagation. (Courtesy Naval Ocean Systems Center.)

Fig. 5 — Ray trace of 14.0-MHz Signals over the Hawaii to California path at 1800 UTC on February 21, 1973. (Courtesy Naval Ocean Systems Center.)

signals. There are exceptions, however, and under ideal conditions even communications using long path signals are possible. These signals are discussed in the next section.

The same signal can be propagated over a given path via several different numbers of hops. The example in Fig. 5 shows that 2-hop, 3-hop, and 4-hop  $F_2$  modes existed at the same time for a 14-MHz path. The receiver sees these three signals all arriving at very slightly different times, causing signal distortion. On CW, there is no real problem. On SSB, the signal is distorted slightly due to time spreading. On RTTY the distortion may be sufficient to degrade the signal to the point that it is useless. Table 1 shows the difference in these three signals, their angles of arrival, path loss and signal to noise ratio. This data was prepared using a sophisticated computer analysis known as Advanced PROPHET, a FORTRAN program run on mainframe computers.

#### Ionospheric Sounder Data

Propagation conditions between the MUF and the LUF are explored by using an ionospheric sounder. The oblique incidence sounder ionogram shown in Fig. 6 was produced by sweeping the entire HF spectrum at the transmitter and measuring all the propagating energy at the receiver. This shows that six modes of propagation

exist for this particular path, each covering a different part of the HF spectrum with some overlapping. For example, if 14.3 MHz was used on this path between California and Hawaii, the signal would arrive at three discreet times, one signal from the two-hop mode, one from the three-hop mode and one from the four-hop mode. At the receiver, the three modes arriving at slightly different times would cause distortion of the signal. It is im-

portant to note that the characteristics seen in Fig. 6 are unique to this HF sky wave circuit. Each and every different point to point circuit will have its own mode structure as a function of time of day. This means that every HF propagation problem has a totally unique solution.

Depending on how intensely the F region is ionized, an HF signal will be refracted in the ionosphere and reflected from the ground several times before it gets to the

Fig. 6 — HF oblique sounder ionogram. This photo shows a typical chirpsounder measurement on a 2500-mile path during midmorning in March.

desired receiver. Fig. 5 illustrates how several propagation modes can be expected, depending on the vertical radiation pattern of the transmitting antenna. The height of the refracting medium, the distance to the desired receiver and the signal radiation angle from the transmitter create the geometry of a path. If a receiver is too close to the transmitter, it will be in the skip zone where the ionosphere is not ionized enough to return very steep angles of signal radiation. There may be places along the transmission path where the signal cannot be heard because of the *geometry* of the situation, even though the transmission frequency is between the MUF and LUF.

The higher the radiation angle, the deeper into the ionosphere the signal penetrates before it is bent back to Earth. In order to establish a successful communications link, a user must choose a frequency between the MUF and the LUF, the antenna radiation pattern must meet the path geometry requirements and the signal must exceed the required signal-to-noise ratio.

## SOLAR PHENOMENA

Man's interest in the sun is older than recorded history. Records of sunspot observations translatable into modern terms go back nearly 300 years. The first complete sunspot cycle to be recorded began in 1755, and is referred to as Cycle 1. Sunspot cycles have been numbered consecutively since then, so we are at the beginning of Cycle 22 now.

Current observations are statistically smoothed, or averaged, to maintain a

continuous record in the form of the International Sunspot Number (ISN). (The smoothed number means that it is an average of the values for six months before and six months after the month in question — International Sunspot Numbers are always six months behind the present date. For example, the latest ISN on January 1, 1987 is for July 1, 1986.) This number is the basis for traditional HF propagation predictions. In this section we will describe solar radiation, how it influences propagation, and how radio amateurs can use the knowledge of its day to day variations to select operating times and frequencies.

## Solar Cycles

The periodic rise and fall of sunspot

numbers have been studied for many years before their correlation with radio-propagation variations was well known. Sunspot cycles average 10.7 years in length (we usually refer to an 11-year cycle), but have been as short as 7.3 years and as long as 17.1 years. The highs and lows also vary greatly. Cycle 19 peaked in 1958 with a sunspot number of over 200. Cycle 20, of more average intensity, reached 120 in 1969, while Cycle 21 rose to 164.5 in December 1979. By contrast, one of the lowest cycles, Cycle 14, peaked at only 60 in 1907. Several cycle lows, called solar minimums, have not reached zero levels on the International scale for any appreciable period, while little or no activity occurs for several months during the minimum of some cycles. (The minimum period of 1985 is a good example of a time with almost no activity.)

What does this mean to the radio amateur? At solar maxima (high sunspot number), the radiation from all the active regions around the sunspots makes the ionosphere capable of returning higher-frequency radio signals to the Earth instead of allowing them to pass through. This means that frequencies up to 40 MHz or higher are usable for long-distance communication. During periods of minimum solar activity, the amount of radiation is reduced, and frequencies above 20 MHz become unreliable for long-distance communication on a day-to-day basis. For this reason, the radio amateur needs to be aware of the current solar cycle status.

Navy scientists have recently revised their predictions for the next five solar cycles, which extends through the year 2040. Fig. 7 shows a graph of sunspot numbers for Solar Cycles 17 through 21 and predictions for Cycles 22 through 26. Fig. 7 predicts that the next solar maximum will occur around 1991-1992 with a peak level similar to Cycle 20 (1969).

Note that the cycles do not have a sine-wave shape. The rise time is shorter than the decay time, but neither is clearly defined. There are no absolutes at either solar maximum or solar minimum; periods

Fig. 7 — Solar sunspot number prediction for the next five sunspot cycles, from the Naval Ocean Systems Center.

of extremely intense activity have been observed from a single sunspot region during solar minimum. This can cause short term openings on the higher frequencies. Large numbers of very low radiation sunspots have also been observed during a solar maximum. This allows unexpected propagation conditions to exist at either solar minimum or maximum.

A useful indication of overall solar activity is the solar-flux index, a number associated with the measured radio noise coming from the sun at 2800 MHz. One such measurement is made at 1700 UTC daily in Ottawa, Canada. The latest solar-flux index is transmitted at 18 minutes past every hour by WWV. Because it is a current measurement for solar activity, it tends to be more useful in predicting propagation conditions than the more traditional sunspot number. This solar flux, more commonly called *10.7-cm solar flux* or *2800-MHz solar flux* can be directly related to sunspot number using the chart shown in Fig. 8.

### Solar Radiation

There are two types of radiation from the sun that influence propagation; electromagnetic and particle emissions. The electromagnetic emissions include X-rays, ultraviolet (UV) and extreme ultraviolet (EUV). Each has an impact on a different part of the ionosphere. Particle emissions come in two forms: high-energy particles (high-energy protons and alpha particles) and low-energy particles (low-energy protons and electrons). The different types of radiation travel from the Earth to the sun at different speeds and have varying effects on sky-wave propagation. The time it takes for each type of radiation to travel from the sun to the Earth is shown in Fig. 9. The effects that result from each radiation type are also summarized in this figure.

EUV ionizes the ionospheric F region and is always present at some level. During solar maxima, the increased number of active regions on the sun provide for increased EUV, which in turn increases the F-region ionization and allows the use of higher frequencies for long-distance communication. UV and X-ray emissions ionize the D region, which absorbs HF energy. During solar flares, UV and X-ray emissions increase, causing increased signal loss on those HF circuits facing the sun. It takes about 8 minutes for electromagnetic emissions from the sun to travel to the Earth, because this energy travels at the speed of light.

High-energy particle radiation travels more slowly than light, and reaches the Earth from 15 minutes to several hours after a large solar flare. The high-energy particle emissions cause much higher absorption in the Earth's polar regions. They also create a radiation hazard to satellite systems and personnel orbiting the Earth in spacecraft. The lower-energy

Fig. 8 — Relationship between the smoothed mean sunspot number and the 2800-MHz (10.7-cm) solar flux. In the low months of a solar cycle, flux values run between about 66 and 86. Intermediate years may see values of 85 to 150. The peak years of Cycle 21 brought readings between 140 and 380, in 1979 and 1980.

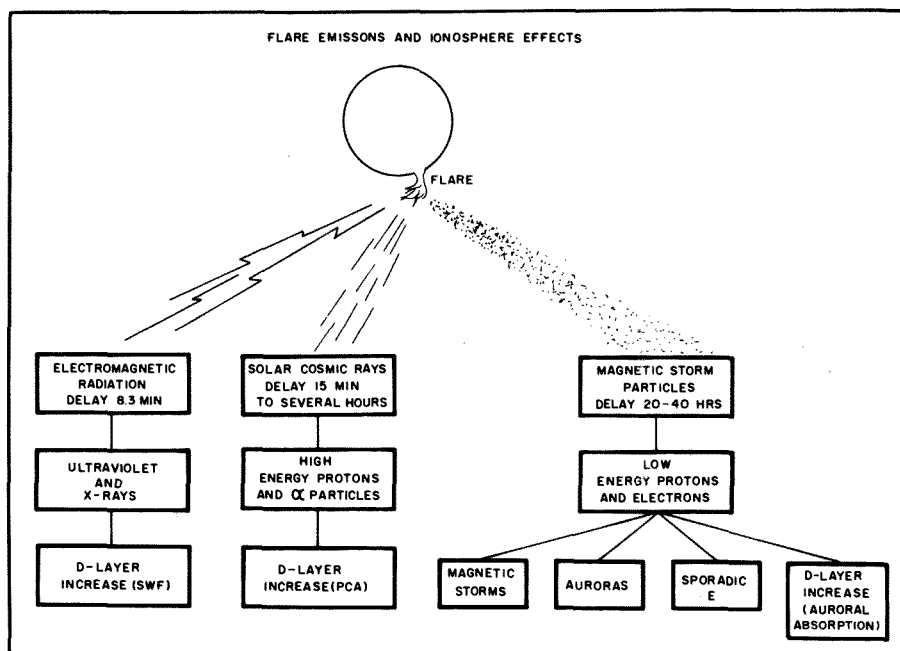

Fig. 9 — A summary of solar flare emissions and ionospheric effects.

particles travel even more slowly, and cause magnetic disturbances, auroras, sporadic E and increased polar-region absorption. These emissions arrive 20 to 40 hours after

the solar flare has occurred.

It is difficult to compare solar activity to ionospheric variations because the chief ionizing agent for the F-region of the

ionosphere is EUV, and this makes the traditional solar sunspot number (SSN) a poor short-term measure of solar effects on the ionosphere. EUV must be measured from satellite platforms, so relatively little is known about its variability. There is evidence, however, that EUV varies in much the same way as the 10.7-cm solar flux, which can be measured at ground level. For that reason, the solar-flux index is replacing the SSN as a short-term measure of solar activity.

Variations in the level of solar radiation can be gradual, as with the passage of sunspot groups and other long-lived activity centers across the solar surface, or the variations may be sudden and abrupt as with solar flares. Because the rotational period of the sun is approximately 28 days, a region of high activity that is on the disk (that region of the sun facing the Earth) will be in a position of affecting propagation for about 14 days and then hidden for about 14 days. A very active region can produce short-term radio blackouts for the full 14 days of its transit across the disk, but will produce particle events such as magnetic storms and radio aurora for only about seven days. Generally, until an active region crosses the central meridian of the sun, a strong flare cannot produce particle disturbances on the Earth because of the Earth/sun trajectory.

### Absorption

When moving particles collide with each other, the one with the higher amount of energy will generally lose some of its energy to the other particle. As a radio wave travels through the ionosphere, it bumps into ionized particles and gives up some of its energy to those particles as it sets them in motion. The ionosphere absorbs energy from the radio wave. Such absorption is greater at lower frequencies, because it is proportional to the inverse square of frequency. It is this absorption that defines the LUF of a circuit. (If too much energy is absorbed, the signal will be too weak to be heard at the receiving station.)

Absorption is caused by X-rays and UV radiation, and it increases markedly during solar flares and auroral disturbances. A signal loses strength every time it passes through the D region. For this reason, a three-hop signal will have more path loss, (or less signal at the destination), than a one-hop signal. In order to minimize absorption, amateurs should use frequencies as near the MUF as possible.

### EFFECTS OF THE EARTH'S MAGNETIC FIELD

The ionosphere has been discussed thus far in terms of simple bending, or refraction. An understanding of long-distance propagation must also take the Earth's

magnetic field into account. Because of the Earth's magnetic field, the ionosphere is a double refracting medium that breaks up plane-polarized waves into what are known as the ordinary and extraordinary waves. This helps to explain the dispersal of plane polarization encountered in most ionospheric communication.

The Earth's magnetic field is disturbed by particle emissions from the sun. These emissions cause the magnetic field to vary, which causes loss of signals in the polar regions, increased aurora, and depleted F<sub>2</sub> ionization (called an ionospheric storm) at mid latitudes. Ionospheric storms tend to migrate southward from the polar region 36 to 72 hours after the actual solar event. This depletion of the ionosphere tends to affect most ham bands, resulting in generally poor operating conditions for the duration of the storm. An indicator of this happening is when the K index, also announced at 18 minutes after the hour on WWV, rises above 3. Remember that K<sub>p</sub> is on a scale of 0 to 9, with 9 being the most disturbed condition.

### RADIATION ANGLE AND SKIP DISTANCE

The lower the angle above the horizon at which a wave leaves the antenna, the less refraction in the ionosphere is required to bring it back to Earth, or to maintain useful signal level. This is the basis for the emphasis on low radiation angles in the pursuit of DX on the HF and VHF bands.

Some of the effects of radiation angle are illustrated in Fig. 10. The high-angle waves from the transmitter, T, are bent only slightly in the ionosphere, and so pass through it. The wave at a somewhat lower angle is just capable of being returned by the ionosphere.

This radiation angle from the antenna is called the critical angle. Radiation at angles more than the critical angle above the horizon will not be returned to Earth, while radiation at angles less than the critical angle will be returned farther from the transmitter. In daylight, if the frequency is low enough, the wave might be returned by the E layer, reaching R1. If the wave is returned from the F<sub>2</sub> layer, it will reach R2. The higher angle wave is returned closer to the transmitting point, T, than is the lowest-angle wave, which returns to R3.

The area between R1 and the outer reaches of the ground wave, near the transmitter, is called the skip zone. If R2 is at the shortest distance where energy returned from the F<sub>2</sub> layer is usable, the distance between R2 and T is the skip distance. The actual distances to both R1 and R2 depend on the ionization density, the radiation angle at T, and on the frequency in use. Table 2 has been included to provide a general indication of typical F-layer skip distances for the MF and HF amateur bands. Because these values can vary as much as 50% or more, they should be used only for comparison.

Fig. 10 — A vertical incidence sounder, shown at the left, measures virtual height and critical frequency of the F<sub>2</sub> layer. The transmitter, T, is shown radiating signals at four different angles. At the two highest radiation angles, the waves pass through the ionosphere after slight refraction. The lower-angle wave is returned to Earth by the E layer, if the frequency is low enough, at a maximum distance of 1250 miles. The signals are returned from the F<sub>2</sub> layer at a maximum distance of about 2500 miles, depending on the radiation angle. The signal may make a double hop, going from R2 to R4, which is beyond the maximum single-hop range. The lowest-angle wave reaches the maximum practical single-hop distance at R3.

# LONG-PATH PROPAGATION

Propagation between any two points on the Earth's surface is usually by the shortest direct route, which is a great-circle path between the two points. A great circle is an imaginary line drawn around the Earth, formed by a plane passing through the center of the Earth. The diameter of a great circle is equal to the diameter of the Earth. You can find a great-circle path between two points by stretching a string tightly between those two points on a globe. If a rubber band is used to mark the entire great circle, you can see that there are really two great-circle paths. See Fig. 11.

Fig. 11 — A sketch of the Earth, showing a great-circle path between two stations. Short-path and long-path bearings are shown from the northern-hemisphere station.

One of those paths will usually be longer than the other, and it may be useful for communications when conditions are favorable. Of course you must have a beam antenna that you can point in the desired direction to make effective use of long-path propagation. The station at the other end of the path must also point his or her antenna in the long-path direction to your station to make the best use of this propagation mode.

The long- and short-path directions always differ by  $180^\circ$ . Since the circumference of the Earth is about 24,000 miles, short-path propagation is always over a path length of less than 12,000 miles. The long-path distance is 24,000 miles minus the short-path distance for a specific communications circuit. For example, if the distance from Gordon, Pennsylvania to the Canary Islands is 3510 miles at a bearing of  $85^\circ$ , then the long-path circuit would be a distance of 20,490 miles at a bearing of  $265^\circ$ . (Chapter 16 of *The ARRL Antenna Book* contains information about distance and bearing calculations.)

Normally, radio signals propagate most effectively along the great-circle path that provides the least absorption. Since the D layer of the ionosphere is most responsible for signal absorption, the amount of sunlight that the signal must travel through

helps determine how strong the signals will be. So at times, your signal will be stronger at the receiving station when it travels over the nighttime side of the Earth.

For paths less than about 6000 miles, the short-path signal will almost always be stronger, because of the increased losses caused by multiple-hop ground-reflection losses and ionospheric absorption over the long path. When the short path is more than 6000 miles, however, long-path propagation will usually be observed either along the "gray line" between darkness and light, or over the nighttime side of the Earth.

While signals will generally travel best along the great-circle path, there is often some deviation from the exact predicted beam heading. Ionospheric conditions can cause radio signals to reflect or refract in unexpected ways. So it is always a good idea to rock your rotator control back and forth around the expected beam heading, and listen for the peak signal strength. If the strongest signals come from a direction that is significantly different from the great-circle headings, then we say the signals are following a crooked path. Anytime signals are not following a great-circle path, you have crooked-path propagation.

## GRAY-LINE PROPAGATION

The *gray line* (sometimes called the *twilight zone*) is a band around the Earth that separates the daylight from darkness. Astronomers call this the terminator. It is a somewhat fuzzy region because the Earth's atmosphere tends to diffuse the light into the darkness. Fig. 12 illustrates the gray line around the Earth. Notice that on one side of the Earth, the gray line is coming into daylight (sunrise), and on the other side it is coming into darkness (sunset).

Propagation along the gray line is very efficient. One major reason for this is that the D layer, which absorbs HF signals, disappears rapidly on the sunset side of the gray line, and it has not yet built up on the sunrise side.

The gray line runs generally north and south, but varies as much as  $23^\circ$  either side of the north-south line. This variation is caused by the tilt of the Earth's axis relative to its orbital plane around the sun. The gray line will be exactly north and south at the equinoxes (March 21 and September 21). On the first day of summer in the northern hemisphere (June 21) it is tilted a maximum of  $23^\circ$  one way and on the first day of winter (December 21) it is tilted a maximum of  $23^\circ$  the other way. Fig. 13 illustrates the changing gray-line tilt. The tilt angle will be between these extremes during the rest of the year.

One way to describe the gray-line tilt is as an angle measured upward from the equator, looking east. It is important to note that if you measure an angle greater than  $90^\circ$  at sunrise, then you will measure an angle less than  $90^\circ$  at sunset on the same day. For example, at sunrise on April 16 the gray line makes an angle of approximately  $99^\circ$  with the equator, and at sunset it makes an angle of  $81^\circ$ . This means you can work into a different area of the world using gray-line propagation at sunset than you could at sunrise on the same day.

## FADING

Changes in signal level, called fading, arise from a variety of phenomena, some natural and some man-made. Two or more parts of the wave may follow different paths, causing phase differences between wave components at the receiving end. Total field strength may be greater or less than the strength of one component. This

Fig. 12 — The gray line is a transition region between daylight and darkness. One side of the Earth is coming into sunrise, and the other side is just past sunset.

Fig. 13 — The angle with which the gray line crosses the equator depends on the time of year, and on whether it is at sunset or sunrise. A shows that the gray line is perpendicular to the equator twice a year, at the vernal equinox and the autumnal equinox. B indicates that the north pole is tilted toward the sun at an angle of 23° at the summer solstice, and C shows that it is tilted away from the sun at an angle of 23° at the winter solstice. These changes in the sun's position relative to the poles cause the gray line to shift position.

type of fading is called multipath interference. Fluctuating signal levels also result from the changing nature of the wave path, as in the case of moving air-mass boundaries in tropospheric propagation on the higher frequencies. Man-made sources of fading include reflections from aircraft and ionospheric discontinuities produced by exhaust from large rocket engines. Routinely, most fading comes from natural sources, like multipath interference.

Under some circumstances the wave path may vary with very small changes in frequency, so that modulation sidebands arrive at the receiver out of phase, causing mild or severe distortion. Called selective fading, this problem increases with signal bandwidth. Double-sideband AM signals suffer much more from selective fading than do single-sideband, suppressed-carrier signals.

## THE SCATTER MODES

Much long-distance propagation can be described in terms of discrete reflection, though the analogy is never precise since

true reflection would be possible only with perfect mirrors in a vacuum. All electromagnetic wave propagation is subject to scattering influences that alter idealized patterns to a great degree. The Earth's atmospheric and ionospheric layers, and objects in the wave path all act to scatter the signal. Strong returns are thought of as reflections and weaker ones as scattering, but both influence wave propagation. Scatter modes are useful in many kinds of communications.

## Forward Scatter

We describe the skip zone as if there were no signal heard between the end of useful ground-wave range and the points R1 or R2 of Fig. 10. But actually, the transmitted signal can be detected over much of the skip zone, if sufficiently sensitive devices and methods are used. A small portion of the transmitted energy is scattered back to Earth in several ways, depending on the frequency.

*Tropospheric scatter* extends the local communications range to an increasing degree with frequencies above 20 MHz, becoming most useful in the VHF range. *Ionospheric scatter*, mostly used from the height of the E region, is most marked at frequencies up to about 60 or 70 MHz. *VHF tropospheric scatter* is usable within the limits of amateur power levels and antenna techniques, out to nearly 500 miles. *Ionospheric forward scatter* is discernible in the skip zone at distances up to 1200 miles or so.

A major component of ionospheric scatter is that contributed by short-lived columns of ionized particles formed around meteors entering the Earth's atmosphere. This can be anything from very short burst of little communications value to sustained periods of usable signal level, lasting up to a minute or more. Most common in the early morning hours, meteor scatter can be an interesting adjunct to amateur communication at 21 MHz and higher, especially in periods of low solar activity. It is at its best during major meteor showers.

## Backscatter

A complex form of scatter is readily observed when working near the maximum usable frequency for the F layer over a particular path at a given time. The transmitted wave is refracted back to Earth at some distant point, which may be an ocean area or a land mass. A small portion of the transmitted signal may be reflected back into the ionosphere toward the transmitter when it reaches the Earth. The reflected wave helps fill in the skip zone, as shown in Fig. 14.

*Backscatter* signals are generally very weak, but there is no evidence of fading. Voice signals have a hollow, barrel-like sound. With optimum equipment, such signals are usable at distances from just beyond the reliable local range out to several hundred miles. Under ideal conditions, backscatter communications are possible over 3000 miles or more, though the term *sidescatter* is more descriptive of what happens on such long paths.

The scatter modes contribute to the usefulness of the higher parts of the DX spectrum, especially during periods of low solar activity when the normal ionospheric modes are often less available.

## MF AND HF PROPAGATION

The amateur MF and HF bands (160 meters being the sole MF entry) are distinct in their propagation characteristics, but share one common bond: All of them utilize the F<sub>2</sub> layer for the primary mode of long-distance propagation. Here are capsule descriptions of propagation on those bands:

- The 1.8-MHz (160-meter) band suffers from extreme daytime D-layer absorption. Therefore, the top band is primarily useful at night. Only daytime signals entering the ionosphere at very high angles will be returned to Earth, which limits communications to 75 miles or so. At night, the D layer dissipates, and lower-angle signals are propagated. Under these conditions, communications over several thousands miles are possible.

Fig. 14 — When radio waves pass into the ionosphere, some energy may be scattered back into the skip zone.

Another factor affecting propagation on this band is noise, both atmospheric and man-made. Since warm weather and noise producing thunderstorms often go hand-in-hand, winter is generally the best time to work DX on 160 meters.

- The 3.5-MHz (80-meter) band is similar to the 1.8-MHz band in many respects. Daytime absorption is significant, but not quite as extreme as on 1.8 MHz. Remember, absorption is proportional to the inverse square of frequency so as frequency is increased, D-layer effects are reduced. Typically, daytime communications range is approximately 250 miles. During nighttime, signals are often propagated halfway around the world. As on 1.8 MHz, atmospheric noise tends to be high, making winter the most attractive season for the 80 meter DXer.

- The 7-MHz (40-meter) band is the lowest frequency band that shows appreciable skip distance (see Table 2). During the day, a typical amateur station can cover a radius of approximately 500 miles. At night, reliable world-wide communications are possible on 40 meters. Atmospheric noise is somewhat more diminished, compared to 80 meters, but still presents a problem during the summer months. However, 40-meter DX signals are often of sufficient amplitude to override even high-level summer static. It is for that reason that 40 meters is the lowest-frequency amateur band considered reliable for year-round DX communication.

**Table 2**

**Approximate Minimum Skip Distances for the Amateur MF and HF Bands**

Band	Noon*	Midnight*
160 m	0	0
80 m	0	0
40 m	0	300 mi
30 m	200 mi	600 mi
20 m	500 mi	1000 mi
17 m	750 mi	(Daytime only)
15 m	800 mi	(Daytime only)
12 m	1000 mi	(Daytime only)
10 m	1200 mi	(Daytime only)

\* Local time at the midpoint of the path.

- The 10-MHz (30-meter) band is unique in that it shares characteristics of both daytime and nighttime bands. Communications of up to 1000 miles are typical during the daytime, with this distance extending halfway around the world at night. In this respect, the band is generally useful on a 24-hour basis. During a solar minimum, the MUF on some DX paths may drop below 10 MHz during the night. Under these conditions, 30 meters adopts the characteristics of the higher frequency, daytime bands described below. Because the 30-meter band is a transitional band that is usable during both the day and night

for long-distance communications, it also shows the least variation in conditions during the swing between solar maximum and solar minimum.

- The 14-MHz (20-meter) band is traditionally regarded as the amateurs' primary long-haul DX band. Regardless of our position in the 11-year cycle, 20 meters can be depended on for world-wide propagation during the daylight hours. During solar maximum periods, 20 meters will often stay open to distant locations throughout the night. Skip distance is appreciable on the band (see Table 2), and is always present to some degree. Atmospheric noise is not too much of a consideration on the band, even in the summer. Because of its popularity, 20 meters tends to be very congested during the daylight hours.

- The 18-MHz (17-meter) band is similar to the 15-meter band in many respects, but the effects of fluctuating solar activity are not quite as pronounced. During the years of high solar activity, 17 meters is reliable for daytime and early-evening long-range communications, often lasting well after sunset. During moderate years, this band resembles 15 meters, opening during sunlight hours and closing shortly after sunset. During solar minimum periods, 17 meters will open to middle and equatorial latitudes, but only for short periods during midday on north-south paths.

- The 21-MHz (15-meter) band has characteristics similar to the 20-meter band, but shows greater fluctuation with changing solar activity. During peak years, 15 meters is reliable for daytime long-distance communications, and will often stay open well into the night. Twenty-four hour, continuous DX operation is possible on occasion, although less often than on 20 meters, and only during the peak of a solar maximum. In periods of moderate solar activity, 15 meters is basically a daytime-only band, closing shortly after sunset. During solar minimum periods, 15 meters may not open at all except for infrequent north-south transequatorial circuits. Sporadic-E is observed occasionally in early summer and mid-winter, although this is not common and the effects are not as pronounced as on the higher frequencies.

- The 24-MHz (12-meter) band offers propagation that combines the best of the 10- and 15-meter bands. While 12 meters is primarily a daytime band during low and moderate sunspot years, periods of solar activity find the band open well after sunset, often over long paths. During years of moderate solar activity, 12 meters opens to the low and middle latitudes during the daytime hours, but seldom remains open after sunset. Unlike 10 meters, periods of low solar activity seldom cause this band to go completely dead except at higher latitudes. Occasional daytime openings, especially in the lower latitudes, have been noted over north-south paths. The main sporadic-E season on 24 MHz lasts from late spring through summer and short

openings may be observed in mid-winter.

- The 28-MHz (10-meter) band is well known for extreme variations in characteristics. During a solar maximum, long-distance propagation is so efficient that very low powers can produce very loud signals half-way around the globe. DX is abundant with very modest equipment. Many a new DXer has been born on 10 meters. During a solar maximum, 10 meters is a daytime band remaining open a few hours past sunset. During periods of moderate solar activity, 10 usually opens only to low and transequatorial latitudes around midday. During a solar minimum, 10 meters is completely dead all day. There are anomalous openings (scatter, meteor burst, sporadic-E) during solar minimum that go unnoticed because most of the amateur population has migrated to lower frequencies. This lack of occupancy tends to enhance the dead appearance of the band. Amateurs who specialize in 10-meter operation make contacts throughout the solar cycle.

Sporadic-E propagation is fairly common on 10 meters, occurring between late April and early August. This phenomenon occurs regardless of F-layer conditions, and provides single-hop communications out to 1300 miles and multiple-hop communications to 2600 miles.

## PROPAGATION PREDICTION

To the casual amateur, part of the thrill in ham radio is the challenge of finding an open frequency to operate on. The more serious amateur, interested in DX or traffic handling, wants to know, in advance, the band that will have the best stability and hearability in the geographical area of interest. Today's amateur has several options in planning his or her operations. These include the propagation charts in *The ARRL Operating Manual*, home computer predictions and the use of HF reference beacons. When these three techniques are used together, they can take a lot of mystery out of propagation conditions.

In December 1982, *QST* published the first MUF prediction program, called MINIMUF, for the ham microcomputer. Response throughout the amateur community was positive and the program quickly proliferated through many of the common home computers. In the early 1980's, a new generation of synthesized, digital HF receivers and transceivers provided full coverage for the entire HF spectrum causing renewed interest in shortwave broadcast listening. With these resources, today's enlightened amateur can schedule his or her operating activities using the long term predictions in *The ARRL Operating Manual*, fine tune them with short term predictions from a home computer and calibrate these signal predictions made in advance with on-the-air observations of known shortwave broadcasters. *The ARRL Operating Manual* contains an extensive set of propagation prediction charts, with

complete information on how to use them to make a realistic estimate of propagation conditions

### MUF Prediction on the Home Computer Using MINIMUF

Traditionally, the prediction of the maximum usable frequency (MUF) is done by a large, complex computer model, nominally consisting of 150,000 to 200,000 bytes of computer code. In 1977, a simple model was developed to emulate the dynamics of the MUF and its sensitivity to solar activity and seasonal changes. Simple is an understatement; the original model consisted of 80 BASIC program steps! Since that time many military, industrial, commercial and amateur HF users have successfully implemented and used MINIMUF.

The initial verification was done by comparing the prediction with oblique-incidence sounder data, which is the only way to observe the actual MUF boundary. The original sounder data base encompassed 196 path months (4074 test points) of observed maximum usable frequencies measured over 23 different HF sounder paths. MINIMUF was found to have an rms error of  $\pm 3.8$  MHz. Current users find it useful from 2 MHz to 50 MHz for MUF predictions out to 6000 miles. However, accuracy degrades for ranges of less than 250 miles.

As one can imagine, anything as simple as MINIMUF invites tinkering. Numerous experimenters have made attempts to improve the model with such features as adding an E and  $F_1$  layer (MINIMUF is a single-layer model), changing constants to reflect local conditions and giving it more diurnal variation. All of these revisions, when compared against oblique-sounder data, degraded the accuracy and made the program more complicated. These exercises only serve to prove the old adage, "If it works, don't fix it." The version of MINIMUF described in this *Handbook* was first published in 1978 (see bibliography) and is still the principal version in use.

#### Application Tips

As solar activity varies, user interest in updating the MINIMUF prediction to reflect current conditions also increases. The updating method found to be most effective was to vary the sunspot number input parameter as a function of the 10.7-cm solar flux. Because of the lag in F-layer response to a rapid increase in solar activity, it is best to use either a 5-day, 15-day or 90-day running average of the 10.7-cm flux. The type of application will determine which is best. The 5-day mean is a short term, more dynamic input while the 90-day mean is more applicable for long term planning. As was indicated in a previous section, the current 10.7-cm solar flux information is transmitted at 18 minutes after every hour on WWV. The

conversion curve to translate the 10.7-cm flux to sunspot number is shown in Fig. 8.

Two other points are borne out by field testing. First, MINIMUF is an F-region approximation. Any intervention by E-region modes of propagation, either as multiple E or EF modes is not predictable by MINIMUF. Such operational situations are proving to represent only a small percentage of the total, however. Second, MINIMUF has the greatest accuracy within the one- and three-hop ranges between 300 miles and 7500 miles. Predictions for transmission paths longer than this should be used with some caution.

Many different conversions of the original MINIMUF article in December 1982 *QST* were received by the Program Exchange Department at ARRL Headquarters. In addition, input was received from numerous amateurs on its modification (see bibliography). A printed listing of an enhanced version of MINIMUF, which includes an LUF-plotting routine, written in BASIC, is available for \$2.00 and an SASE. Write to ARRL Headquarters, Technical Department, 225 Main St., Newington, CT 06111. A table of benchmark data is also included to assure correct program loading.

#### Further Notes on Use

After you have a version of MINIMUF running on your computer, there are countless ways to test it yourself. One method is to observe the passage of the MUF through a frequency where a reference transmitter operates. WWV, WWVH and many shortwave broadcast signals will do nicely. Normally,  $\pm 30$  minutes from the predicted time of MUF passage (either the signal appears or goes away) is a good window.

Do not be misled by comparing your prediction to published propagation charts. All HF prediction programs do well on some paths and poorly on others (and not necessarily the same paths). Comparing one HF prediction program against another is not valid unless all of the assumptions within the models are approached in the same manner. Such comparisons should be used with great caution because they are comparisons of apples and strawberries.

For those that are interested in calculating the Frequency of Optimum Transmission (FOT) and the LUF, two simplified approaches may suffice. The FOT may be approximated by  $0.85 \times \text{MUF}$ . This is the frequency which is supposed to have the highest circuit reliability and the least multipath interference. The LUF may be approximated by  $0.25 \times \text{MUF}$  with an upper limit of 12 MHz. After sunset, the LUF drops to below 2 MHz and remains there until sunrise.

#### HF Reference Beacons

Another method to assist day to day operations is establishing the habit of monitoring an HF signal that regularly

appears on the same frequency, at the same time, and maintains fairly constant transmission characteristics. The three most available sources of signals to monitor are (1) HF shortwave broadcasters; (2) time standard stations; and (3) amateur beacons. This method of environmental assessment is made even more attractive by a new generation of fully synthesized, programmable, general-coverage receivers, both in receive-only and transceive configurations. In general, these receivers are state-of-the-art, sensitive and very frequency agile. Stations to be monitored may be programmed in any order, with almost any revisit time and dwell time. This allows you to browse around the HF spectrum. You will find a whole new world of interesting signals; commercial, military, business, affairs of state, and broadcast; signals most amateurs don't normally listen to.

The most prolific HF signals that are useful for routinely monitoring conditions are those of the high power broadcasters. Most countries in the world maintain a foreign radio service to transmit news, music, and shows of interest from that country to large portions of the world. These signals, mostly double-sideband, amplitude modulation (AM), have 100 kW or more power and use large directive antennas. It takes effective radiated powers such as this to maintain broadcast quality at HF. The main advantage of using these signals is that they transmit on several frequencies simultaneously, allowing a listener to estimate the propagating bandwidth (LUF to MUF) over a given reference path.

While there are literally hundreds of these stations, some of the stronger signals to listen for in the USA are Voice of America (USA), BBC (UK), Radio Moscow (USSR), Deutsche-Welle (FDR), Radio Canada International (Canada), Radio South Africa (South Africa), Radio Nacional Buenos Aires (Argentina) and Radio Australia (Australia). The most useful frequencies to listen on are 5.9 to 6.2 MHz, 7.1 to 7.3 MHz, 9.5 to 9.775 MHz, 11.7 to 11.975 MHz, 15.1 to 15.4 MHz, 17.7 to 17.9 MHz, 21.4 to 21.75 MHz, and 25.6 to 26.1 MHz.

To use these broadcasts, one must establish routine listening habits and monitor the same transmissions at the same time each day. Develop a sense of trend. Are conditions improving or degrading? Monitoring several different signals can yield a picture of global conditions. Are BBC's signals making it over the Polar regions? Can you hear both the 6.0-MHz and 9.5-MHz signals from Radio Australia, and are they of equal strength?

In general, there are HF broadcasters in almost any part of the world an amateur may be interested in. If they are properly monitored they can provide an excellent assessment of global propagation. You should be aware, however, that the programs from some of these stations are transmitted from locations outside of the

country. So if you hear a program from Radio Moscow, the Voice of America or the BBC, for example, you may not be listening to radio signals coming from Moscow, the USA or Great Britain. Shortwave listener's guides can help you learn where the broadcast is coming from, and program schedules from the stations themselves will often list the transmitter locations.

#### *Time Standard Stations*

Probably the most-used HF reference signals are the US Time Standard signals from WWV and WWVH. The Department of Commerce, National Oceanic and Atmospheric Administration, Environmental Research Laboratories in Boulder, Colorado maintain time standard stations at Ft. Collins, Colorado (WWV) and Kauai, Hawaii (WWVH). These stations transmit standard "tic" pulses each second, with minute announcements and special bulletins periodically (such as 10.7 cm flux at 18 minutes after the hour on WWV). WWV transmits on 1.5, 5, 10, 15 and 20 MHz with very precise time and frequency stability. For amateurs in the

USA, these signals are very useful to calibrate MINIMUF predictions, and to assess day to day communications reliability over one-hop ranges.

#### *Amateur Beacon Stations*

Historically, DX clubs and experimenters have established special interest beacons to alert DX operators of new long-range openings. There is a series of beacons on 10 meters between 28.1 and 28.5 MHz. These beacons have been established to alert 10-meter fans to long-haul openings or a sporadic-E opening. DX organizations are now establishing beacons at lower frequencies to optimize their DX-search operations.

Because these beacons emerge and leave the ham bands on a sporadic basis, no attempt will be made to list them here. A current list of beacons appears periodically in the "How's DX?" column of *QST*.

## **THE WORLD ABOVE 50 MHz**

### *50-54 MHz (6-meter band)*

The lowest amateur VHF band shares many of the characteristics of both lower and higher frequencies. Nearly every form of propagation is found in the 6-meter band, which contributes greatly to its popularity. In the absence of any favorable propagation conditions, well-equipped 50-MHz stations work regularly over a radius of at least 300 miles, depending on terrain, power, receiver capabilities, and antenna. Weak-signal tropo scatter allows the very best stations to make 500-mile contacts nearly any time. Weather effects may extend the normal range by a few hundred miles, especially during the summer months, but true ducting is rare.

Sporadic-E is probably the most common and certainly the most popular form of propagation on the 6-meter band. Single-hop E-skip openings may last many hours for contacts in the 400- to 1300-mile range, primarily during the spring and early summer. Multiple-hop sporadic-E provides transcontinental contacts several times a year, and contacts between the U.S. and South America, Europe, and Japan via multiple-hop E-skip have been made on rare occasions. During the peak of the 11-year sunspot cycle, world-wide 50-MHz DX is possible due to F<sub>2</sub> reflections during daylight hours. F<sub>2</sub> backscatter provides an additional propagation mode for contacts up to 2000 miles when the maximum usable

frequency (MUF) is just below 50 MHz.

Other types of ionospheric propagation make 6 meters an exciting band. Aurora effects in the temperate latitudes allow contacts up to 1300 miles and sometimes farther. In the early morning hours, meteor scatter is a popular 50-MHz endeavor that provides brief contacts in the 500- to 1300-mile range. Transequatorial spread F (TE) creates 50-MHz paths as long as 5000 miles across the equator during peak sunspot years. Propagation by field-aligned irregularities (FAI) may provide additional hours of contacts at distances of up to 1300 miles.

### *144-148 MHz (2-meter band)*

Ionospheric effects are significantly reduced at 144 MHz, but they are far from absent. F-layer propagation is unknown except for TE, which is responsible for the current 144-MHz terrestrial DX record of nearly 5000 miles. Sporadic-E occurs as high as 144 MHz about a tenth as often as at 50 MHz, but the maximum single-hop distance is the same, about 1300 miles. Sporadic-E contacts greater than 2000 miles have been made across the U.S. and Canada, as well as in Europe, but they are rare.

Auroral propagation is quite similar to that found on 50 MHz, except that signals tend to be weaker and more distorted. Meteor-scatter contacts up to 1300 miles are limited primarily to the periods of the

great annual meteor showers. Contacts have been made via FAI on 144 MHz, but its potential has not been fully explored.

Tropospheric effects improve with increasing frequency, and 144 MHz is the lowest VHF band at which weather plays an important propagation role. Weather-induced enhancements may extend the normal 300- to 400-mile range of well equipped stations to 500 miles and more, especially in the summer and early fall. Tropospheric ducting makes it possible for contacts of more than 1200 miles over the continent and at least 2500 miles over water.

### *220-225 MHz (135-cm band)*

The 135-cm band shares many characteristics with the 2-meter band. The normal working range of better 220-MHz stations is nearly as good as comparably equipped 144-MHz stations. The 135-cm band is slightly more sensitive to tropospheric effects, but ionospheric modes are more difficult to use.

Aurora and meteor-scatter signals are somewhat weaker than on 144 MHz. Sporadic-E contacts on 220 MHz are extremely rare, but may become more common as use of this band increases. TE is well within the possibilities of 220 MHz, and FAI may be possible as well. Increased activity on the 135-cm band will surely reveal the extent of 220-MHz propagation modes.

### 420-450 MHz (70-cm band)

The lowest amateur UHF band marks the highest frequency on which ionospheric propagation is commonly observed. Aurora signals are much weaker, and the range is usually less, than on 144 or 220 MHz. Meteor scatter is much more difficult than on the lower bands because signals are significantly weaker and of much shorter duration. Although sporadic-E and FAI are unknown as high as 432 MHz and probably impossible, TE may be useful. TE reception has been observed on this band, but no two-way 432-MHz contacts have been reported.

Well equipped 432-MHz stations can expect to work over a radius of at least 300 miles in the absence of any propagation enhancement. Tropospheric bending is more pronounced at 432 MHz and provides the most frequent and useful means of extended range contacts. Tropospheric ducting supports contacts of 1000 miles and farther over land and more than 2500 miles over water. The current 432-MHz terrestrial DX record of 2550 miles was accomplished via ducting over water. Reflections from airplanes, mountains and other stationary objects may also be useful adjuncts to 70-cm propagation.

### 902-928 MHz (33-cm band) and Higher

Ionospheric modes of propagation are nearly unknown in the UHF bands above 902 MHz. Aurora scatter may be within the range of amateur power levels at 902 and 1296 MHz, but signal levels will be well below those at 432 MHz. Doppler shift and distortion will be considerable, and the signal bandwidth may be quite wide. No

other ionospheric propagation modes are likely.

Almost all extended distance work in the UHF and microwave bands is accomplished with the aid of tropospheric enhancements. The frequencies above 902 MHz are very sensitive to changes in the weather. Tropospheric ducting is more common than in the VHF bands. Contacts up to 2500 miles have been made on 1296 MHz and more than 1000 miles on 10 GHz by ducting. Limited amateur experiences have shown that well equipped stations can work reliably up to 200 miles and farther on 1296 MHz, but in general, normal working ranges are reduced with increasing frequency. Above 10 GHz, attenuation caused by atmospheric water vapor and oxygen become the most significant limiting factors in long-distance communications.

### VHF/UHF/MICROWAVE PROPAGATION MODES

There is a wide variety of means by which radio frequencies above 50 MHz may be propagated beyond the horizon. They can be divided into three broad categories: propagation modes involving the ionosphere, such as  $F_2$ -layer reflections and meteor scatter; those limited to the troposphere (the weather-producing lower 10 miles of the atmosphere), such as ducting; and reflections from large solid objects, such as mountains and airplanes. Each of these is discussed in turn. Table 3 summarizes the characteristics of these propagation effects.

### $F_2$ -Layer Reflections

Most long-distance radio communications in the HF range (3-30 MHz) result from one or more reflections in the  $F_2$ -layer of the ionosphere, 150 to 250 miles in altitude. The MUF of  $F_2$  reflections reaches only as high as 70 MHz during the peak years of the sunspot cycle, making 6 meters the only useful VHF band for this type of communications. The skip distance at 50 MHz is usually between 1800 and 2500 miles, but multiple-hop paths make world-wide DX possible. The MUF may exceed 50 MHz during a three-year period around the peak of the 11-year sunspot maximum. The last solar peak was in 1980 and the next maximum is predicted for 1991. World-wide 50-MHz  $F_2$  DX may be possible as early as the winter of 1989.

The MUF follows seasonal and daily cycles as well as the sunspot cycle. Even during the peak sunspot years, the MUF may reach 50 MHz only during the fall and winter. 50-MHz  $F_2$  contacts are generally completed only over paths entirely in daylight, since the MUF declines sharply after sunset. Stations running as few as ten watts and simple antennas can work  $F_2$  DX easily.

It is possible to forecast  $F_2$ -layer MUF using the 2800-MHz solar flux values broadcast by WWV at 18 minutes after each hour. The MUF approaches 50 MHz when the solar flux rises to 175 (equivalent to a sunspot number of 125). The MUF can also be followed more directly from the high frequencies through 50 MHz, using a suitable general coverage receiver.

Just before the MUF reaches 50 MHz  $F_2$  backscatter is often evident on the

**Table 3**  
**VHF, UHF and Microwave Propagation**

Propagation Mode	Useful Frequency	Expected Distances	Most Favorable Times
<b>Ionospheric Modes</b>			
$F_2$ Backscatter	50 MHz	100-2000 miles	Daylight during peak sunspot years
$F_2$ Reflection	50 MHz	1800-12,500 miles	Daylight during peak sunspot years
Transequatorial Spread-F	50-432 MHz	2000-5000 miles	1700-2200 local time during peak sunspot years
Sporadic-E	50-220 MHz	400-2500 miles and farther	Anytime, but common late mornings and early evenings May-July and December-January
Field-aligned irregularities	50-144 MHz, possibly 220 MHz	400-1300 miles	During and just after intense sporadic-E sessions
Aurora	50-432 MHz, possibly to 1296 MHz	100-1300 miles	Anytime, but more likely late afternoons during March-April and September-October
Meteor scatter	50-432 MHz	500-1300 miles	Early mornings, especially during one of the great annual meteor showers
<b>Tropospheric Modes</b>			
Line of sight	50 MHz-300 GHz	1-200 miles	Anytime, but cold weather better for bands above 10 GHz
Tropo scatter	50 MHz-300 GHz	50-500 miles	Anytime
Rain scatter	1296 MHz-10 GHz	5-100 miles	During periods of heavy rain
Ducting	50 MHz-300 GHz	100-2500 miles and farther	During favorable weather conditions
<b>Reflection and diffraction by solid objects</b>			
Stationary object reflections	144 MHz-300 GHz	5-150 miles	Anytime. Objects must be above the radio horizon for both stations
Airplane reflection	144 MHz-300 GHz	5-400 miles	During passage of an airplane between two stations
Earth-moon-earth reflection	50 MHz-2304 MHz, and higher	100-12,500 miles	When the moon is at perigee and within sight of the two stations
Knife-edge diffraction	432 MHz-300 GHz	5-200 miles	Anytime. Hills or mountains must lie between the two stations

6-meter band. Signals transmitted in the direction of an F<sub>2</sub> region with an MUF just below 50 MHz will be scattered back toward the transmitter over a wide area. Backscatter may provide another useful way of making contacts up to 2000 miles and farther. Backscattered signals are generally weak and have a characteristic hollow or ringing sound to them. High power and directive antennas are usually required to make backscatter contacts.

### Transequatorial Spread-F

Discovered in 1947, *transequatorial spread-F (TE)* propagation makes it possible for contacts between 3000 and 5000 miles across the equator on frequencies as high as 432 MHz. Stations attempting TE contacts must be nearly equidistant from the geomagnetic equator. Many contacts have been made on 50 and 144 MHz between Europe and South Africa, Japan and Australia, and the Caribbean region and South America. Fewer contacts have been made on the 220-MHz band. TE signals have been heard on 432 MHz, but so far, no two-way contacts have resulted.

Unfortunately, for most continental U.S. stations, the geomagnetic equator dips south of the geographic equator in the western hemisphere, making only the most southerly portions of Florida and Texas within TE range. TE contacts from the southeast part of the country may be possible with Argentina, Chile, and even South Africa.

Limited experience with TE indicates that it peaks between 1700 and 2200 local time during years with high sunspot numbers. Signals have a rough aurora-like note. High power and large antennas are not required to work TE, as stations with 100 watts and single long Yagis have been successful.

The physics of TE propagation is not well understood, but a popular hypothesis suggests that during peak sunspot years, the F<sub>2</sub> layer near the equator bulges and intensifies slightly. The MUF late in the day may increase to 1.5 times its normal level 15° either side of the magnetic equator. VHF and UHF signals are refracted twice over the magnetic equatorial region at angles that normally would be insufficient to reflect the signals back toward Earth. The geometry is such, however, that two shallow reflections in the F<sub>2</sub> layer can create north-south terrestrial paths up to 5000 miles.

### Sporadic-E

"Short skip," long familiar on the 10-meter band during the summer months, also affects the VHF bands as high as 220 MHz. *Sporadic-E*, as it is more properly called, propagates 50- and 144-MHz signals between 400 and 1300 miles. Multiple-hop sporadic-E has supported contacts up to 5000 miles on 50 MHz and more than 2000

miles on 144 MHz. The first confirmed 220-MHz sporadic-E contact was made in June 1987, but such contacts are likely to be very rare in the future.

Although sporadic-E is most common during the months of May, June and July, with a less-intense season at the end of December and early January, it can appear anytime. It is apparently unaffected by the sunspot cycle, and its association with the weather is highly uncertain. It is most likely to occur from 0900 to 1200 and again early in the evening between 1700 and 2000 local time.

Efforts to predict sporadic-E openings have not been highly successful, probably because its causes are not well understood. Studies have demonstrated that small and unusually dense patches of ionization in the E-layer, between 50 and 60 miles in altitude, are responsible for sporadic-E reflections. These sporadic-E clouds, as they are called, may form suddenly, move quickly from their birthplace, and dissipate within a few hours.

Sporadic-E clouds also exhibit an MUF that can be followed from 28 MHz through the 50-MHz band and higher. When the skip distance on 28 MHz is as short as 300 or 400 miles, it is a good sign that the MUF has reached 50 MHz. Contacts at the maximum sporadic-E distance, about 1300 miles, should then be possible at 50 MHz. E-skip contacts as short as 400 miles on 50 MHz, in turn, may be a sign that 144-MHz contacts in the 1200-mile range can be completed. Backscatter from sporadic-E clouds may also be evident on frequencies just below the MUF of the cloud.

The alert VHF operator will monitor

6-meter openings for signs that the MUF may be approaching 144 MHz. Hearing a 50-MHz station work progressively shorter paths suggests that the MUF is rising rapidly and gives clues to possible 144-MHz paths. See Fig. 15. The MUF can also be followed through TV channels 2 through 6 (56-88 MHz), the FM broadcast band (88-108 MHz), and into the aircraft band above that. Sporadic-E openings occur about a tenth as often on 144 MHz as on 50 MHz and for much shorter periods. It is common for the 6-meter band to be open for hours via sporadic-E, but 2-meter openings typically last only a matter of minutes. A few spectacular 2-meter sporadic-E sessions have lasted for longer than an hour. Sporadic-E may also affect the frequencies above the 2-meter band; this can be followed on TV channels 6 through 13 (174-216 MHz). The MUF for sporadic-E has been observed to exceed 200 MHz on a few occasions, but 220-MHz contacts are still very rare events.

### Field-Aligned Irregularities

Amateurs have experimented with a little-known scattering mode known as *field-aligned irregularities (FAI)* on 50 and 144 MHz since 1978. Propagation via FAI accompanies sporadic-E openings and may persist for several hours after E-skip as disappeared. There are indications that 2000 to 2400 local time may be the most productive for FAI. Stations attempting FAI contacts direct their antennas toward a common scattering region that corresponds to a known sporadic-E reflection point. They need not be along a single great-circle path. Stations in southern

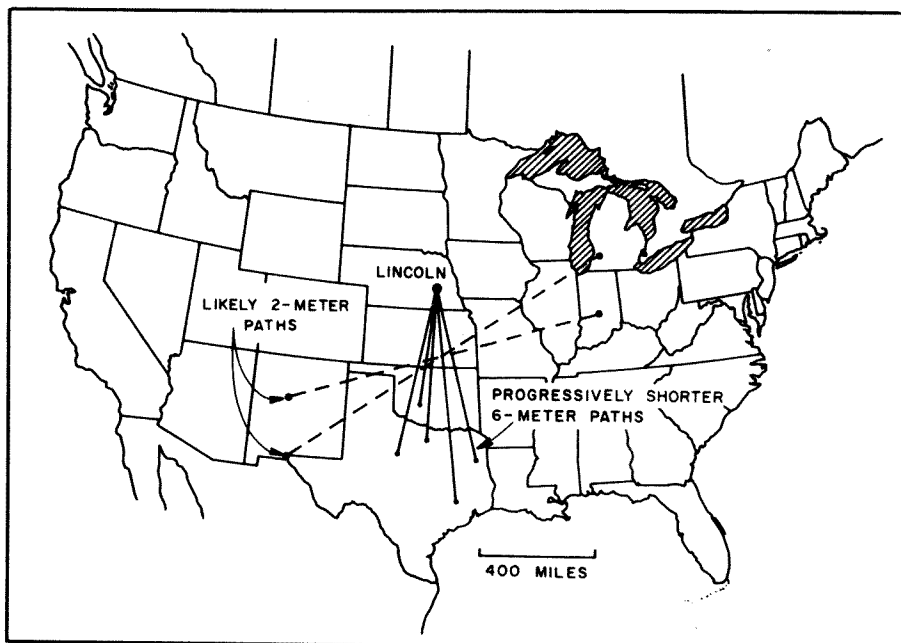

Fig. 15 — Sporadic-E contacts of 400 miles on 50 MHz indicate that 1200-mile paths may be open on 144 MHz. Hearing a 50-MHz station in Lincoln, Nebraska, work progressively shorter paths into Texas and Oklahoma (solid lines) suggests that 144-MHz contacts (dashed lines) may be possible. The midpoint of all paths is the same area of high-MUF, sporadic-E activity, in this case just north of the Kansas-Oklahoma border.

Florida, for example, have completed 144-MHz FAI contacts with Dallas, Texas, when all participating stations were beamed toward a common scattering region over northern Alabama.

FAI-propagated signals are weak and fluttery, reminiscent of aurora signals. Doppler shifts of as much as 3 kHz have been observed in some tests. Stations running as little as 100 watts and a single Yagi should be able to complete FAI contacts during the most favorable times, but higher power and larger antennas may yield better results. Contacts have been made on 50 and 144 MHz, and 220-MHz FAI seems probable as well. Expected maximum distances should be similar to other forms of E-layer propagation — up to 1300 miles.

### Aurora

Radio signals with frequencies as high as 3000 MHz have been scattered by the aurora borealis or northern lights (aurora australis in the Southern Hemisphere), but amateur *aurora* contacts have been reported only through 432 MHz. By pointing directional antennas toward the center of aurora activity (generally north in the Northern Hemisphere) contacts up to 1300 miles distant are possible. Stations north of 42° latitude experience many aurora openings each year, while those in the Gulf Coast states may hear aurora signals no more than once a year, if that often.

The appearance of aurora is closely linked to solar activity. During massive solar storms, high energy streams of electrons and protons spew out from the sun. These high-energy particles are trapped by the Earth's magnetic field in the polar regions. They ionize the gases of the E-layer and higher, giving rise to spectacular visual displays as well as affecting radio communications. Aurora generally absorbs radio signals below 20 MHz, while those above 20 MHz are scattered and reflected.

Auroras occur most often around the spring and fall equinoxes (March-April and September-October), but aurora may appear in any month. Radio aurora activity generally peaks between 1600 and 2000 local time and may reappear later in the evening. Aurora may be anticipated by following the A- and K-index reports on WWV at 18 minutes after each hour. A K-index of 4 or greater and an A-index of at least 30 are indications that a geomagnetic solar storm is in progress and an aurora likely. The probability, intensity, and southerly extent of aurora increase as the two index numbers rise. Weak and watery signals on the AM broadcast band through the 40-meter band late in the afternoon may be an indication that an aurora is already in progress. The 20-meter band may close down altogether. Satellite operators have also noticed that 144-MHz downlink signals are often weak

and distorted when satellites pass near the polar regions during magnetic storms.

You do not have to be able to see an aurora to make aurora contacts. Useful aurora may be as distant as 650 miles and well below the visual horizon. Auroras scatter radio signals back toward the transmitter over a very wide area, making possible contacts with stations up to 1300 miles away. Antennas should be pointed generally north and then used to probe east and west to peak signals. Offsets from north are usually greatest when the aurora is closest. There may be some advantage to antennas that can be elevated, especially when auroras are nearby. High power and large antennas are not necessary to work aurora. Stations with as little as 10 watts output have made aurora contacts on frequencies as high as 432 MHz.

Aurora-scattered signals are easy to identify. On 50-MHz SSB, signals sound very distorted and somewhat wider than normal; on 144 MHz and above, the distortion may be so severe that only CW is useful. Aurora CW signals have a distinctive note variously described as a buzz, hiss, or mushy sound. Doppler shifts of 1 kHz may be evident on 144 MHz and several kHz on 432 MHz. Signal strength dramatically decreases with higher frequencies, while Doppler shift and distortion increase. Especially strong aurora may evolve into a mode known as auroral-E on 50 MHz. Distortion disappears and path lengths may increase well beyond the usual 1300-mile limit for aurora.

### Meteor Scatter

Contacts between 500 and 1300 miles distance can be made on 50 through 432 MHz via reflections from the ionized trails left by meteors as they travel through the ionosphere. The kinetic energy of meteors no larger than peas, and more commonly the size of grains of sand, are sufficient to ionize a column of air up to 12 miles long in the E-layer. The particle itself evaporates and never reaches the ground, but the ionized column may persist for a few seconds to a minute or more before it dissipates. This is enough time to make very brief contacts by reflections from the ionized trails. Hundreds of thousands of meteors enter the Earth's atmosphere every day, but relatively few have the required size, speed, and orientation to the Earth to make them useful for *meteor-scatter* propagation.

Radio signals in the 30- to 100-MHz range are reflected best by meteor trails, making the 50-MHz band prime for meteor-scatter work. The early morning hours around dawn are the most productive, because the Earth's rotation sweeps up incoming meteors and contributes to their apparent velocity. Meteor contacts ranging from a second or two to more than a minute can be made nearly any morning on 50 MHz. Meteor-scatter contacts on 144 MHz and higher are more

difficult because reflected signal strength and duration drop sharply with increasing frequency. A meteor trail that provides 30 seconds of communication on 50 MHz will last only 3 seconds on 144 MHz and less than 1 second on 432 MHz.

Meteor scatter may be somewhat better during July and August because the average number of meteors entering the Earth's atmosphere peaks during those months. The very best times are during one of the great annual meteor showers, when the number of useful meteors may increase 50-fold over the normal rate of one or two per hour. See Table 4. A meteor shower occurs when the Earth passes through a relatively dense stream of particles, thought to be the remnants of a comet, that are also in orbit around the sun. The greatest showers are relatively consistent from year to year, both in their recurrence and meteor density.

**Table 4**  
**Prominent Annual Meteor Showers**

Name	Peak dates	Rate, meteors/hour
Quadrantids	January 3	50
Arietids	June 7-8	60
Perseids	August 12-13	50
Geminids	December 12-13	60

Because meteors provide only fleeting moments of communication even during one of the great meteor showers, especially on 144 MHz and above, special operating techniques are often used to increase the chances of completing a contact. Pre-arranged schedules between two stations establish times, frequencies, and precise operating standards. Usually, each station transmits on alternate 15-second periods until enough information is pieced together a bit at a time to confirm contact. Nonscheduled random meteor contacts are quite common on 50 MHz and 144 MHz during meteor showers, but short transmissions and alert operating habits are required.

It is helpful to run several hundred watts to a large antenna, but meteor-scatter can be used by modest stations under optimal conditions. During the best showers, a few watts and a small Yagi are sufficient on 50 MHz. On 144 MHz, at least 100 watts output and a long Yagi are needed for consistent results. Proportionately higher power is required for 220 and 432 MHz even under the best conditions.

### Line of Sight

At one time it was thought that communications in the VHF range and higher would be restricted to "line of sight" paths. Although this has not proven to be the case even in the microwave region, the concept

of line of sight is still useful in understanding propagation. In the absence of any kind of enhancement, radio waves traveling through the weather-producing lower few thousand feet of the atmosphere, called the troposphere, do not travel in straight lines. Radio waves are normally refracted, or bent, slightly earthward. The reason is not hard to understand. The normal drop in temperature, pressure, and water vapor content of air with increasing altitude affects the refractive properties of the atmosphere. Just as light is refracted as it crosses the boundary between two dissimilar media, such as water and air, radio waves are refracted as they pass through an atmosphere whose refractive properties change with altitude. Under average conditions, radio waves are refracted toward Earth enough to make the horizon appear 1.34 times farther away than the visual horizon.

A simple formula can be used to estimate the distance to the radio horizon under average conditions:

$$d = \sqrt{2h}$$

where

$d$  = distance to the radio horizon in miles

$h$  = height above average terrain in feet

The distance to the radio horizon for an antenna 100 feet above average terrain is thus 14.1 miles; a station on top of a 5000-foot mountain would have a radio horizon of 100 miles. The line-of-sight distance for any pair of stations is their combined distance to a common horizon. Stations on top of two 5000-foot mountains no more than 200 miles distant would be within each other's radio horizon.

### Tropospheric Scatter

Contacts beyond the horizon are made every day on the VHF bands and higher without the aid of obvious propagation enhancement. "Ground wave," a term that is more appropriate to propagation on the frequencies below 3 MHz, plays no important role above 50 MHz. Beyond-the-horizon communication in the VHF range and higher is possible because a tiny portion of the transmitted signal is scattered by small changes in the index of refraction of air, and by dust, clouds, and other naturally occurring particles in the troposphere. Most amateurs are unaware that they use *tropo scatter*, even though it plays an essential role in most ordinary VHF and UHF communication. The normal ranges for well equipped stations provided in the propagation summaries of each band, for example, are really the maximum distances commonly worked via tropo scatter.

The theoretical maximum distance that can be worked via tropo scatter is limited ultimately by the line-of-sight distance two stations have of the same scattering region

Fig. 16 — Tropospheric scatter is the most common form of propagation in the bands above 50 MHz. A small portion of transmitted signals is scattered by the atmosphere, but only that portion scattered within sight of two stations — the common scattering volume — provides the vital tropo-scatter link. The maximum theoretical range of 500 miles for tropo scatter is limited by the highest part of the atmosphere useful for scattering, about 6 miles in altitude. At 6 miles, the radio horizon is 250 miles distant.

of the troposphere. See Fig. 16. The highest altitude for which scattering is efficient at amateur power levels is about 6 miles. An application of the distance-to-horizon formula shows that 500 miles is the maximum distance for stations relying only on tropo scatter at any frequency.

In practice, tropo scatter paths are shorter than 500 miles because most stations are less than optimal, and scattering path losses increase with frequency. Almost all extended-distance tropo scatter work involves weak signals and considerable fading. Scatter may be worked any time or season. Weather affects scattering efficiency, but its effects are nearly impossible to predict over any given path.

*Rain scatter* is a special case of tropo scatter that is practical in the 1296 MHz to 10 GHz range. Stations simply point their antennas toward a common area of rain. A certain portion of radio energy is scattered by the raindrops, making over-the-horizon or obstructed-path contacts possible, even with low power. The theoretical range for rain scatter is as great as 400 miles, but the experiences of amateurs in the microwave bands suggests that expected ranges are less than 100 miles. Snow and hail make less efficient scattering media unless the ice particles are partially melted. Smoke and dust particles are too small for extraordinary scattering, even in the microwave bands.

### Tropospheric Enhancement and Ducting

Weather dramatically affects tropospheric refraction, and specific weather conditions can be linked to enhanced propagation. Enhancement refers to tropospheric refraction that is greater than normal but insufficient to bend radio waves back to the surface of the Earth. Increased signal strength and extended path distances to the limits of tropo scatter, or about 500 miles, result from enhanced tropospheric conditions. Ducting takes place when refraction is so great that radio

signals are bent all the way back to the surface of the Earth. When ducting conditions in the troposphere exist over a wide geographic area, signals may remain very strong over distances of 1000 miles or more. Higher frequencies are more sensitive to tropospheric refraction, and effects may be observed in the microwave bands before they affect the lower frequencies.

Enhancement and ducting occur when the normal lapse in air temperature with altitude is reversed, that is when temperature increases with altitude. This condition is known as a temperature inversion. Temperature inversions are often accompanied by unusual drying of air with altitude, which contributes to increased refractivity. A large number of weather conditions are known to create temperature inversions. Some of the more common and most useful inversion-producing weather conditions are discussed in turn.

*Radiation inversions* are probably the most common and widespread of the various weather conditions useful to propagation. Radiation inversions form only over land after sunset as a result of progressive cooling of the air near the Earth's surface. As the Earth cools by radiating heat into space, the air just above the ground is cooled in turn. At higher altitudes, the air remains relatively warmer, thus creating the inversion. The cooling process may continue through the evening and predawn hours, creating inversions that extend as high as 1500 feet. Radiation inversions are most common during clear, calm, summer evenings. They are more distinct in dry climates, in valleys, and over open ground. Their formation is inhibited by wind, wet ground, and cloud cover. Although such inversions are common and widespread, they are rarely strong enough to cause true ducting. The enhanced conditions so often observed on summer evenings are usually a result of radiation inversions.

Large, sluggish, *high-pressure systems*

(or anticyclones) create the most dramatic and widespread tropospheric ducts. Inversions in high-pressure systems are created by the sinking and compressing of air within the high. Useful inversions appear between 1000 and 5000 feet. Ducts intensify during the evening and early morning hours. The longest and strongest radio paths usually lie to the south and southwest of the high-pressure centers. See Fig. 17.

Over continental areas, sluggish high-pressure systems that are likely to contain strong temperature inversions are most common in late summer over the eastern half of the U.S. They move very slowly out of Canada, generally southeastward, and may linger for days, providing many hours of extended propagation. The southeastern part of the country, including the Gulf and the lower Midwest, experiences the most high-pressure openings; the upper Midwest and East Coast somewhat less frequently; the mountain states and the West Coast rarely.

Semipermanent high-pressure systems — nearly constant climatic features in certain parts of the world — have created the longest and most exciting ducting paths. The Eastern Pacific High, which migrates northward off the coast of California during the summer, has been responsible for the longest ducting paths reported to date, more than 2500 miles on 144 MHz through 1296 MHz between California and Hawaii. The Bermuda High is a nearly permanent feature in the Caribbean area. During the summer, it too moves north and often covers the southeastern U.S. It has produced contacts in excess of 1800 miles from Florida and the Carolinas to the West Indies, but its potential has not been exploited. Other semipermanent highs lie in the Indian Ocean, the western Pacific, and off the coast of west Africa.

The *wave cyclone* is a more dynamic weather system seen primarily during the spring months over the middle part of the American continent. The wave begins as a disturbance in a long continental front, which creates two distinct parts. On the western leg, a cold front forms and moves rapidly eastward; to the east, a warm front moves slowly northward. When the wave is in its open position, as shown in Fig. 18, north-south radio paths 1000 miles and longer may be possible in the warm sector — that area to the east of the cold front and south of the warm front. East-west paths nearly as long may also open up in the southerly parts of the warm sector. Evening and early morning are generally the best times. Wave cyclones are rarely productive for more than 24 to 36 hours, because the eastward moving cold front eventually closes off the warm sector. Temperature inversions associated with wave cyclones are created by a fast stream of warm, dry air above 3000 feet that covers relatively cooler and moister Gulf air flowing northward near the Earth's surface in the warm sector.

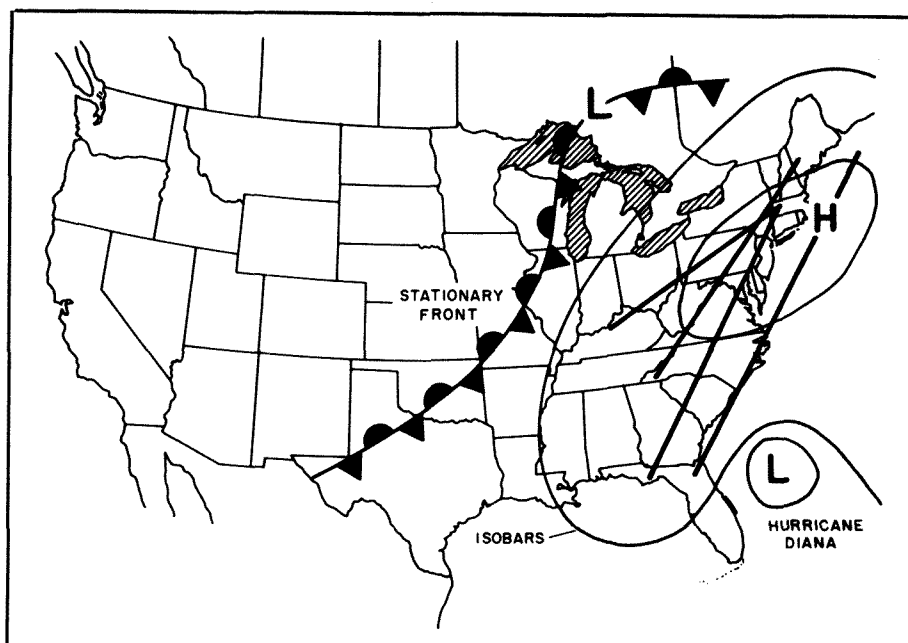

Fig. 17 — Sprawling, slow-moving, high-pressure systems, a common feature in the eastern half of the country during the late summer, provide the majority of extended tropospheric ducts. Shown here are the surface weather features on September 8, 1984, when many contacts of 1000 miles or more were made on all bands from 144 MHz through 1296 MHz. Solid lines represent typical paths reported during the early evening hours. Note that long paths appeared to the southwest of the high-pressure center. For more details about this tropospheric event, see January 1985 QST, pp. 74-77; and March 1986 QEX, pp. 5-12.

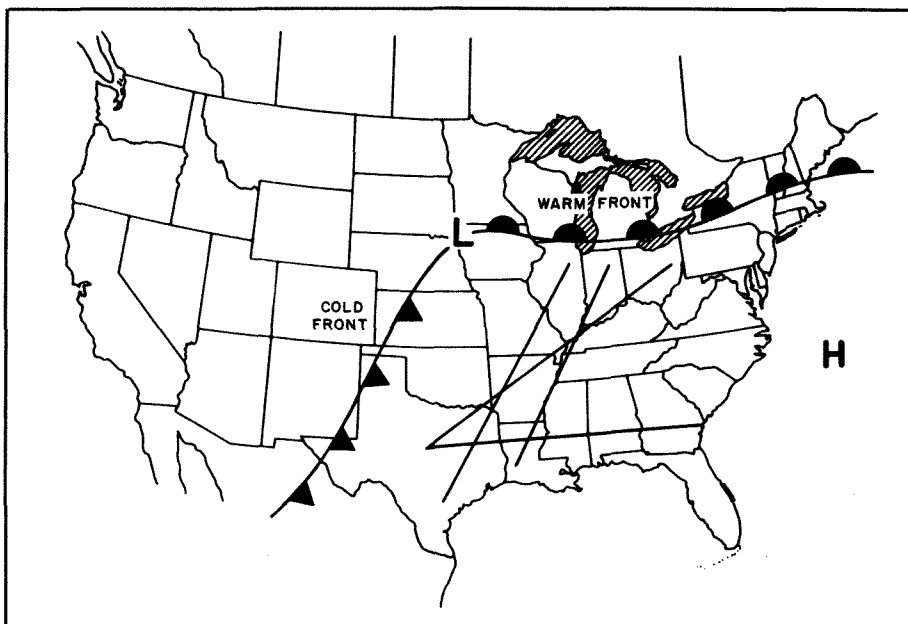

Fig. 18 — The wave cyclone also creates tropospheric ducts that support contacts in excess of 1000 miles in the bands above 144 MHz. Shown here is a wave that formed on June 2, 1980. Solid lines show typical contacts made on 144 MHz and 432 MHz. Similar contacts were made on the following day, before the wave collapsed. Another wave formed along the same continental front on June 6-7 and that provided an additional period of VHF and UHF DX.

*Warm fronts and cold fronts* sometimes bring enhanced conditions, but rarely true ducting. A warm front marks the surface boundary between a mass of warm air flowing over an area of relatively cooler and more stationary air. Inversion condi-

tions may be stable enough for several hundred miles ahead of the warm front to bring enhancement and sometimes ducting. A cold front marks the surface boundary between a mass of cool air that is trying to wedge itself under more stationary warm

air. The warmer air is pushed aloft in a narrow band behind the cold front, creating a strong but highly unstable temperature inversion. The best chance for enhancement occurs during the two or three hours after the front passes. Long paths, if they are possible, will open parallel to the passing front.

Certain kinds of wind may also create useful inversions. The *Chinook wind* of the American high plains (and similar winds in other parts of the world) floods the eastern slopes of the Rockies and the Great Plains with warm and very dry air, primarily in the springtime. Inversion effects may be felt from Canada to Texas and east to the Mississippi River. *Land breezes*, the cool air that blows in from the ocean in coastal areas after sunset during the warmer months, is accompanied by a return flow of warm air at 1000 feet or so in altitude. Land breeze inversions often bring enhanced conditions and occasionally allow contacts in excess of 500 miles along the East Coast and other coastal areas. In southern Europe, a hot, dry wind known as the *sirocco* that blows northward from the Sahara Desert across the Mediterranean has probably been responsible for record-breaking microwave contacts in excess of 1000 miles.

Over warm water areas, such as the Caribbean and other tropical waters, *evaporation inversions* may create ducts that are useful only in the microwave region between 3.3 and 24 GHz. These are among the few inversions that depend on a sharp drop in water-vapor content rather than on temperature inversion. Air just above the surface of warm bodies of water is saturated because of evaporation. Within 10 to 30 feet in altitude, the water-vapor content drops significantly, creating a very shallow but stable and strong duct.

### Reflections

At frequencies above 144 MHz, reflections from a variety of large objects, such as buildings, airplanes, mountains, water towers, and the like can provide a useful means of extending over-the-horizon paths to several hundred miles. Two stations need only beam toward a common reflector, whether stationary or moving. The reflector must be within the radio line-of-sight of both stations and be large in terms of wavelength. Contrary to common sense notions, the best position for a reflector is not midway between two stations. Signal strength increases as the reflector approaches one end of the path; the reflector may even be positioned on the far side of one station with good result.

The maximum range is limited by the line-of-sight distance of both stations to the reflector and to a lesser extent by reflector size. A water tower on top of a hill 500 feet above average terrain could extend reliable microwave coverage of a station in a near-

by valley to more than 30 miles. The extreme limit for airplane reflections is about 550 miles, assuming the largest jets fly no higher than 40,000 feet. Actual airplane reflection contacts are likely to be considerably shorter.

In addition to making fair reflectors, hills and mountains can also serve as effective knife-edge diffractors at VHF and higher. A small portion of signals traveling over the crest of a mountain range or a line of hills at least 100 wavelengths long will be diffracted downward on the far side. (Diffraction is a bending of the wave as it passes across the edge of a well defined object.) Only a small portion of the signal energy will be diffracted into the "shadow" area, but it may make it possible to complete paths up to 100 miles or more that might otherwise be obstructed by the terrain.

The moon has also been used as reflector on 50 MHz through at least 2304 MHz. Very high power and large antennas, along with the very best receivers, are required to overcome the extreme losses involved in Earth-Moon-Earth (EME) paths. Contacts from one side of the Earth to the other, 12,500 miles, are possible. The techniques of EME communication are specialized enough to be discussed in detail elsewhere in the *Handbook*.

# Space Communications

Terrestrial communication range is limited by the spherical shape of the earth. Various propagation mechanisms can be used to transmit a signal around the earth. Beyond line-of-sight distances, however, reliable communication may require the use of higher effective radiated power and may not be possible at all.

When a space object is visible from a point on earth, there is nothing in the path to block or scatter the signal. When that object is visible at two points on earth, communication between these two points is possible using the object as a reflector (passive relay) or a transponder (active relay). The signal trip to space and back avoids the greater attenuation involved in sending a signal around the earth.

Amateur Radio space communication has two major facets: artificial satellites and earth-moon-earth (EME). Both are rich with technical and operational achievements by radio amateurs. Together, they make the VHF and higher frequencies usable for amateur transcontinental communications and push today's technology to the limit.

## SATELLITE COMMUNICATIONS

The excitement of global VHF/UHF DX can be within the reach of nearly every amateur, and it can be experienced with small antennas, low power and comparatively simple equipment. Amateur satellite communications is a mature program that has been developing for more than a quarter of a century. It began in 1961 and has been enhanced with every launch. The rich history of the amateur satellite program is well covered in *The Satellite Experimenter's Handbook*, published by the ARRL. Presented here is detailed information on setting up a ground station for this fascinating facet of Amateur Radio. Along with the satellite tracking and operating techniques presented in *The ARRL Operating Manual*, amateurs now have the most up-to-date information available on satellite communications.

### Spacecraft

Amateurs currently enjoy communications through the thirteenth OSCAR (Orbiting Satellite Carrying Amateur Radio). OSCAR 13 is the second phase III

**Table 1**  
**OSCAR Operating Modes**

Mode	Uplink Band	Downlink Band
A	2 m (145 MHz)	10 m (29 MHz)
B	70 cm (435 MHz)	2 m (145 MHz)
J	2 m (145 MHz)	70 cm (435 MHz)
L	24 cm (1269 MHz)	70 cm (436 MHz)
S	70 cm (436 MHz)	13 cm (2401 MHz)
JL	2 m/23 cm	70 cm
K	15 m	10 m
T	15 m	2m

satellite. The first successful phase III satellite, OSCAR 10, demonstrated a noteworthy capability for global communications since it was first made available in August 1983. While it had a few problems, they were in the shadow of the success that introduced many thousands of amateurs to satellite communications. This success provided a host of new transceivers, preamplifiers and antennas for the amateur world.

**Table 2**  
**Spacecraft Frequencies**

<b>OSCAR 9</b>			
HF Beacons	7.050, 14.002, 21.002, and 29.510 MHz. CW keyed telemetry		
VHF Beacon	145.825 MHz NBFM $\pm$ 5 kHz. ASCII, Baudot, voice, AFSK and Morse telemetry and bulletins.		
UHF Beacon	435.025 MHz NBFM $\pm$ 5 kHz. ASCII, Baudot, voice, AFSK and Morse telemetry and bulletins.		
S-Band Beacon	2401.0 MHz NBFM $\pm$ 10 kHz. ASCII, Baudot, voice, AFSK and Morse telemetry and bulletins.		
X-Band Beacon	10.470 GHz steady carrier, LHCP		

### OSCAR 10

	Uplink (MHz)	Downlink (MHz)	Beacon (MHz)
Mode B	435.025-435.175	145.975-145.825	General 145.810 Engrg. 145.990
Mode L	1269.050-1269.850	436.950-436.150	General 436.040 Engrg. 436.020

### OSCAR 11

VHF Beacon	145.825 MHz NBFM FSK Telemetry
UHF Beacon	435.025 MHz NBFM FSK, PSK Telemetry
S-Band Beacon	2401.5 MHz AFSK, PSK

### OSCAR 13

	Uplink (MHz)	Downlink (MHz)	Beacon (MHz)
Mode B	435.425-435.575	145.975-145.825	General 145.8125 Engrg. 145.975
Mode L	1269.575-1269.325	435.725-435.975	General 435.650 Engrg. 436.020
Mode J	145.820-145.860 144.440-144.480	435.930-435.970 (Note 1) 435.930-435.970	
Digital Mode L	1269.675	435.675 (Note 2)	
Mode S	435.625	2401.337 (Note 3)	2401.267

### Notes:

- 1) Both Mode J options are expected to be implemented with software control of the uplink frequency selection.
- 2) RUDAK is a digital-only transponder that will use PSK encoding.
- 3) Mode S will be a soft-limited FM transponder that can also accommodate up to four SSB signals.
- 4) Although minor revisions in frequencies may be anticipated, the frequencies shown are those currently planned.

### FO-12

	Uplink (MHz)	Downlink (MHz)
Linear Service Mode J	145.900-146.000	435.900-435.800
Packet Digital Service Mode J	145.850, 145.870, 145.890, and 145.910	435.910 (1 channel)
Beacon		435.795

Fig. 1 — FO-12 provides for conventional amateur communications through its transponders, as well as a digital store-and-forward capability.

As this *Handbook* is being prepared, the Phase III-C spacecraft (OSCAR 13) has been successfully launched, with improved capabilities taken from lessons learned from AO-10. In addition to Mode B, OSCAR 13 has an improved Mode L transponder that should be much more sensitive than that aboard AO-10. See Tables 1 and 2. This Mode L transponder is coupled with a Mode J unit. Both transponders offer QRN-free 70-cm downlinks. The world of packet digital communications is served by the RUDAK Mode L transponder using PSK, Manchester II modulation. OSCAR 13 will also be an experimental test bed to prove the feasibility of 2.4 GHz Mode S transponders for use in future OSCARs.

Amateurs in more countries are participating in the process of designing and

Fig. 2 — The OSCAR 10 band plan allows for CW only, mixed CW/SSB and SSB only operation. Courteous operators observe this voluntary band plan at all times.

constructing spacecraft. In addition to the launch of OSCAR 13 in 1988, there is the first Japanese OSCAR, called FO-12. This is a joint effort between the Japan Amateur Radio League (JARL) and the Japanese AMSAT (JAMSAT) organization. It was launched by the Japanese National Space Development Agency (NASDA) as the payload on an experimental launch vehicle H-1 — truly a Japanese product in total. FO-12 is a Phase II spacecraft in a 1500 km circular orbit. It carries a Mode J transponder that serves two functions: linear SSB service and an advanced packet store-and-forward global message service with a 1.5 megabyte RAM storage bank. See Fig. 1.

Russian spacecraft designs have concentrated more on HF communications links to accommodate the kinds of equipment readily available in that country. RS 10/11, two separate "satellites" on the same spacecraft, include mode A and mode K transponders. The spacecraft is in a stable circular orbit at fairly low altitude.

### Operating Frequencies

Early OSCARs used Mode A transponders that were affected by F2-layer ionization phenomena during periods of high solar activity. As shown in Table 1, Mode A uses a 2-meter uplink (ground-to-spacecraft frequency) and a 10-meter downlink (spacecraft-to-ground). When the ionosphere is active, 10-meter satellite downlinks can be seriously affected.

Newer classes of amateur satellites have been designed to use higher-frequency amateur bands for a number of reasons. In addition to avoiding ionospheric effects, spectrum capacity and attainable antenna directivity are among some of the other strong reasons for moving to the UHF region for future satellites. OSCAR 10 (also called AO-10) features a combination of Mode B and Mode L transponders. OSCAR 13 carries a combination of Modes B, J, L, and S (see Table 2).

Future satellites will make use of higher frequencies. They will be placed in highly elliptical orbits, like OSCAR 13, or into the geostationary orbits. From these high altitudes, more than 45% of the Earth's surface can be viewed at one time, so the potential number of users is tremendous. A span of several hundred kilohertz is needed to afford sufficient spectrum for these users, and this much free space can only be found in the UHF region.

Another reason for using UHF with OSCARs is that high-gain, directional antennas are needed to make communications possible over such long paths. Since satellites are powered by batteries and solar cells, there are limitations on the amount of power the satellite transmitter can consume. The most efficient way to get the needed ERP is through the use of high-gain, narrow beamwidth antennas. Such

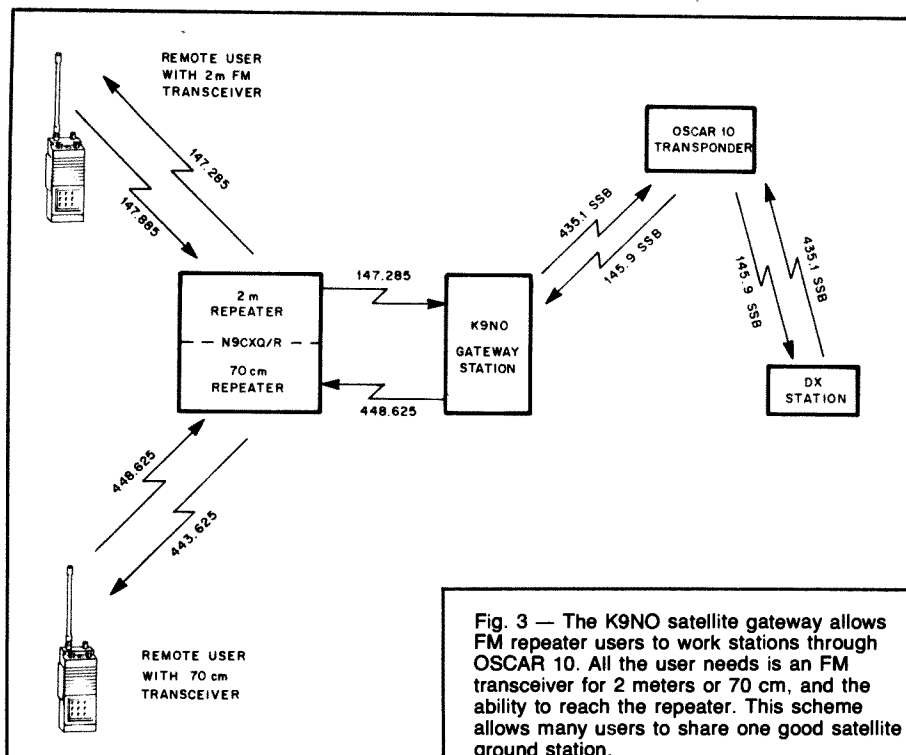

Fig. 3 — The K9NO satellite gateway allows FM repeater users to work stations through OSCAR 10. All the user needs is an FM transceiver for 2 meters or 70 cm, and the ability to reach the repeater. This scheme allows many users to share one good satellite ground station.

### Amateur Satellites: A History

OSCAR 1, the first of the Phase I satellites, was launched on December 12, 1961. The 0.10 W transmitter onboard discharged its batteries after only three weeks.

OSCAR 11 was launched on June 2, 1962. Identical to OSCAR 1, Amateur Radio's second venture into space lasted 18 days.

OSCAR 111, launched on March 9, 1965, was the first satellite for amateur communications. During its two-week life, more than 100 amateurs in 16 countries communicated through the linear transponder.

OSCAR 1V was launched on December 21, 1965. This satellite had a Mode J linear transponder. A launch vehicle defect placed OSCAR 1V into poor orbit, preventing widespread amateur use.

OSCAR 5, built by students at Melbourne University in Australia, transmitted telemetry on both 2 m and 10 m for more than a month.

OSCAR 6, the first of the Phase II satellites, was launched on October 15, 1972. It carried a Mode A linear transponder and lasted nearly five years.

OSCAR 7, built by hams from many countries was launched on November 15, 1974. It carried Mode A and Mode B linear transponders and served the amateur community for six years.

OSCAR 8, again a cooperative international effort, was launched on March 5, 1978. Mode A and Mode J transponders were carried on board. The spacecraft lasted six years.

Radio Sputniks 1 and 2, launched from the Soviet Union on October 26, 1978, each carried a sensitive Mode A transponder. Their useful lifetimes were only a few months.

OSCAR Phase 111-A, the first of a new satellite series, was launched on May 23, 1980, but it failed to achieve orbit because of a failure in the launch vehicle.

OSCAR 9, built at the University of Surrey in England, was launched in October 1981. This is a scientific/educational low-orbit satellite containing many experiments and beacons, but no amateur transponders. UoSAT-OSCAR 9 is fully operational as this is written.

Radio Sputniks 3-8 were simultaneously launched aboard a single vehicle in December 1981. Several carried Mode A transponders and two carried a device nicknamed "Robot" that could automatically handle a CW QSO.

Iskra 2 was launched manually from the Salyut 7 space station in May 1982 and sported a Mode K HF transponder. It was destroyed upon re-entering the atmosphere a few weeks after launch.

Iskra 3, launched in November 1982 from Salyut 7, was even shorter lived than its predecessor.

OSCAR 10, the second Phase III satellite, was launched on June 16, 1983, aboard an ESA Ariane rocket, and was placed in an elliptical orbit. OSCAR 10 carries Mode B and Mode L transponders. OSCAR 10 is operational only part time as this is written. Listen to W1AW bulletins for operating schedules.

OSCAR 11, another scientific/educational low-orbit satellite like OSCAR 9, was built at the University of Surrey in England and launched on March 1, 1984. This spacecraft has also demonstrated the feasibility of store-and-forward packet digital communications and is fully operational as this is written.

OSCAR 12, built in Japan and launched by the Japanese in August 1986, is a low-orbit (Phase II) satellite carrying Mode J and Mode JD (digital store-and-forward) transponders.

Radio Sputnik 10/11, launched in June 1987, is two separate "satellites" on the same low-orbit spacecraft. The satellites carry Mode A, K and T transponders and CW QSO "Robots."

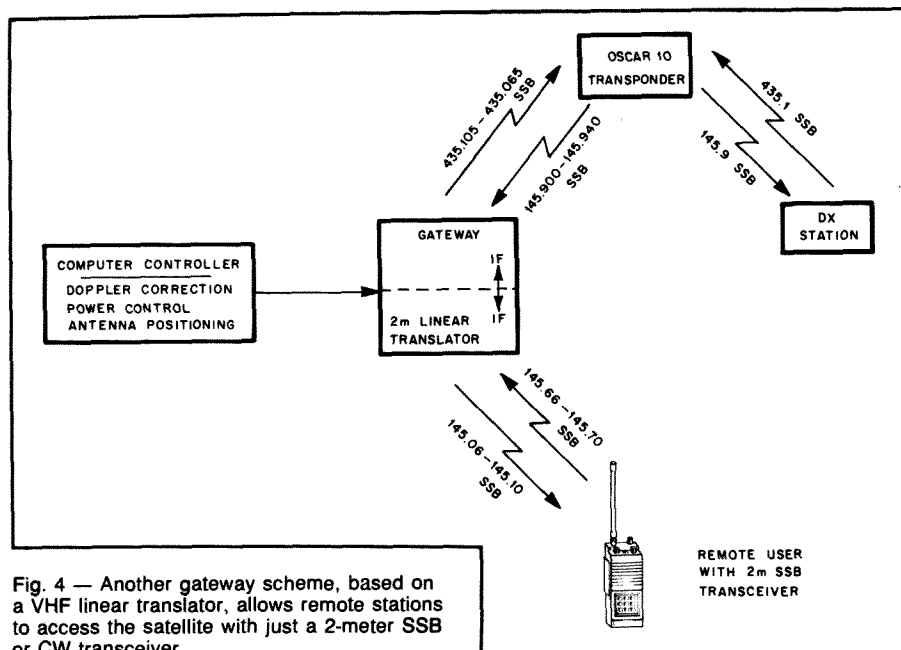

Fig. 4 — Another gateway scheme, based on a VHF linear translator, allows remote stations to access the satellite with just a 2-meter SSB or CW transceiver.

antennas would be too large and heavy at HF and VHF for the strict size and mass constraints imposed by the launch vehicle.

### Communications Methods

Amateurs who use satellites for communications must be alert to the needs of using that resource efficiently. Only narrow bandwidth modulation methods, such as CW and SSB, should be used for general QSOs. NBFM is *not* an efficient use of the limited satellite transponder spectrum. Also, the 100% duty cycle of FM voice is a very inefficient use of transponder RF power. Conventional RTTY is allowed on AO-10 on the calling frequency of 145.880. Packet radio is the preferred data-transmission mode, though, because the information-rate/duty-cycle ratio is much higher.

Most satellites have recommended use patterns for their transponders. Attention is placed on devoting portions of the bandwidth of the transponder to various uses. Typical band segments include CW only, mixed CW and SSB, SSB only, channels for specialized or experimental modes, and special channels for telemetry and bulletins. Fig. 2 shows the OSCAR 10 band plan. Satellite users should consult *The ARRL Operating Manual* for operating information for amateur satellites.

Another interesting use of AO-10's global communications capability is the service provided by "gateway" stations. A gateway station provides an interface between differing services. In the case of AO-10, some amateur communities of VHF FM operators have been served by gateways that translate their FM repeater signals into satellite SSB signals, and vice-versa. Global and transcontinental contacts have been made through AO-10 by operators using VHF hand-held transceivers.

Fig. 3 shows the block diagram of a manually operated gateway that has been active from Illinois. Another interesting form of gateway is the land-based linear translator that provides a portion of the AO-10 passband for operators with limited resources for satellite operation. One particular translator gateway provides a 40-kHz-wide band segment for SSB service as shown in Fig. 4. Both of these gateways operate in half-duplex for the remote user. Other schemes permit a remote user to operate full duplex, but at the expense of more equipment on his part.

A variant of SSB holds promise for satellite users. Amplitude companded single sideband, ACSSB, is spectrally and duty-cycle efficient. It can enhance the signal-to-noise ratio of satellite signals, all of which are relatively weak. ARRL, AMSAT and Project OSCAR are jointly sponsoring a test program called Project Companion to introduce ACSSB to Amateur Radio by way of OSCAR 10. The initial trials are very encouraging, but the program needs devoted participants to keep it on track.

### COMMUNICATIONS REQUIREMENTS

Most long-distance communications depend on natural propagation phenomena. Some days, a kilowatt and high Yagi are needed to establish communications; at other times, 5 W and a long wire will do the trick. Stations designed to take advantage of ionospheric propagation are largely a matter of personal preference. Bigger stations usually mean bigger signals.

Operation through a satellite is somewhat different. Fixed conditions such as transponder receiver sensitivity and power output, and variable conditions such as spacecraft attitude and path losses, are the

dominating factors in establishing minimum ground station requirements. Once the minimum requirements are met, you can have reliable communications any time the satellite is in view regardless of changing propagation phenomena. The communications requirements for OSCAR 10 have been pretty well defined since the spacecraft became operational in 1983. Unlike other areas of amateur interest, an inadequate station won't merely limit your ability to communicate — it may well prohibit communications entirely.

Satisfactory satellite communications might be possible with an existing station, but planning the ground station around certain parameters will enhance its effectiveness. Ground stations for Phase III satellites such as OSCAR 10 need to consider such subtleties as low-loss feed line, a single-transistor low-noise GaAsFET preamplifier, and high-gain VHF/UHF antennas that can be pointed accurately.

The parameters that should be considered for an OSCAR ground station are:

- 1) 146-MHz antenna gain of at least 13 dBi, circularly polarized. Right-hand circular polarization is a must for effective operation. More antenna gain is always desirable for better performance. Antenna gain of much more than 18 dBi, however, is not cost effective — satellite transponder noise floors will limit further benefits.

- 2) 435-MHz antenna gain of at least 13 dBi, circularly polarized. For this band, it is highly desirable to be able to switch between right-hand circular polarization (RHCP) and left-hand circular polarization (LHCP). Gains of 14 to 18 dBi are preferred for OSCAR 10, Mode B. For OSCAR 10, Mode L, antenna gain around 20 dBi is necessary. Future Mode L operations are expected to be satisfactory with the 14- to 18-dBi class antenna.

- 3) 1269-MHz antenna gain of 20+ dBi is required for OSCAR 10, Mode L. Current AO-10 users are having success with linear antenna polarization, even though the spacecraft antenna uses RHCP. Future operations will probably demand a switchable circular polarization. Future Mode L operations are also expected to be less demanding in the antenna department. Gain in the range of 16 to 20 dBi should yield satisfactory results.

- 4) Circularly polarized antennas must be mounted on nonmetallic booms so that the antenna performance is not degraded by a metal boom in the antenna field. Similarly, coaxial feed lines must be routed axially rearward past the antenna reflector to avoid pattern distortion.

- 5) Feed-line loss of less than 2 dB is needed; less than 1 dB is better. This can be achieved without expensive Hardline through the use of antenna mounted preamplifiers and other equipment.

- 6) 435-MHz EIRP (effective isotropic radiated power) of no more than 500 W. Most operations can be conducted with 100-W EIRP, and at times it's possible to use only 10-W EIRP.

7) 1269-MHz EIRP of 3000 to 25,000 W for OSCAR 10, Mode L. Future satellite requirements expected to be in the 500 to 3000 W category.

8) 146-MHz receive system noise figure no greater than 2 dB. Noise figures less than 1 dB are not warranted because of the limitations imposed by terrestrial noise sources.

9) 435-MHz receive system noise figure of less than 1 dB. Terrestrial noise levels are not a limiting factor on this band.

10) Frequency readout resolution of 1 kHz on transmit and receive. Accurate frequency readout allows you to find your signal on the downlink without causing needless QRM.

11) An accurate means of determining antenna direction at all times during an orbit. This means knowing where the antennas are pointed, and where to point them. Accurate graphical plotting or computer printout of pointing angles is required.

Like many other aspects of amateur radio, tradeoffs can be made to minimize expenditure of time and money. Up to a point, antenna gain is easier to obtain than transmitter power. It is easier to put up a bigger Yagi to increase your EIRP than to build or buy an amplifier. For example, a commercially available 40-element 435 MHz crossed Yagi makes enough EIRP for AO-10, Mode B communications with only 25 W of 435-MHz RF at the antenna. Often, only 5 to 15 W are all that's necessary.

Better antennas also improve receive performance. All things considered, it is much more cost effective — and desirable from a performance standpoint — to optimize the receiving set-up before investing in higher transmit EIRP. Don't be an alligator!

AMSAT and Project OSCAR have jointly produced a very useful manual that defines the details of the satellite link characteristics. This manual is recommended reading for all interested amateurs.

### Circular Polarization

In the HF bands, polarization differences between antennas are not really noticeable because of the nonlinearities of ionospheric reflections. On the VHF and UHF bands, however, there is little ionospheric reflection. Cross-polarized stations (one using a vertical antenna, the other a horizontal antenna) often find considerable difficulty, with upwards of 20-dB loss. Such linearly polarized antennas are "horizontal" or "vertical" in terms of the antenna's position relative to the surface of the Earth, a reference that loses its meaning in space.

The use of circularly polarized (CP) antennas for space communications is well established. If spacecraft antennas used linear polarization, ground stations would not be able to maintain polarization alignment with the spacecraft because of changing orientation. Ground stations

**Table 3**

### Polarization and Gain of the Phase III-B Antennas

Frequency (MHz)	High Gain Antennas		Omni Antennas	
	Polarization	Gain (dBi)	Polarization	Gain (dBi)
146	RHCP	9.0	Linear	0.0
436	RHCP	9.5	Linear	2.1
1269	RHCP	12.0	RHCP	0.0

Fig. 5 — This diagram shows the far-field radiation pattern (undeformed) for the 2-meter high-gain antenna on OSCAR 10. (Adapted from *The AMSAT-Phase III Satellite Operations Manual* prepared by AMSAT and Project OSCAR.)

using CP antennas are not sensitive to the polarization motions of the spacecraft antenna, and therefore will maintain a better communications link.

All AO-10 gain antennas (for 2 m, 70

cm, and 24 cm) are configured for RHCP operation along their maximum gain direction. See Table 3 and Fig. 5. Since this direction is also the main antenna lobe along the spacecraft + Z axis, the best communications with AO-10 will also be along that direction. Since the AO-10 radiations are RHCP, ground stations should also be RHCP for optimum communications.

There are times, however, when LHCP provides a better satellite link. AO-10 is designed so that the main antenna lobe is oriented toward the center of the Earth when the satellite is at apogee. It is only so oriented for up to a few hours either side of apogee, however. As the satellite moves away from apogee, the orientation changes and the RHCP main lobe is not centered on Earth. At other times, ground command stations have to orient the spacecraft to odd angles to maintain proper sunlight on the solar cells that are used for prime power. Again, at such times the satellite antenna's main lobe is not pointed directly at Earth. During the periods when the main lobe is directed away from Earth, communications are still possible through the use of OSCAR 10's antenna side lobes. CP antenna patterns, however, exhibit side lobes that can be polarized in the opposite sense to the main lobe. At times when only LHCP side lobes are available, ground stations must be able to switch to LHCP to maintain optimum communications.

Link computations are based on the following parameters:

11.7 hour elliptical orbit  
 Eccentricity = 0.6  
 Slant range = 41,395 km at AOS/LOS  
 2.4 kHz SSB Signal  
 6 dB Peak (PEP) to Average signal ratio  
 Ground Station Receiving Noise Characteristics:  
 at 2m: T = 505 K, NF = 4.4 dB  
 at 70cm: T = 65 K, NF = 0.9 dB

(adapted from *The AMSAT-Phase III Satellite Operations Manual* prepared by AMSAT and Project OSCAR)

Independently switchable RHCP/LHCP antenna circularity is necessary, especially for 70 cm. It is expected to be required for 24 cm operation on Phase III-C as well.

Operators who use AO-10, Mode L have determined that the uplink can be affected by LHCP antenna lobes when the satellite is located off-axis to the ground station.

Switchable RHCP/LHCP on 2 m may be convenient, but it is rarely needed.

### Spin Modulation

An AO-10 design characteristic is that the 2-m high-gain array pattern has three side lobes located along the spin axis that are only about 3 dB weaker than the primary axial lobe. The effective radiation pattern intended for this antenna is shown in Fig. 5. The axial radiation lobes of the 70-cm and 24-cm high-gain antennas are similarly symmetrical about the spin axis. Lobes in the off-axis antenna patterns produce amplitude modulation of signal strength as the spacecraft spins about its axis. Off-axis operations of AO-10 are an established fact of life, creating spin modulation frequencies of about 0.5 Hz from a 10 r/min spin rate.

Stations using CP antennas are much less prone to be affected by spin modulation than those using linearly polarized antennas. Good signals are maintainable even far off-axis from the main lobe, if the ground station is using CP.

### Path Loss

In free space, a station located at a distance from an RF source will receive an average power flow from that source that is inversely proportional to the square of the distance. Doubling the range will reduce the signal by 6 dB. Since Phase III satellites have substantially elliptical orbits, the changes in path length (slant range) and loss is correspondingly sizable. Fig. 6 illustrates the changes in path length of AO-10 signals for all conditions from apogee to perigee and for direct overhead passes (SSP location) to the far-limb viewing at AOS or LOS.

Other physical processes introduce additional losses in signals traveling to and from AO-10 through the troposphere and ionosphere. While many of these effects are frequency dependent, the additional path losses for AO-10 signals are small compared to the slant range path losses. Table 4 summarizes the path losses for each band used on AO-10.

### Link Budget

Link budget computations can be deceiving to the unwary observer. The problems arise from the application of wide-bandwidth spacecraft transponders to handle a wide variety of complex, time-averaged, narrow-bandwidth QSOs. The analysis presented in Table 5 employs a somewhat lower signal-to-noise ratio than the source information. Actual on-the-air experience has shown these lower values to be workable. The computation is also performed on the basis of averaged RF power levels. The conversion to PEP is done at the end, assuming a 6 dB relationship between PEP and average.

In the link computations, no allowances have been made for ground station transmission line attenuation. Information for

attenuation of a variety of popular feed lines is shown in Chapter 16. If you measure RF power near the antenna and have a tower-mounted, low-noise preamp, the link computations can be used as presented. The computation is based on two possible worst-case conditions: with the maximum slant range values at AOS/LOS, and with the spacecraft at apogee. An important assumption that the spacecraft antenna pattern is on-axis to the communications path, a highly unusual spacecraft orientation condition. Of course, an infinite number of cases could be presented in such a tabular assessment.

Another highly variable parameter that must be taken into account is pointing and polarization loss. With the wide variety of OSCAR 10 offset pointing situations that have been seen in the first few years of AO-10 operation, the pointing and polarization losses can easily achieve values of 10 dB or more. Also witnessed in AO-10 operations is the very sharp degradation of the communications link when the satellite is at very low elevation angles (essentially on the horizon). Nevertheless, the presentation of Table 5 is in the ballpark for Mode B operations for those power level and received signal conditions seen in practice.

Mode L operations on OSCAR 10 have not achieved the performance values seen in Table 5 owing to a faulty voltage regulator in the Mode L transponder. Consistent Mode L performance, with the spacecraft at apogee, can be attained with uplink power in the range of 10 to 25 kW ERP. Also required is a good receiving setup, with 70-cm downlink antenna gain about 22 dBi and a low-noise GaAsFET preamp at the antenna. When the satellite is at lower altitudes, successful OSCAR 10, Mode L QSOs can be made with uplink power as low as 3 kW ERP.

Table 5 also provides a good guide for expected link operations for Phase III-C. Mode JL transponder link performance can be determined easily, provided there are no unusual equipment failures when the spacecraft is launched.

## EQUIPPING A STATION

Perhaps the biggest difference between terrestrial and satellite communications is that the latter is full-duplex operation. This means that you transmit and receive simultaneously. You can hear your own downlink signal while transmitting, as well as that of the station being worked. Full duplex provides the opportunity for a fully interactive conversation, as if the other station is in the very same room.

Successful satellite operation demands that you can locate and hear your own signal from the spacecraft. Choose equipment with this goal in mind. Equipping a station for full-duplex operation is not too difficult because the transmitter is on a different band than the receiver. Satellite ground-station configurations vary ac-

cording to the satellite communications "mode" being used. Figs. 7, 8 and 9 show several different configurations for Mode B, Mode L and Mode J. Each of these options will be discussed.

## Receivers

Receiving requirements for OSCAR 10 are demanding, but pleasurable results can be achieved with the right kind of equipment. Do not expect to find 60-dB-over-S9 signals on the downlink. OSCAR operation is a weak-signal situation where contacts can be made with signals that are 4 dB stronger than the noise. Conversational quality can be assured with signals that are 6-9 dB or greater out of the noise.

The old adage "You can't work 'em if you can't hear 'em" especially applies to satellite work. The first step that should be taken toward gearing up for OSCAR 10 is to assemble the best receiving setup possible. There is no point in getting transmitting capability until the satellite signals can be comfortably heard.

There are a number of options for starting a satellite station from scratch. You may wish to try building almost any part of the station from a simple controller, all the way up to a complete station. Alternatively, the busy operator may wish to purchase everything. All of the necessary components are readily available from commercial suppliers.

Amateurs active on 2 meters with a multimode transceiver already have the basic building block for receiving Mode B and transmitting on Modes L and J. If you currently have no VHF equipment, consider that a multimode transceiver will also allow you to explore the exciting world of terrestrial 2-meter SSB operation. The basic requirements are that the rig includes SSB and CW modes and that it covers the entire 2-meter band. A multimode transceiver

also makes an excellent replacement for an FM-only 2-meter rig.

The major equipment manufacturers listed in Table 6 all make suitable transceivers. The current crop of base-station rigs includes the Kenwood TS-711A, ICOM IC-271A and Yaesu FT-726R. There are also several compact multimode radios intended for mobile use that will be quite usable. These include the Yaesu FT-480R, Kenwood TR-9130 and ICOM IC-290H. In addition, there are often good buys on the used market, if you're interested in an older radio. Gear such as the Kenwood TS-700 series, Yaesu FT-225RD and ICOM IC-251 are still popular. Many of these transceivers have been reviewed in *QST*.

An excellent solution to receiving satellite signals can be found in the form of receiving converters used with your quality HF transceiver or receiver. The receiving converter consists of a mixer and a local oscillator and may contain a preamplifier. The local oscillator frequency is usually chosen so that signals will be converted for reception by any receiver that covers the 10-meter band. In addition, a number of manufacturers offer transverters that include a receiving converter and transmitting converter in the same package.

Receiving converters are available commercially from several suppliers listed in Table 6. For those who enjoy building equipment, there are several suitable construction projects in Chapter 31.

There are several advantages to using a receiving converter. Modern HF transceivers and receivers most likely have excellent frequency stability, a frequency readout in 1 kHz or smaller steps, good SSB and CW crystal filters, an effective noise blanker and high dynamic range. Chances are good that a multimode VHF transceiver will offer some, but not all, of these features. Cost is another factor. If

The ICOM IC-271A is typical of the 2-meter multimode transceivers on the market today. It can be used for reception on the OSCAR 10 downlink. The IC-471A, virtually identical in appearance, offers a matching 70-cm, 25-W signal for the uplink.

Note: This is a partial list. The ARRL does not endorse specific products.

you already own an HF rig, but are not interested in terrestrial VHF/UHF SSB operation (you don't need 2-meter transmit capability for Mode B), the cost of building or buying a superior receiving converter will be significantly less than that of even an older multimode transceiver.

Experience has often shown that daytime noise will often raise the practical 2-meter receiver noise floor by 10 to 20 dB, thus making OSCAR 10, Mode B, daytime communications difficult, at best. Weak downlink signals are often no match for the noise. In general, noise is not a problem on 70-cm (for Mode J and Mode L reception), but in some areas interference from airport radar can be troublesome. In addition, local FM repeaters may be heard in the satellite passband of the ground-based receiver because the VHF transceiver may offer poor rejection of strong nearby signals. Use of a high-dynamic-range receiving converter with a good HF transceiver has been shown to solve both of these problems. The lesson here is that many VHF transceiver noise blankers are inadequate for VHF/UHF satellite operation, and that some VHF transceivers do not work well in areas with many strong, nearby signals. Better results may be had with a receiving converter than with a VHF

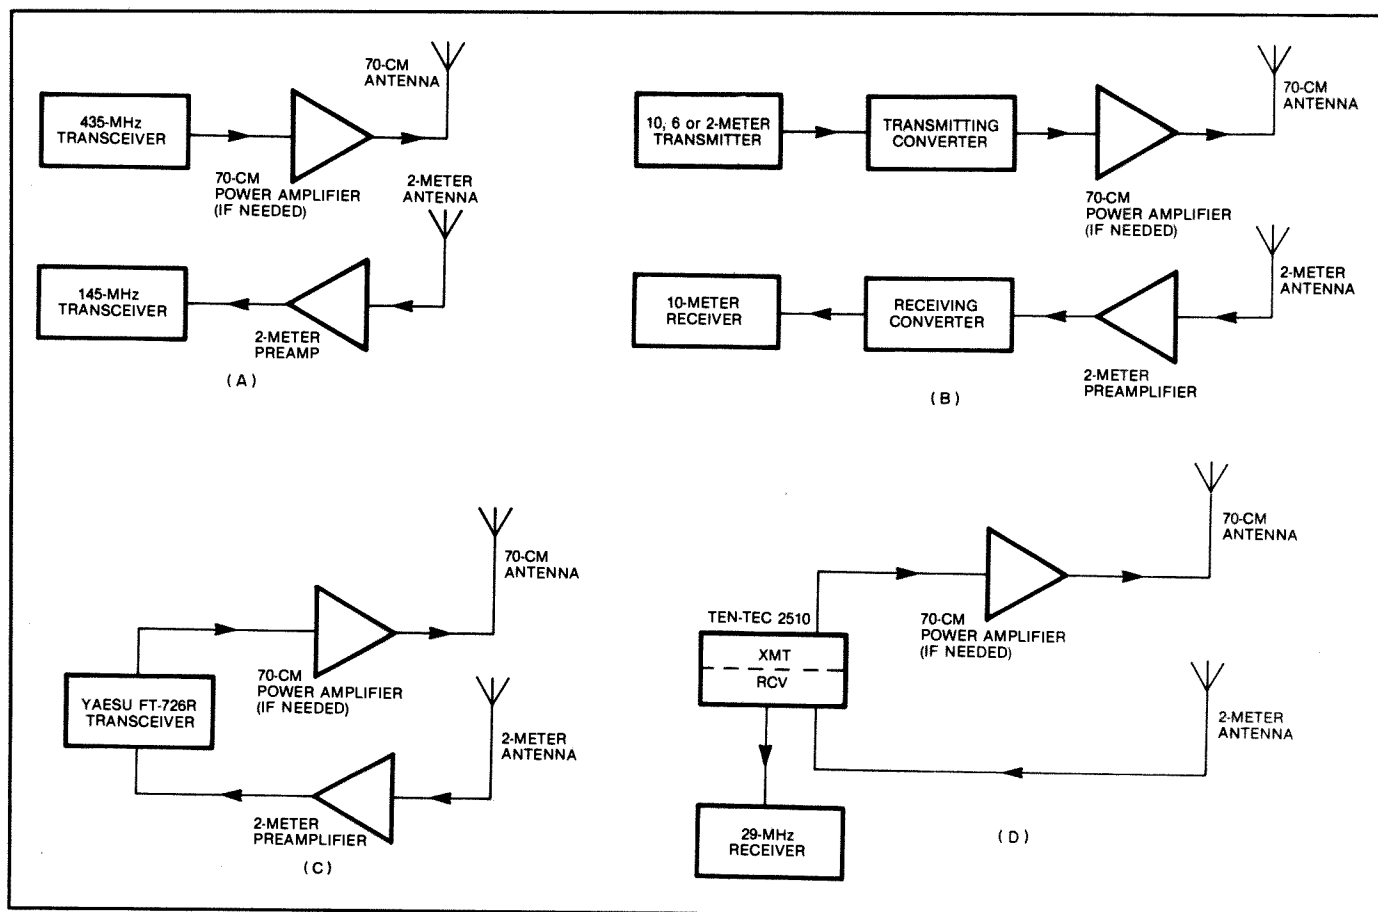

Fig. 7 — Several different Mode B satellite-station configurations are shown here. At A, separate VHF/UHF multimode transceivers are used for transmitting and receiving. The configuration shown at B uses transmitting and receiving converters or transverters with HF equipment. At C, the Yaesu FT-726R can perform both transmitting and receiving functions, full duplex, in one package. The Ten-Tec 2510 shown at D contains a 435-MHz transmitter and a 2-meter to 10-meter receiving converter.

For amateurs with HF receivers or transceivers who have no desire for transceive operation on 2 meters, a receiving converter such as this Advanced Receiver Research R144VDA may be the answer. Shown with matching low-noise GaAsFET preamplifier, this unit converts 2-meter OSCAR 10 downlink signals for reception on any receiver that can tune to 29 MHz.

multimode transceiver.

### Preamplifiers

No discussion of satellite receiving systems would be complete without mentioning preamplifiers. Good, low-noise preamplifiers are essential for receiving weak downlink signals. Multimode rigs and most transverters will hear much better with the addition of a GaAsFET preamplifier ahead of the receiver front end, albeit at the expense of a considerable reduction in the third-order intercept point of the receiver. While a preamplifier can be added right at the receiver in the station, it may not do much good there. Considerably better results can be obtained if the preamp

is mounted at the antenna. Indeed, antenna mounting of a preamp is essential for UHF operation. Losses in the feed line will seriously degrade the noise figure of even the best preamplifier mounted at the receiver.

Table 6 lists several sources of commercially-built preamplifiers. These are available in several configurations. Some models are designed to be mounted in a receive-only line, for use with a receiving converter or transverter. Others, designed with multimode transceivers in mind, have built-in relays and circuitry that automatically switch the preamplifier out of the antenna line during transmit. Still others are housed, with relays, in weatherproof

A low-noise GaAsFET preamplifier such as this Angle Linear model is essential if you want to maximize your downlink reception. The preamplifier should be mounted at the antenna for best results.

enclosures that mount right at the antenna. For the equipment builder, several suitable designs appear in Chapter 31 and in *The Satellite Experimenter's Handbook*.

### Transmitters

The OSCAR 10, Mode B uplink requires 5 to 20 W of 435.1-MHz RF at the antenna. This assumes a good antenna, which will be discussed later. Feed-line losses in a typical 435-MHz installation can easily run 3 dB, so you'll need anywhere between 10 and 50 W output from your transmitter. OSCAR 10, Mode L, presents rather high transmitting power requirements (approximately 10 to 25 kW ERP), caused by the failure of a single transistor. The Phase III-C spacecraft is expected to have a more normal 2 kW ERP requirement.

Since the possible number of combinations of transmitter power and antenna gain needed to give a satisfactory signal through OSCAR 10 is infinite, satellite users generally talk about their uplink capability in terms of effective radiated power (ERP). ERP takes into account antenna gain, feed-line loss and RF output power. For example, a 10-W signal into a 3-dB-gain antenna will have an ERP of 20 W (3 dB greater than, or twice as strong as, 10 W). This assumes no loss in the feed line; all 10 W from the transmitter reaches the antenna. If the signal is 10 W into a 10-dB-gain antenna, the ERP is 100 W. The same 100-W ERP can be achieved with a 50-W transmitter and a 3-dB-gain antenna.

Stations with an uplink ERP as low as 10 W can be copied through OSCAR 10, Mode B, but ERP levels of 100 to 400 W are the norm. No matter what your ERP, your signal on the downlink should never be stronger than the AO-10 general beacon at 145.81 MHz. You must have a way of adjusting your uplink signal so that it is no stronger than the beacon. This point is discussed in detail in *The ARRL Operating Manual*.

If the Mode B satellite ground station has a 10-W transmitter, a short run of low-loss feed line and good antenna gain, an additional amplifier would probably not be needed. If losses and gains do not add up to enough station ERP, a 30- to 40-W amplifier may be needed. Some operators have 100-W amplifiers, but with the antennas available today, use of that much power is guaranteed to create an uplink signal that far exceeds the beacon level. This is considered by good operators to be an antisocial action. Considerate operators with the 100-W amplifiers quickly reduce drive power to lower the ERP to acceptable levels.

Most satellite operators use UHF multimode transceivers to generate Mode B uplink signals. The manufacturers listed in Table 6 all make 70-cm multimode transceivers that are similar to the 2-meter units described earlier. Although most of these transceivers provide 10-W output, some can deliver 25 W or more.

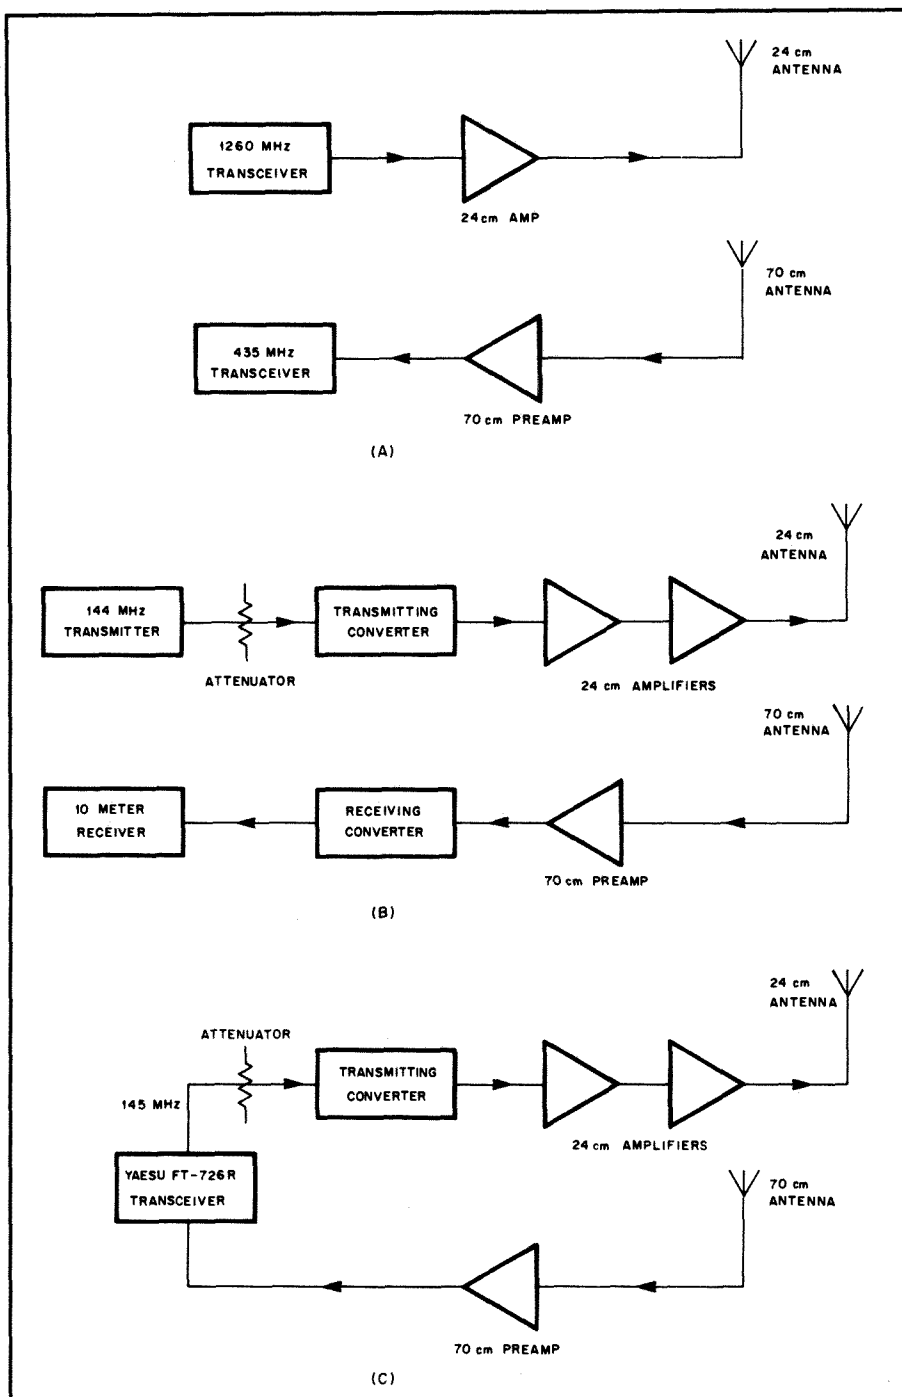

Fig. 8 — Several different Mode L satellite-station configurations are shown here. At A, separate VHF/UHF multimode transceivers are used for transmitting and receiving. The configuration shown at B uses transmitting and receiving converters or transverters with HF equipment. At C, the Yaesu FT-726R can be used for full duplex receiving and transmitting (with the addition of a 2-meter to 24-cm transmitting converter).

Unless you want to try 70-cm terrestrial communication (and that can be fun, too), there is no need for a complete UHF transceiver. Transmitting converters for use with HF transceivers are available from suppliers listed in Table 6. In addition, some of those manufacturers make transverters that are suitable for satellite work. If more 435-MHz power is needed, there are a number of solid-state amplifiers on the market. See Table 6. Choose care-

fully; you don't need a rock crusher.

For Mode L transmitting, there are several transmitting converters, transverters, amplifiers and even a multimode transceiver available from the suppliers listed in Table 6. Chapter 32 details several construction projects that will get you on Mode L. AO-10, Mode L operation will require the power levels offered by a tube-type amplifier, while it is expected that Phase III-C will only need power levels that

can be generated by transistors.

### Specialty Equipment

Separate transceivers or transmitting and receiving converters are no longer the only way to go. Modern equipment offerings by Yaesu and Ten-Tec, tailored for the satellite user, do it all in one package.

The Yaesu FT-726R starts out as a 2-meter multimode transceiver. It is, however, expandable to work on other bands with the addition of optional modules. The Mode-B satellite operator would most likely be interested in an FT-726R with the stock 144-MHz and optional 430-MHz modules. These same RF modules will also serve well for Mode J directly, and Mode L using an outboard 23-cm transmitting converter. To tie it all together, Yaesu offers an optional satellite module that allows the amateur to transmit on one band for the uplink while receiving on another band for the downlink. This is full duplex operation; the effect is the same as having two separate radios in one box.

Ten-Tec's 2510 is tailored specifically for Mode-B satellite operation. This unusual piece of equipment includes a hot receiving converter that converts 145-MHz signals to 10 meters for reception on any HF receiver or transceiver. A low-noise GaAsFET preamplifier is built in, so no external preamp is required. For the uplink, the 2510 has a complete 10-W, 435-MHz SSB and CW transmitter. The 2510 has only one frequency tuning control for the receiver and the transmitter. The receiver automatically tracks the transmitter, an exceptionally useful feature for busy satellite operators.

### Antennas

The best antennas for OSCAR 10 have circular polarization (CP). Helical antennas like the ones shown in Fig. 10 were the way to go for Phase II satellites. An eight-turn helical for 70 cm and a huge six-turn helical for 2 meters provided excellent results for OSCAR 8. For OSCAR 10, however, more gain is needed than a reasonably sized helical antenna can supply. In addition, successful OSCAR 10 operation requires the ability to conveniently switch from RHCP to LHCP.

The present trend in satellite arrays uses a different method to achieve circular polarization. These antennas, shown in Fig. 11, are essentially two complete Yagis mounted perpendicular to each other on the same boom. One set of elements is mounted  $\frac{1}{4}$  wavelength ahead of the other. The antennas are fed in phase and are switchable from RHCP to LHCP. These particular antennas, manufactured by KLM, have proved to be excellent performers. Cushcraft and Telex/HyGain also manufacture crossed-Yagi satellite antennas for OSCAR service. Emphasis must be placed on achieving CP operation on single boom antennas, rather than multiple separate Yagis mounted orthogonal to

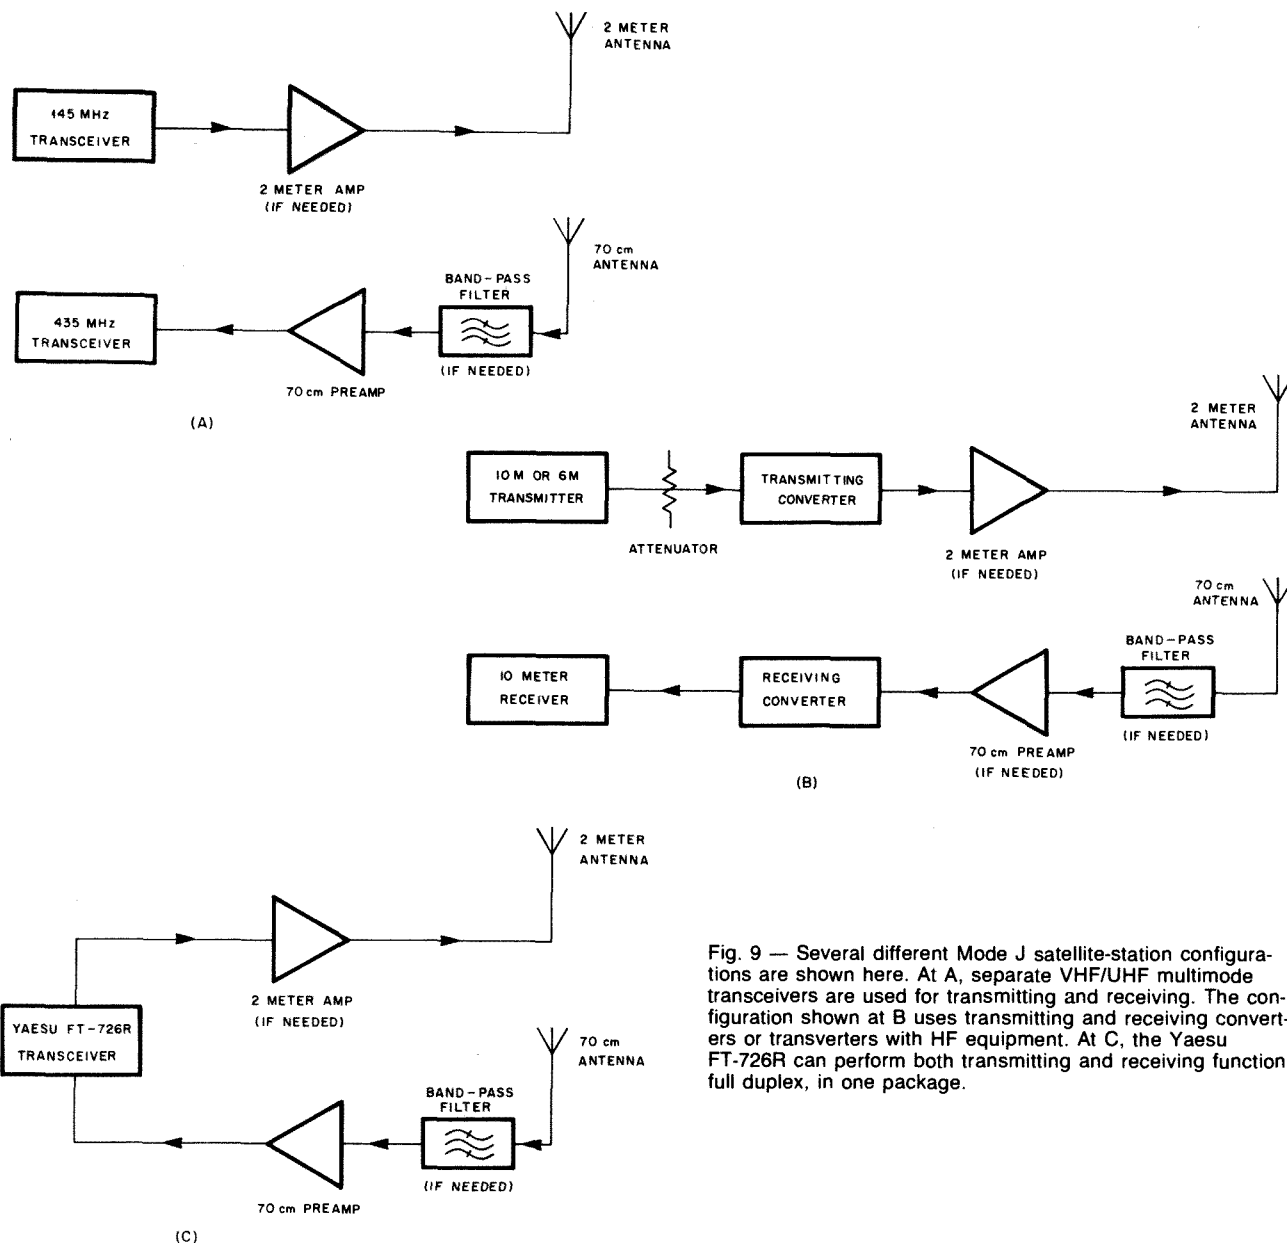

Fig. 9 — Several different Mode J satellite-station configurations are shown here. At A, separate VHF/UHF multimode transceivers are used for transmitting and receiving. The configuration shown at B uses transmitting and receiving converters or transverters with HF equipment. At C, the Yaesu FT-726R can perform both transmitting and receiving functions, full duplex, in one package.

each other. The latter can lead to somewhat uncertain circularity.

Satellite antennas should be mounted as close to the station as possible. Height above ground makes no difference for satellite work, except that the antennas must be mounted high enough that trees and other obstructions do not block the view of the satellite at low elevations. A low mount allows use of shorter feed lines (lower losses) and often reduces QRN pickup by the antennas. Many operators are able to set up their antennas on a 10 to 15-foot mast right next to the shack and have only 20 feet of feed line. Plan to use good-quality, low-loss coaxial cable from the start, such as Belden 9913. Even better is a run of Hardline.

Mode L transmitting antennas have taken numerous forms, mostly based on

the technology needed for EME communications. Loop Yagis, such as those presented in Chapter 32, are popular, but you must stack several in an array to achieve the 24 dBi gain necessary for AO-10, Mode L. Also popular are the large parabolic reflector antennas seen in EME service. For Mode L, and especially for the upcoming Phase III-C satellite, some of these higher gain antennas are overkill. While higher gain means lower transmitter power, the narrow beamwidths require the operator to reposition the antenna more often.

Although a practical CP Yagi for 24 cm has not yet been demonstrated, such an approach may be feasible. Active Mode L operators have found that a small parabolic dish (4 to 6 feet in diameter) with a circularly polarized feed makes a fine Mode

L antenna. A number of reasonably priced TVRO dishes are available, and they require only the addition of a suitable feed for Mode L service. A low-cost, home built parabolic Mode L antenna is presented later in this chapter.

## STATION ACCESSORIES

Satellite communications, like any other specialized facet of Amateur Radio, requires some specialized station accessories. Having the best equipment does not necessarily guarantee success. There are a number of "hints-and-kinks" type ideas that can make OSCAR operation far more satisfying. These items convert a basic receiver, transmitter and a pair of antennas into a very workable operating position. Some of the items discussed here will

Fig. 10 — Helical antennas such as these gave excellent performance for low-orbiting Phase II satellites.

Fig. 11 — A very popular commercially manufactured antenna array for OSCAR 10. Mode B is a pair of KLM crossed Yagis. The large box on the mast contains a 2-meter preamplifier and a 70-cm power amplifier, as well as power-supply circuitry.

The Kenwood TS-811A is a 70-cm multimode transceiver that can be used to generate a 10-W, 435-MHz signal for the uplink. A similar unit, the TS-711A, may be used for the 2-meter downlink.

Another means of generating a 435-MHz uplink signal is with an HF transceiver and a 10-meter to 70-cm transverter such as this SSB Electronics TV28-432.

Usually, a little more than 10-W uplink power is required for a good downlink signal. Solid-state "brick" amplifiers such as this Mirage D1010 provide the extra power needed. Care must be taken, however, to use only the minimum power necessary to maintain reliable communications.

W1INF, the ARRL Laboratory station, has OSCAR 10 Mode-B capability. The uplink is a 2-meter multimode transceiver driving a 2-meter to 70-cm transverter, while the downlink is a receiving converter and 10-meter receiver. A GaAsFET preamplifier is mounted at the antenna.

Yaesu's FT-726R is a favorite among satellite users because it can work on both 2 meters and 70 cm. With the optional satellite module that allows full-duplex operation, the effect is practically the same as having two separate transceivers in one box.

The Ten-Tec 2510 Mode-B satellite station is designed specifically for Mode-B operation. The box contains a 435-MHz SSB and CW transmitter, as well as a 145- to 28-MHz receiving converter with a low-noise front end.

provide capabilities beyond that of satellite operation. They also apply to VHF and UHF terrestrial work. Design your station to suit your own needs.

### Antenna Rotators

Unlike stations located on the surface of the Earth, OSCAR 10 will be found somewhere in the sky above. Operators commonly aim antennas toward another station by changing the pointing angle, or azimuth (sometimes called az). Aiming antennas toward OSCAR 10 requires the control of antenna elevation (el). Satellite

antennas must be able to rotate from side to side and up and down simultaneously. See Fig. 12. While the use of electrically controlled antenna rotators will be discussed here, it might be noted that OSCAR 10's motions are slow enough that hand-operated, "armstrong" antenna control is feasible. At times, the antennas do not need

to be repositioned for periods of up to four hours.

### Azimuth Rotators

Azimuth rotators are commonly used for positioning terrestrial HF and VHF antennas. Antennas for OSCAR 8 and other low-orbit satellites were on the

Fig. 12 — Some of the finer points of this OSCAR array are discussed in the text.

smaller and lighter side, so light-duty TV-antenna rotators such as those sold by Alliance, Channel Master, Radio Shack and others could be used for the azimuth rotator. Today's high-gain satellite arrays are a bit large for these light-duty rotators. Look for something more robust, such as a rotator recommended for turning a small HF beam or VHF array. Various models manufactured by Alliance, Daiwa, Kenpro, Telex and others are routinely advertised in *QST*.

### Elevation Rotators

Elevation rotator selection is somewhat more limited, but there are some interesting things that can be done. Commercially manufactured models are available. The Kenpro KR500, designed specifically for elevating small- to medium-size VHF or UHF arrays, is quite popular among satellite operators. Other offerings include the Dynetic Systems DR10 and Kenpro KR5400, both of which are combined az-el rotators.

A lower cost, commercially manufactured alternative is the Alliance U110 TV-antenna rotator. Rotators of this type have been used by satellite operators for quite a few years. Despite its relatively light construction, the U110 will handle antenna loads weighing up to 80 pounds or more. The key to success is to achieve a static

balance of the antenna mass so that the rotator does not have to elevate a "dead" load. A highly attractive feature of the elevation rotators noted previously is that the cross boom to be rotated passes completely through the rotator. This allows the mounting of one antenna on each side of center and the adjustment of their respective positions for a side-to-side balanced load.

Figs. 13 and 14 show one particular method of mounting the U110. The rotator is clamped to the mast (the one that the azimuth rotator turns) with a plate that permits it to mount 90° from its normal orientation. With the rotator mounted in this position, it is not protected from rain or snow as well as it is in the normal position. A cover (an appropriately sized plastic dishpan or bucket is ideal) is added to afford protection from the elements. A problem with polyethylene plastics, commonly used in kitchenware, is that solar radiation quickly deteriorates their polymeric structure and causes the plastic to break apart. As shown, the plastic cover has been protected from the sun with an aluminum baking pan.

### Antenna Cross Boom Construction

One requirement not commonly discussed is that of using a nonmetallic elevation axis boom for antennas that have their boom-to-mast mounting hardware in the center of the boom. A metal cross boom will seriously distort the beam pattern of a circularly polarized antenna, so it is important to make the cross boom from nonmetallic material.

From a structur-

al standpoint, the best nonmetallic material for this job is glass-epoxy composite tubing, because its stiffness is excellent. Lengths of this material may be found at an industrial supply house that specializes in plastics. Also, KLM sells lengths of 1½ inch OD fiberglass masting for this purpose, and Telex/HyGain includes fiberglass masting with their OSCAR antennas. If you have a rotator that will accept a 1½ inch elevation boom, then your best bet is to use a single piece of this tubing.

A less expensive alternative is to make the cross boom from a combination of metallic and nonmetallic tubing. For strength and stiffness, use a short length of steel or aluminum tubing through the middle of the rotator. Let the metal tubing extend for about 6 inches on each side of the rotator. Then install nonmetallic masting, such as common PVC pipe, over the steel stubs.

The elevation boom pictured in Figs. 12 to 14 was constructed with this method. The center piece that fits through the U110 is a 2-foot section of 1.33-inch-OD steel tubing that originally was part of the top support rail of a chain-link fence. Attached to the steel stub on each side of the rotator is a 4-foot length of 1¼ inch, schedule-40 PVC pipe. PVC pipe is specified by the nominal ID, here 1¼ inches. There are several varieties of 1¼ inch PVC pipe — schedule 40 indicates a thick-wall, heavy-duty version. This pipe slipped nicely over the center stub. The fit is perfect — no machining was needed.

Unlike glass-epoxy tubing, PVC pipe is not very stiff; it needs help. The secret to making PVC pipe capable of supporting satellite Yagis is to insert a wooden dowel into the PVC pipe, along its entire length. The finished dimension of 1-3/8 inch wooden clothes-rod dowel (the kind you might hang inside a closet) is just perfect for a slide fit into the pipe. This material is available from most lumber yards. Add a few ¼ inch bolts to each side to secure the

Fig. 13 — The elevation rotator, an Alliance U110, is protected from the elements by plastic and aluminum covers. The large white box holds tower-mounted equipment.

Fig. 14 — Close-up of the U110 showing how it mounts to the mast. Note the PVC pipe that slides over the steel stub protruding from the rotator.

Fig. 15 — Details of the position potentiometer mounting and weighted arm.

pieces, and you've got a sturdy, inexpensive, nonmetallic elevation boom.

#### Position Indicators

You may notice additional hardware around the elevation rotator shown in the photos. With the use of high-directivity antennas, the accuracy of the U110 control box is questionable. Adding a single-turn, 1-k $\Omega$  precision potentiometer provides the ability to closely control and position the elevation boom. See Fig. 15. The potentiometer (a large surplus instrumentation model) is attached to the elevation boom with a U bolt and angle bracket. A metal arm with lead weights at the end is attached to the potentiometer shaft. The weighted arm and gravity hold the shaft still while the potentiometer body turns with the elevation boom.

A simple circuit, shown in Fig. 16, is all that is needed to control the U110 and to use signals from the precision potentiometer (R3) for an accurate position indicator. R1 is used to zero the scale, while R2 calibrates the range of the indicator. The value of R2 will depend on the value of the voltmeter you use. For example, a 0- to 100-mV meter might be used, adjusted so that 10 mV equals 10° elevation, 30 mV equals 30° elevation, and so on.

#### Tower-Mounted Preamplifiers

To get the most out of your satellite

station, you'll need to mount a low-noise preamplifier on the tower or mast, near the antenna, so that feed-line losses do not degrade low-noise performance. Feed-line losses ahead

of the preamplifier add directly to receiver noise figure. A preamp with a 0.5-dB noise figure will not do you much good if there is 3 dB of feed-line loss between it and the antenna.

There is a variety of good preamplifiers available. Chapters 31 and 32 detail several suitable construction projects, and Table 6 lists many commercial suppliers. Mast mounting of sensitive electronic equipment has been a fact of life for the serious VHF/UHFer for years, although it may seem to be a strange or difficult technology for many HF operators. A mast-mounted preamp is not difficult to construct, and there is a growing number of commercially available models as well. See the list of equipment suppliers in Table 6.

Take another look at Fig. 13. The large white box located below the elevation rotator can't be missed. Fig. 17 shows the interior of this box: It contains a lot of items besides a simple preamplifier. The box holds two racks of equipment. On the right are two dc voltage regulators with their pass-transistor heat sinks. These regulators provide on-site-regulated 28-V dc and 12-V dc from an unregulated 50-V dc supply located in the shack. Below the regulators is a 24-cm transmitting converter for the Mode L uplink. Opposite the regulators on the other rack panel is a 70-cm solid-state power amplifier for the

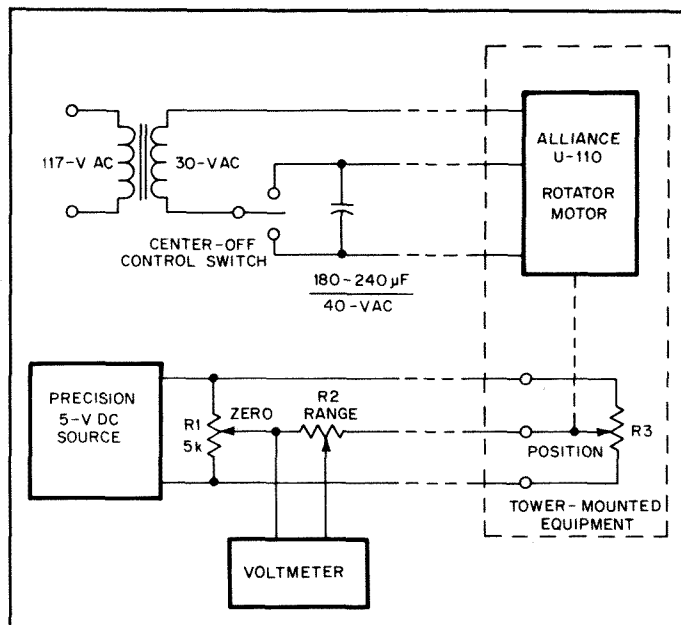

Fig. 16 — Block diagram of the elevation rotator direction control and position readout.

station, you'll need to mount a low-noise preamplifier on the tower or mast, near the antenna, so that feed-line losses do not degrade low-noise performance. Feed-line losses ahead

Mode B uplink, a 70-cm preamplifier for the Mode L downlink, and relays.

Fig. 18 is another view that details the area below the 24-cm transmitting converter. A close look shows a 2-meter preamplifier for the Mode B downlink and relays to switch it in and out of the line to the antenna. This setup is overkill to beat excessive feed-line losses. Normal installations require only the receiving preamplifier (2 meters for Mode B and 70 cm for Mode L) to be mounted on the mast.

#### Station Control Circuitry

Fig. 19 is a schematic diagram of the control circuitry for the tower-mounted rack. Parts of this diagram will be helpful, even if only the preamp is just mounted at the antenna. Note that this circuit is designed around the surplus coaxial relays that were available at the time. Your version will probably be different and will depend on the relays available to you. Switching requirements for coaxial relays were the subject of a comprehensive discussion by Joe Reisert, W1JR. Fig. 19 is one version of his concepts.

This circuitry performs several functions. For starters, it places the preamp in the line only during receiving periods and takes it out of the line during transmitting periods as well as at those times when the station is not in use. This is needed if the satellite array is used for terrestrial transceive operation as well. The switching arrangement shown also protects the preamp from stray electromagnetic pulses (EMP), such as lightning strokes, when the station is not in use. EMP protection is desirable even if the antenna and preamp are used only for receiving OSCAR 10 signals.

Fig. 19 is a bit more complicated than the average mast-mounted preamp setup

Fig. 17 — Interior of the tower-mounted equipment rack with the cover removed. The 70-cm equipment is on the left, while power-supply regulators, a 24-cm transmit converter and a 2-meter preamp are mounted on the right.

Fig. 18 — Close-up of the 2-meter preamplifier and relays.

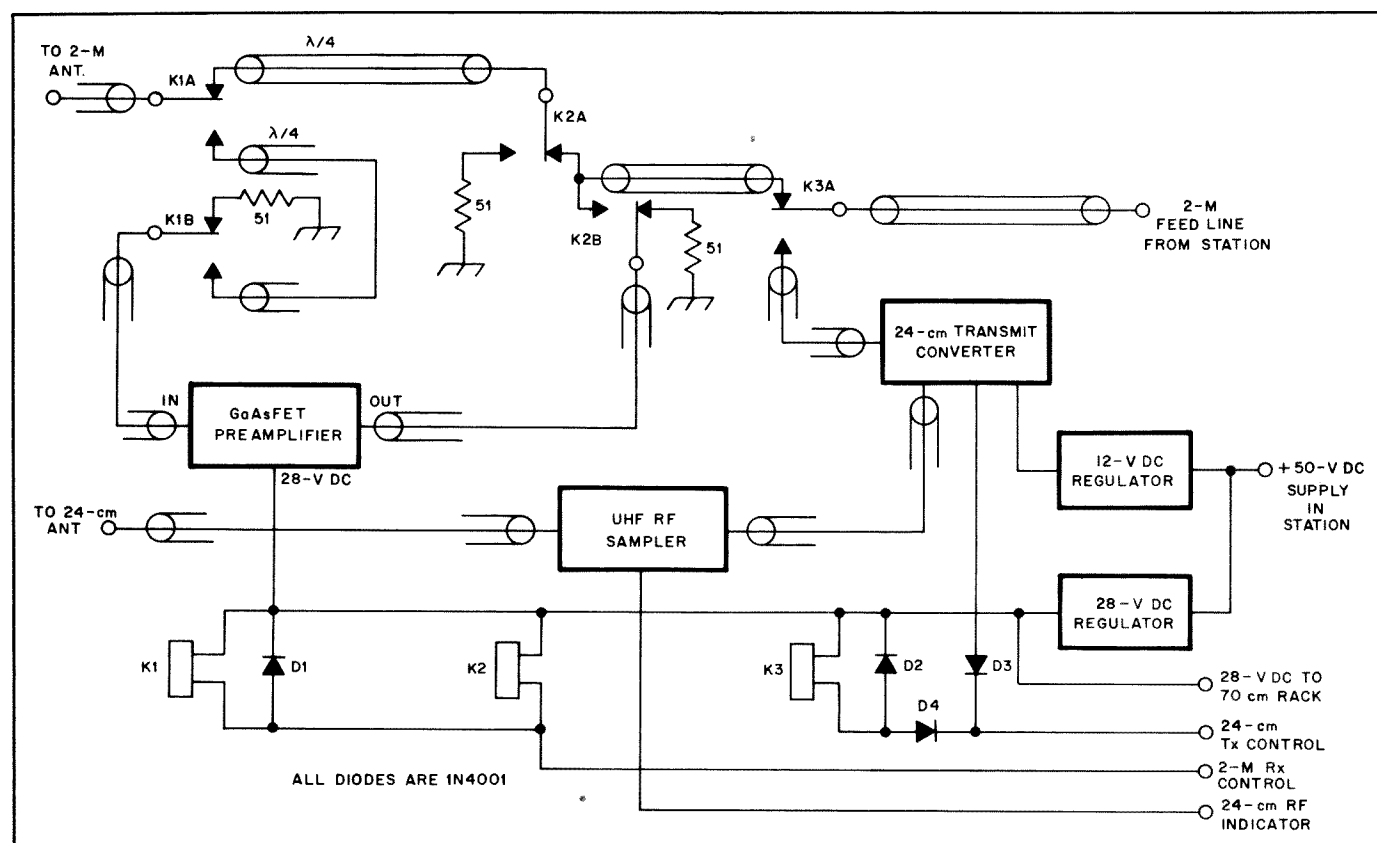

Fig. 19 — Control circuitry for the mast-mounted 2-meter preamplifier. K1-K3 are surplus coaxial relays.

because it also allows 2-meter RF to drive a 24-cm Mode L transmitting converter. An extra relay (K3) is used to switch between 2-meter and 24-cm operation. K1, a DPDT transfer relay, switches the input of the preamp between the antenna and a 50-ohm termination. K2, another DPDT relay, switches the preamp output between a 50-ohm termination and the feed line to the shack. The coaxial cable used for connections between the relays is cut to 0.1 to 0.2 electrical wavelength to achieve maximum isolation between the transmitted RF and the preamp input. The relays are connected so that they must be energized to place the preamp in line.

### Tower-Mounted Equipment Shelters

A great many amateurs seem apprehensive about placing their valuable radio equipment outdoors. Such fears are unfounded if adequate care is taken to protect the equipment from the elements. The equipment shown in the photos has been outdoors for years without any adverse effects.

The present mast-mounted enclosure shown earlier is a welded aluminum box purchased from a surplus dealer. It was used because it was available and the price was right. You don't really need a big box like this if you just want to protect a preamp and relays.

Fig. 20 shows the basic scheme for weatherproofing tower-mounted equipment. The fundamental concept is to provide a cover to shelter equipment from rain. A 2-inch-deep aluminum cake pan is about the minimum acceptable cover. A trip to the housewares section of the local department store will reveal a variety of plastic and aluminum trays and pans that can make suitable rain covers. As mentioned before, polyethylene plastic must be protected from sunlight. Clear polystyrene refrigerator containers work better than those made of polyethylene, and aluminum is best of all. Choose a cover that is large enough for your equipment; remember to leave room for connecting cables.

The bottom of the rain cover is open to the elements. This is done on purpose and will not cause any problems. Do *not* try to hermetically seal the enclosure. By leaving the bottom open, adequate ventilation will prevent accumulation of water condensation. Just make sure that water cannot run into the enclosure by way of cables coming from above. Form the cables as shown in Fig. 20 to provide drip loops. Adding a piece of window screen over the opening should be considered to avoid infestations of nesting insects, such as wasps.

### Transmitting Accessories

Fig. 21 shows the 70-cm rack from the mast-mounted equipment box. The 70-cm power amplifier (built on the heat sink at the left of the photo) is mounted in the box near the antenna to avoid feed-line losses.

Fig. 20 — Protection for tower-mounted equipment need not be elaborate. Be sure to dress the cables as shown so that water drips off the cable jacket before it reaches the enclosure.

Tower mounting of a transmitter is probably unnecessary for 70 cm, but becomes more important for higher frequencies. Feed-line losses at 70 cm are generally twice those of 2 meters, while those at 24 cm are about twice those of 70 cm, or four times those of 2 meters. For an 80 foot feed line, the losses at 24 cm can easily reach 6 dB for even the best flexible coaxial cable. A 100-W amplifier in the

shack will only yield 25 W at the antenna. A good alternative is to place the transmitting converter and a 20-W solid-state amplifier in the tower mounted box near the antennas. The results are nearly the same, and you avoid the time and money needed to generate high power that will just be lost in the feed line anyway.

A coaxial RF sampler is connected to the output of the 70-cm amplifier shown also in Fig. 21. It's nice to be able to monitor the power at the antenna to be sure that everything is working properly. To the right of the power amplifier is a 70-cm preamp and coaxial relays used for OSCAR Mode L reception and terrestrial operation.

One very important aspect of using GaAsFET preamps with transmitting equipment is getting everything to switch in the proper sequence. If transmitters, amplifiers and antenna relays are keyed simultaneously, it's likely that RF will be applied to the feed line before the relays are fully closed. Such *hot switching* can easily arc the contacts on expensive coaxial relays. In addition, if the TR relay is not fully closed, RF may be applied to the pre-amplifier. Such bursts of RF energy are guaranteed to destroy the GaAsFET in the preamplifier. Many pieces of transmitting equipment (especially multimode transceivers) emit a short burst of RF power when switched on or off, so there is the risk of transmitting into your preamp even if you are careful to pause before keying.

Ideally, keying of a transmitter should follow a sequence that will ensure the safety of the equipment. When you switch into transmit from receive, the coaxial relays change state to remove the preamplifier from the line. Next, the power amplifier is keyed on. The last thing that happens is that the transmitter RF is enabled. When switching back to receive, the sequence is just the opposite. First, the transmitter RF is switched off, the power amplifier is disabled, and then the TR relays change state to place the preamp back in service.

Fig. 21 — The 70-cm equipment panel holds a power amplifier, preamp and TR relays.

Solid-state sequencers to control station TR switching are shown in Chapters 31 and 32. In addition, a unit designed specifically for use with the Yaesu FT-726R is presented later in this chapter.

### Receiving Accessories

The only additional useful equipment applies to those stations using a receiving converter and an HF receiver for downlink reception. An in-line switchable attenuator can be installed between the converter output and the antenna jack of the 10-meter receiver. Such an attenuator can be used to lower the AGC level and improve the perceived signal-to-noise ratio. In addition, by adjusting the attenuator so that the S meter on the HF rig rests at zero at no signal, more accurate signal reports can be given. The attenuator circuit is shown in Chapter 25. A modified form has been found useful so that there are only three steps: 5, 10 and 20 dB. These three settings allow attenuation in 5-dB steps from 0 to 35 dB.

### Antenna Accessories

Long-boom Yagis, such as the KLM antennas shown in Fig. 11, can suffer from boom sag that might cause pattern distortion and pointing errors. In addition, a boom support is desirable in areas where high winds or ice are a problem. To avoid possible interference with the antenna pattern, the boom brace should be made from nonconductive material such as Phillystran™ HPTG2100 guy cable.

Details are shown in Fig. 22. The vertical boom-brace support member is also non-conductive, made from a fiberglass fishing rod blank. A short piece of threaded stainless-steel rod inserted in the top of the tube is used to adjust tension on the boom brace. A 2-inch piece of 5/16-inch copper tubing brazed across the threaded rod in a "T" fashion holds the Phillystran cable in place. Jam nuts secure the threaded rod once the boom is straight.

Experience with the exposed relays on the circularity switchers used on some commercial antennas has shown that they are prone to failure caused by an elusive mechanism known as "diurnal pumping." The relay is covered with a plastic case, and the seam between the case and PC board is sealed with a silicone sealant. It is not hermetically sealed, however. As a result, the day/night temperature swings pump air and moisture in and out of the relay case. Under the right conditions of temperature and moisture content, moisture from the air will condense inside the relay case. Water builds up inside the case, promoting extensive corrosion and unwanted electrical conduction, seriously degrading relay performance in a short time.

A good rain shelter keeps water from falling directly on the equipment, yet allows the enclosure to "breathe," eliminating water buildup. Equipment in such an enclosure will stay dry and healthy, save

Fig. 22 — A boom brace may be desirable for long Yagis. This arrangement is made from non-conductive material to prevent undesirable effects on the antenna pattern.

Fig. 23 — KLM 2M-22C antenna CP switcher relay with relocated balun and protective cover.

perhaps for minor corrosion on unprotected steel.

If you have antennas with sealed plastic relays, such as the KLM CX series, you can avoid problems by making the modifications shown in Fig. 23. Relocate the 4:1 balun as shown and place a clear polystyrene plastic refrigerator container over the relay. Notch the container edges

for the driven element and the boom so that the container will sit down over the relay, sheltering it from the elements. Bond the container in place with a few dabs of RTV adhesive sealant.

Position the antenna in an "X" orientation, so that neither set of elements is parallel to the ground. The switcher board should now be canted at an angle, and one

Fig. 24 — This low-profile control unit houses a TR sequencer and provides instant control of many station functions.

side of the relay case should be lower than the other. Carefully drill, by hand, a pair of 3/32-inch holes through the low side to vent the relay case. See Fig. 23. The added cover keeps rain water off the relay, and the holes prevent any condensation buildup inside the relay case.

### Station Control

Depending on the complexity of your satellite station, you might want to combine most of the switching and control circuitry into a single box so that it provides ready access to all controls. Fig. 24 shows a Minibox cut to a low profile (small enough to fit underneath a transceiver) that contains all of the switches needed to control the station. It houses a TR se-

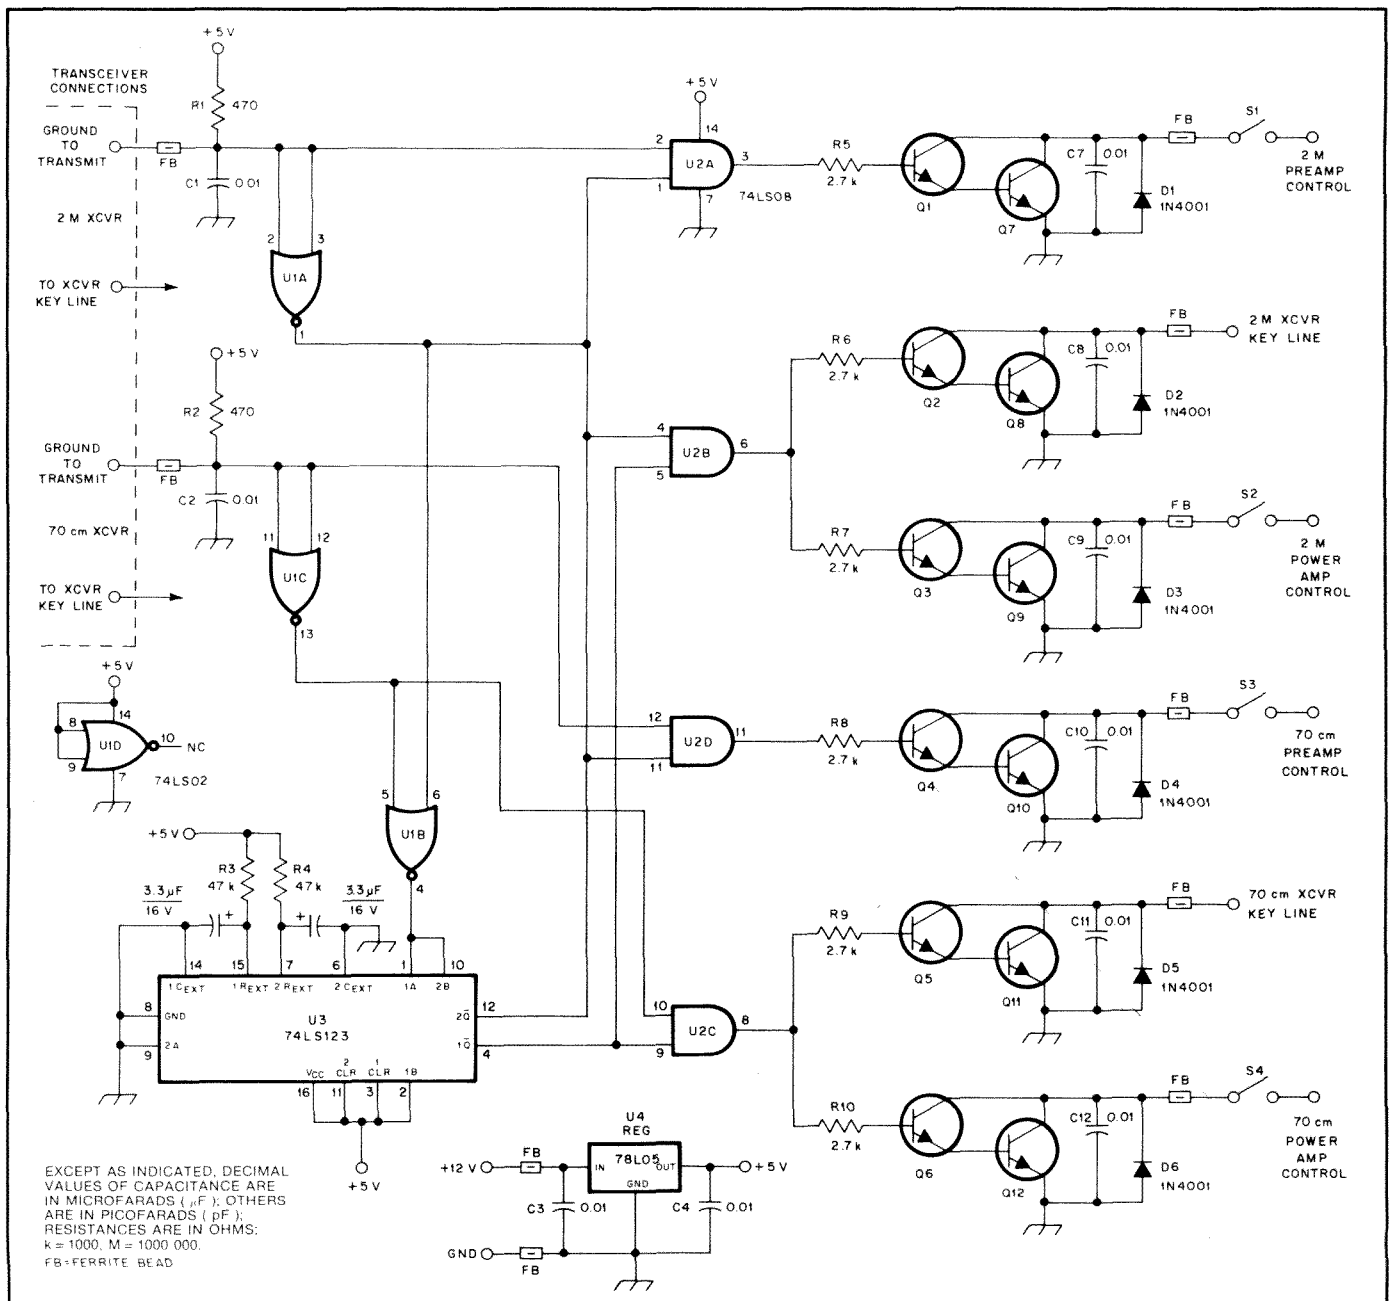

Fig. 25 — Schematic diagram of the digital TR sequencer. All resistors are  $\frac{1}{4}$  W unless noted. Capacitors are disc ceramic unless noted. Capacitors marked with polarity are electrolytic. The output switching transistors (Q1-Q12) can be just about anything that will handle the current requirements.

Fig. 26 — Parts placement diagram for the digital TR sequencer. A full-size etching pattern is given at the back of this book.

Fig. 27 — The digital TR sequencer is built on a PC board. The output switching transistors can be mounted to the chassis for improved thermal dissipation.

quencer circuit board as well. This box controls the following functions: change antenna polarization from RHCP to LHCP on 2 meters and 70 cm; switch the 2-meter and 70-cm preamplifiers in and out of the circuit; and switch the power amplifier in or out of the line. Also provided is the option for control of the PTT. The microphone connects to the box, which allows the PTT line to be intercepted before going to the transceiver. The mic PTT switch activates the sequencer, which controls all the other switching, including transmitter PTT.

## A DIGITAL TR SEQUENCER FOR SATELLITE WORK

The need for properly controlling the sequence of events in switching a station from transmit to receive is covered in detail in Chapters 31 and 32. The main advantage of sequencing, rather than just switching everything simultaneously, is to protect equipment from damage. For example, sequencing will prevent you from transmitting into a preamplifier or hot switching relays. The TR sequencer described here can be used for other aspects of VHF and UHF operation, but it was built with full duplex (on two bands) satellite operation in mind. Dick Jansson, WD4FAB, designed and built this sequencer for use with a Yaesu FT-726R transceiver.

### Circuit Details

Fig. 25 is a schematic diagram of the sequencer. The component count is quite low. Most of the discrete components have been added to protect the circuit from RFI problems. U1 and U2 provide control signal conditioning and digital switching logic, while U3 provides both the key-down and key-release timing. A pair of Darlington-connected transistors were used for each relay driver (Q1-Q12) so that practically any garden-variety transistors can be used. The tabs of the TO220 transistors are mounted to a heat sink for conservative operation. Although most of the switching needs in a modern amateur station require transistors that can handle a few milliamperes of current, some surplus coaxial relays require 500 mA or more. These "generic" control transistors will handle all jobs.

This sequencer provides a 50-ms delay for the transmitter and power amplifier outputs, giving the preamp relays time to settle. Another 50-ms delay is provided for returning the preamps to the line after the transmitter and power amplifier have been turned off. These time delays are conservative, but not at all noticeable in operation. If 50 ms is too long, the 3.3  $\mu$ F timing capacitors could be reduced to 2.2  $\mu$ F to get into the 30 ms timing range.

### Construction and Installation

Construction is straightforward. All components are mounted on a PC board as shown in Fig. 26. Etched circuit boards

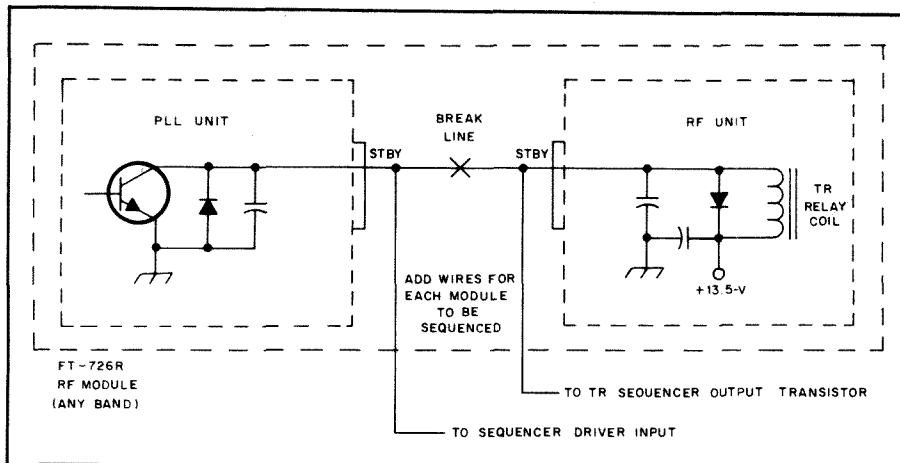

Fig. 28 — The Yaesu FT-726R can be modified so that the TR sequencer can be used to switch it into transmit.

and partial parts kits are available from A&A Engineering (see Chapter 35 parts suppliers list). The output transistors are mounted so that they hang over the edge of the board and can be mounted to the chassis to dissipate heat. See the detail in Fig. 26. Fig. 27 is a photo of the finished unit.

Although this unit was designed with the FT-726R in mind, it can be used with any equipment. If you wish to use it with the FT-726R, Fig. 28 shows a good way to connect everything. This modification allows you to intercept the TR switching for each FT-726R RF module, but it requires no drilling or irreversible modifications. Each RF module in the Yaesu rig has a TR relay and driver transistor that are on separate PC boards within the module. A small three wire cable and connector join them. Simply break the lead and run wires out through the louvers on the bottom of the transceiver.

## A MODE-L PARABOLIC ANTENNA AND FEEDHORN FOR OSCAR-10

OSCAR 10, Mode L requires a high-gain antenna for the uplink. This parabolic dish antenna, first described by Eugene F. Ruperto, W3KH, in May 1986 *QST*, provides adequate gain for successful Mode L QSOs. It can be built at home for a small investment in time and money, and is made from readily available materials.

### Design Strategy

Some Mode L stations are using commercially built TV dishes. Considering the work needed to put them together, cover them with screen, build a feed antenna and supports, add a mount, and live with a deep f/D (usually 0.375), the buyer basically gets only a preformed wire grid for his money. The custom-design approach advocated here offers the builder some measure of control over the finished product. It's possible to design and construct parabolic reflectors of any reasonable size for any amateur endeavor.

This dish was designed with a three-step approach. First, the dish should be effective, which means that a study of size versus power must be considered. Calculations indicate that a gain between 21 dBi and 27 dBi would be sufficient, provided that the transmitter power is enough to reach the target value of 3 kW EIRP (see Table 7). Second, the dish should be light so that it can be mounted at the mast with other satellite antennas. This prevents an aiming discrepancy later on (such as the downlink antenna pointing at the bird and the uplink antenna pointing toward some meaningless position in space). This becomes more apparent as dish size increases, which brings up the third requirement — beamwidth. A wide-beamwidth dish is nice to have for a moving satellite, but it means a sacrifice in gain. On the other hand, too large a dish will narrow the beamwidth sufficiently to make tracking a chore. Although the Phase III satellites don't require much beam pointing near apogee, the Mode-L operating period is sometimes changed to a lower mean anomaly for operational reasons, and the ground track can cover a considerable angle in terms of antenna movement. It's a nice feeling to not have to aim the antenna more than once every 10 or 15 minutes during the Mode-L period. Calculations indicate that a five-foot (1.52-m) dish, with 12 watts of power at the feed horn, should do the job.

### Materials

The dish ribs are made from ¼-inch diameter steel pencil rod (a mild steel). With a weight of 0.167 pounds per foot, it allows the antenna to be light enough to rotate with other antennas. This pencil stock is usually sold in 20-foot lengths, called "joints," and at this length they are extremely flexible. To get them home, plan to cut them in half with a hacksaw or carry them on an extension ladder on top of the pickup. Keeping the original length will minimize waste when making your cuts. The cost of a 20-foot joint is less than

Table 7

### Design Considerations for Parabolic Dish Antennas

Dish Size	4'	5'	6'
Beamwidth (Deg)	13.2	10.5	8.7
Gain (dBi)	21.8	23.7	25.3
Output Power (W)	EIRP	EIRP	EIRP
100 W	16.2 kW	25.4 kW	36 kW
50 W	8 kW	12.75 kW	18.3 kW
30 W	4.8 kW	7.65 kW	11 kW
15 W	2.4 kW	3.75 kW	5.4 kW
10 W	1.6 kW	2.5 kW	3.6 kW
5 W	800 W	1.25 kW	1.8 kW
2.5 W	400 W	625 W	900 W

<sup>†</sup>Based upon 50% reflection efficiency and 10-dB taper feedhorn for 0.4 f/D dish

\$2.00. Roughly figured, five joints will be needed for a 5-foot dish. Excluding the price of a piece of pipe and three hose clamps, the steel needed for the 5-foot dish will set you back about \$10, which is a lot less than the cost of your average catalog TV dish.

The dish covering is common aluminum screen-door material, which is a lot easier to work with than hardware cloth. The door screen material mesh size is much smaller than the one-tenth wavelength required to be a perfect reflector at this frequency, but it also presents greater wind loading, with the probability of ice and snow accumulation. The fact that the dish can be pointed to a stored position when not in use, however, minimizes these effects. A 16-foot-long by 3-foot-wide piece of aluminum screen, which can be obtained at most hardware stores for less than \$10, is more than ample for the 5-foot dish.

A very neat, taut covering can be accomplished by using Liquid Nail™ or similar material to glue the screen to the ribs. Use a caulking tube (price less than \$2) to apply the glue. Make sure the glue is waterproof since it will be exposed to the weather. A question arises concerning possible galvanic action between the steel rod and the aluminum screen. The glue matrix acts as a buffer between the metals and, for the most part, as an insulator between the two. As a consequence, only very small areas will occasionally make contact. Though these could disintegrate over a period of time, the glued surface area will be much larger and still retain the original strength. The entire screen surface may be removed with a pair of scissors or a sharp knife. After grinding the rib surfaces free of glue, a new screen surface can be applied.

### Dish Construction

A ¼-inch-thick piece of scrap steel plate, 2 × 4 feet, is used as a jig to build the ribs. The parabolic X and Y coordinates (see Table 8) are transferred to the plate, spaced roughly every 3 inches, by tracing the figure on the plate. Short pieces of ¼ inch steel strap are tack welded along the curve to

Table 8

## Detailed Design for Three Parabolic Dish Antenna Sizes

of the rib to clamp around a slightly longer piece of 1/2 inch pipe, threaded at both ends, that forms the central hub.

Once the jig is completed, and the first rib welded and checked, the remaining five ribs can be constructed in a short time. The rib accuracy is checked using a plywood curve gauge cut out on a bandsaw. Because of the six-rib design, a sloppy fit results when the ribs are clamped to the hub piece. Add additional 9-inch pieces of pencil rod as fillers to make a tighter fit when attaching the ribs to the 1/2 inch pipe hub. Place the ribs and pipe face down to space the ribs evenly. The dish shown used a joint of pencil rod, bent to a diameter of five feet around a tractor tire, that was welded to the outer tip of each rib before tightening the hose clamps. Alternatively, single pieces of rod may be cut to fit between the ribs at the edge of the dish to form the rim. The completed dish, with center pipe hub, weighs approximately 12 pounds. More ribs could be added, at the expense of additional weight.

Cut sectors of aluminum screen that are slightly larger than the rib spacing so that the sectors will overlap. Run a bead of Liquid Nail, or other glue, on the front side of two ribs and the included part of the external ring and press the screen sector in place. The glue dries fairly rapidly at room temperature. Run a strip of thin wood over the screen surface to tighten it and allow the glue to penetrate and hold the screen surface. By the time this operation is complete, the next sector can be applied in the same manner.

### Feed-horn Construction

Many tin-can feed horn designs have been described in past articles. Designs that use motor oil and coffee cans seem to work well enough, but require some modification, usually in the length, to perform optimally at the design frequency. In addition, they also have a tendency to disintegrate after a short stay in the elements, even when painted. The feed horn used here was custom built from 26-gauge galvanized steel capped and soldered at one end. It has only one seam running longitudinally along the feed axis. A piece of copper tubing, threaded to accommodate a no. 8-32 bolt for tuning, is soldered to an N connector (see Fig. 31). The N connector is then soldered with a propane torch into a 5/8-inch hole, located as shown in Fig 31. Apply two coats of paint to the outside of the horn for protection.

The feed used here is linear-polarized for several reasons. Most of the stations heard on Mode L are using linear polarization, and the downlink signals sound okay, primarily because of favorable scheduling of OSCAR 10. Feed horns can be easily replaced, so you can try a switchable left- or right-hand circularly polarized feed at a later date. Such a feed horn is described later. The design described here has an SWR of 1.15:1 at 1269.5 MHz, measured

Fig. 29 — Rib construction details. Dimensions are as specified in Table 8.

hold the pencil rod along the front of the curve; then similar pieces are tack welded along the back to hold the pencil rod at the desired shape (see Figs. 29 and 30). The process is repeated for the back rib member

as well as the piece of pencil rod that forms the hub portion of the rib. The hub pieces extend about 2 inches beyond the rib dimensions so that when completed, a hose clamp can be fitted on both front and back

Fig. 30 — Rib assembly jig.

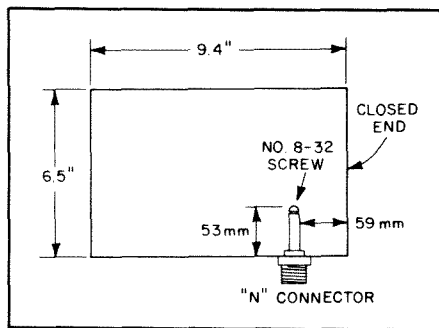

Fig. 31 — Feedhorn construction dimensions. See text for details.

at the feed horn.

The feed horn is mounted on a small plywood saddle attached to a length of  $\frac{1}{4}$ -inch pipe by two small U clamps. The  $\frac{1}{4}$ -inch pipe is offset at the center of the dish with a  $\frac{3}{4}$ -inch,  $90^\circ$  elbow, a short nipple, another  $90^\circ$  elbow, another short

nipple, and a reducer from  $\frac{3}{4}$  to  $\frac{1}{2}$  inch (see Fig. 32).

### Conclusion

The rib design is very strong. During initial testing, the dish took an unscheduled trip across the back yard during a severe windstorm. It suffered only one small deformation on the outer ring and a bent feed horn mount, both of which were easily repaired. The antenna is now tower mounted, as shown in Fig. 33. With 40 W at the feed horn, performance is satisfactory and the pointing angles for tracking are reasonable.

### MODE L FEED HORN WITH CIRCULAR POLARIZATION

The feed horn described here provides circular polarization, which might well prove to be the most effective feed method for Mode L use. It was originally described by Dr. John L. DuBois, W1HDX, in the March/April 1983 issue of

the AMSAT journal, *Orbit*.

A popular feed among 1296 MHz EME operators is a circular horn with two quarter-wavelength stub radiators inside, set at right angles and fed  $90^\circ$  out of phase. This produces the required circular polarization and is inherently unbalanced for simple coaxial cable feed. The feed horn described here is based on that design, but scaled for 1269 MHz.

The feed horn is basically a piece of circular waveguide operated above the TE<sub>11</sub> mode cutoff and below the TM<sub>01</sub> mode cutoff. It is excited by stub radiators approximately  $\frac{1}{4}$  wavelength long and  $\frac{1}{2}$  wavelength from the closed end of the guide. A #10 food can, generally used for institutional quantities of fruits or vegetables, is 6.1 inches in diameter and 6.85 inches long. This gives a TE<sub>11</sub> cutoff of 1135 MHz and TM<sub>01</sub> cutoff of 1484 MHz, neatly positioning 1269 MHz in between. The length should be approximately one wavelength long. This length turned out to be extremely important in tuning the feed for 1269 MHz and determining bandwidth. The diameter and length of the feed stubs are also important tuning factors, determining primarily the input impedance.

Much time was spent optimizing these dimensions with an HP swept return-loss measurement system. The result for a single feed stub (linear polarization) is 20 dB return loss at 1269 MHz over a 20 MHz bandwidth in a 50 ohm system. This corresponds to a 1.2:1 SWR.

Dimensions of the feed horn and placement of the feed stubs are shown in Fig. 34. Two full length #10 cans and part of a third are soldered together. It is necessary to file or steel brush the rims very clean before soldering to get good solder flow. The feed stubs are made from a two inch length of  $\frac{1}{8}$  inch hobby brass tubing soldered to the center pin of a chassis-mount Type N connector. Cut a hole in the assembled feed can to clear the rear insulator diameter of the N connector and scrape paint away from the edges of the hole for about one inch diameter. Then solder the connector shell (already assembled to the brass stub) directly to the outside of the can. This will take a very hot iron and some patience, but you should end up with a solder bead uniformly around the edge forming a weather seal. Be sure to measure carefully to place the second connector and probe exactly  $90^\circ$  around the can and at the same distance from the open end as the first one. After this, the can should be coated with plastic spray to prevent rusting.

The last required detail is a method of splitting the 50 ohm transmitter power into two lines with a phase difference of  $90^\circ$  degrees to feed the two radiator stubs. This is ideally handled by a 3-dB quadrature hybrid. The fourth terminal of the hybrid is terminated in 50 ohms and absorbs any reflections from the antenna. It could also be fed to a power meter to continuously monitor SWR.

Fig. 32 — Completed dish assembly. Note the feedhorn mounting scheme.

Fig. 33 — The completed Mode L dish is mounted on an elevation cross boom with other satellite antennas.

Fig. 34 — Feed horn and radiator probe details. All dimensions are in inches.

Fig. 35 — 1269 MHz quadrature hybrid. All dimensions are in inches.

In this case, the hybrid and termination were designed to handle up to 100 W forward power. The hybrid was designed on 1/16 inch, double-sided, Teflon circuit board. It is a single square design shown in Fig. 35. The shells of the N connectors

connectors are soldered directly to the top foil of the board. The post passes through the board and is soldered to the hybrid pattern on the other side. The termination is made from two 5-W, 100-ohm, carbon-composition (not wirewound!) resistors in

Fig. 36 — Follow this wiring method for right-hand circular polarization. Reversing the connections at the hybrid would yield left-hand circular polarization.

parallel. These resistors are mounted on top of the board and the grounded ends are soldered to the top ground foil with extremely short lead length. The other leads pass through the board and are soldered to the fourth hybrid arm. Keep lead length to the absolute minimum.

Cover the resistors with a liberal amount of silicone sealant and mount the board as the cover of a 2½- × 3- × 1¼-inch Pomona box. Four screws secure the board at the corners and all edges are covered with silicone sealant for a weather tight seal.

Secure the box to the rear of the feed horn. Two coaxial cables of equal length (about 16 inches long) connect the hybrid to the feed stubs in the can. Use RG-213, Belden 9913 or similar low-loss cable. Follow the connection pattern in Fig. 36 for right-hand circular polarization. Reversing the feed cables would yield left-hand circular polarization. The exact details of mounting this feed to your dish will depend on dish design.

## Glossary of Satellite Terminology

- AMSAT** — A registered trademark of the Radio Amateur Satellite Corporation, a non-profit scientific/educational organization located in Washington, DC. It builds and operates Amateur Radio satellites and has sponsored the OSCAR program since the launch of OSCAR 5. (AMSAT, P.O. Box 27, Washington, DC 20044.)
- Anomalous period** — The elapsed time between two successive perigees of a satellite.
- AO-#** — The designator used for AMSAT OSCAR spacecraft in flight, by sequence number (AO-5 through AO-10).
- AOS** — Acquisition of signal — The time at which radio signals are first heard from a satellite, usually just after it rises above the horizon.
- Apogee** — The point in a satellite's orbit where it is farthest from Earth.
- Area coordinators** — An AMSAT corp of volunteers who organize and coordinate amateur satellite user activity in their particular state, municipality, region, or country. This is the AMSAT grass roots organization set up to assist all current and prospective OSCAR users.
- Argument of perigee** — The polar angle that locates the perigee point of a satellite in the orbital plane; drawn between the ascending node, geocenter, and perigee; and measured from the ascending node in the direction of satellite motion.
- Ascending node** — The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Southern Hemisphere into the Northern Hemisphere.
- Az-el mount** — An antenna mount that allows antenna positioning in both the azimuth and elevation planes.
- Azimuth** — Direction (side-to-side in the horizontal plane) from a given point on Earth, usually expressed in degrees. North = 0° or 360°; East = 90°; South = 180°; West = 270°.
- Circular polarization (CP)** — A special case of radio energy emission where the electric and magnetic field vectors rotate about the central axis of radiation. As viewed along the radiation path, the rotation directions are considered to be right-hand (RHCP) if the rotation is clockwise, and left-hand (LHCP) if the rotation is counterclockwise.
- Descending node** — The point on the ground track of the satellite orbit where the sub-satellite point (SSP) crosses the equator from the Northern Hemisphere into the

Southern Hemisphere.

**Desense** — A problem characteristic of many radio receivers in which a strong RF signal overloads the receiver, reducing sensitivity.

**Doppler effect** — An apparent shift in frequency caused by satellite movement toward or away from your location.

**Downlink** — The frequency on which radio signals originate from a satellite for reception by stations on Earth.

**Eccentricity** — The orbital parameter used to describe the geometric shape of an elliptical orbit; eccentricity values vary from  $e = 0$  to  $e = 1$ , where  $e = 0$  describes a circle and  $e = 1$  describes a straight line.

**EIRP** — Effective isotropic radiated power — same as ERP except the antenna reference is an isotropic radiator.

**Elliptical orbit** — Those orbits in which the satellite path describes an ellipse with the Earth at one focus.

**Elevation** — Angle above the local horizontal plane, usually specified in degrees. (0° = plane of the Earth's surface at your location; 90° = straight up, perpendicular to the plane of the Earth).

**Epoch** — The reference time at which a particular set of parameters describing satellite motion (Keplerian elements) are defined.

**EQX** — The reference equator crossing of the ascending node of a satellite orbit, usually specified in UTC time and degrees of longitude of the crossing.

**ERP** — Effective radiated power — System power output after transmission-line losses and antenna gain (referenced to a dipole) are considered.

**ESA** — European Space Agency — A consortium of European governmental groups pooling resources for space exploration and development.

**FO-12** — Japanese Amateur Radio satellite, Fuji-OSCAR 12.

**Geocenter** — The center of the Earth.

**Geostationary orbit** — A satellite orbit at such an altitude (approximately 22,300 miles) over the equator that the satellite appears to be fixed above a given point.

**Ground station** — A radio station, on or near the surface of the earth, designed to transmit or receive to/from a spacecraft.

**Groundtrack** — The imaginary line traced on the surface of the Earth by the sub-satellite point (SSP).

**Inclination** — The angle between the orbital plane of a satellite and the equatorial plane of the Earth.

**Increment** — The change in longitude of

ascending node between two successive passes of a specified satellite, measured in degrees West per orbit.

**Iskra** — Soviet low-orbit satellites launched manually by cosmonauts aboard Salyut missions. Iskra means "spark" in Russian.

**JAMSAT** — Japan AMSAT organization.

**Keplerian Elements** — The classical set of six orbital element numbers used to define and compute satellite orbital motions. The set is comprised of inclination, Right Ascension of Ascending Node (RAAN), eccentricity, argument of perigee, mean anomaly and mean motion, all specified at a particular epoch or reference year, day and time. Additionally, a decay rate or drag factor is usually included to refine the computation.

**LHCP** — Left hand circular polarization.

**LOS** — Loss of signal — The time when a satellite passes out of range and signals from it can no longer be heard. This usually occurs just after the satellite goes below the horizon.

**Mean anomaly (MA)** — An angle that increases uniformly with time, starting at perigee, used to indicate where a satellite is located along its orbit. MA is usually specified at the reference epoch time where the Keplerian elements are defined. For AO-10 the orbital time is divided into 256 parts, rather than degrees of a circle, and MA (sometimes called phase) is specified from 0 to 255. Perigee is therefore at MA = 0 with apogee at MA = 127.

**Mean motion** — The Keplerian element to indicate the complete number of orbits a satellite makes in a day.

**NASA** — National Aeronautics and Space Administration, the U.S. space agency.

**Nodal period** — The amount of time between two successive ascending nodes of a satellite orbit.

**Orbital elements** — See Keplerian Elements.

**Orbital plane** — An imaginary plane, extending throughout space, that contains the satellite orbit.

**OSCAR** — Orbiting Satellite Carrying Amateur Radio.

**OSCARLOCATOR** — A graphical satellite tracking device used to locate a satellite in its orbit and aid in pointing antennas. Available from ARRL.

**PACSAT** — A proposed AMSAT packet radio satellite with store-and-forward capability.

**Pass** — An orbit of a satellite.

**Passband** — The range of frequencies handled by a satellite translator or transponder.

*Perigee* — The point in a satellite's orbit where it is closest to Earth.

*Period* — The time required for a satellite to make one complete revolution about the Earth. See anomalistic period and nodal period.

*Phase I* — The term given to the earliest, short-lived OSCAR satellites that were not equipped with solar cells. When their batteries were depleted, they ceased operating.

*Phase II* — Low altitude, long-lived OSCAR satellites. Equipped with solar panels that powered the spacecraft systems and recharged their batteries, these satellites have been shown to be capable of lasting up to five years (OSCARs 6, 7 and 8, for example).

*Phase III* — Extended-range, high-orbit OSCAR satellites with very long-lived solar power systems (OSCAR 10 and Phase IIIC).

*Phase IV* — Proposed OSCAR satellites in geostationary orbits.

*Precession* — An effect that is characteristic of AO-10 and Phase III orbits. The satellite apogee SSP will gradually change over time.

*Project OSCAR* — The California-based group, among the first to recognize the potential of space for Amateur Radio; responsible for OSCARs I through IV.

*QRP days* — Special orbits set aside for very low power uplink operating through the satellites.

*RAAN* — Right Ascension of Ascending Node

— The Keplerian element specifying the angular distance along the celestial equator, between the vernal equinox and the ascending node of a spacecraft. This can be simplified to mean roughly the longitude of the ascending node.

*Radio Sputnik* — Soviet Amateur Radio satellites (see RS #).

*Reference orbit* — The orbit of Phase II satellites beginning with the first ascending node during that UTC day.

*RHCP* — Right-hand circular polarization.

*RS #* — The designator used for most Soviet Amateur Radio satellites (RS-1 through RS-8, for example).

*Satellite* — A graphical tracking device, similar to OSCARLOCATOR, designed to be used with satellites in elliptical orbits.

*Satellite pass* — Segment of orbit during which the satellite "passes" nearby and in range of a particular ground station.

*Sidereal day* — The amount of time required for the Earth to rotate exactly 360 degrees about its axis with respect to the "fixed" stars. The sidereal day contains 1436.07 minutes (see Solar day).

*Solar day* — The solar day, by definition, contains exactly 24 hours (1440 minutes). During the solar day, the Earth rotates slightly more than 360 degrees about its axis with respect to "fixed" stars (see Sidereal day).

*Spin modulation* — Periodic amplitude fade-and-peak resulting from the rotation of a

satellite's antennas about its spin axis, rotating the antenna peaks-and-nulls.

*SSC* — Special service channels — Frequencies in the downlink passband of AO-10 that are set aside for authorized, scheduled use in such areas as education, data exchange, scientific experimentation, bulletins and official traffic.

*SSP* — Subsatellite point — Point on the surface of the Earth directly between the satellite and the geocenter.

*Telemetry* — Radio signals, originating at a satellite, that convey information on the performance or status of onboard subsystems. Also refers to the information itself.

*Transponder* — A device onboard a satellite that receives radio signals in one segment of the spectrum, amplifies them, translates (shifts) their frequency to another segment of the spectrum and retransmits them. Also called linear translator.

*UoSAT-OSCAR (UO #)* — Amateur Radio satellite built under the coordination of Radio Amateurs and educators at the University of Surrey, England.

*Uplink* — The frequency at which signals are transmitted from ground stations to a satellite.

*Window* — Overlap region between acquisition circles of two ground stations referenced to a specific satellite. Communication between two stations is possible when the subsatellite point is within the window.

# Earth-Moon-Earth

Popularly known as moonbounce, EME is the most popular method of space communication after OSCAR. The concept is straightforward: Stations that can simultaneously see the moon communicate by reflecting VHF and UHF signals off the lunar surface. Unlike OSCAR, though, the two stations have a relatively stable target and may be separated by virtually 180 degrees of arc on the earth's surface, which translates to more than 11,000 miles.

There is a trade-off, though; since the moon's mean distance from earth is 239,000 miles, path losses are huge when compared to "local" VHF work. Thus, each station on an EME circuit demands the most out of the transmitter, antenna, receiver and operator skills. Even with all those factors in an optimum state, the signal in the headphones may be barely perceptible above the noise. Nevertheless, for any type of amateur communication over a distance of 500 miles or more at 432 MHz, for example, moonbounce comes out the winner over terrestrial methods when various factors are figured on a balance sheet.

EME thus presents amateurs with the ultimate challenge in strengthening radio systems. Before amateur involvement, the only other known moon relay circuit was operated by the U.S. Navy between Washington, DC and Hawaii. Their 400 megawatts of effective radiated power carried four multiplexed RTTY channels. The first two-way amateur link took place between the EIMAC Radio Club, W6HB, and the Rhododendron Swamp VHF Society, W1BU, on 1296 MHz in July 1960.

Only a few amateurs heard anything more than their own echoes during the next few years. Hams at government and private institutions began conducting tests with other hams by using very large arrays such as the 150-foot steerable dish at WA6LET (Stanford University) or the 1000-foot parabolic surface at KP4BPZ (Arecibo). Amateur-to-amateur contacts did not become established until the early '70s, a notable effort being between VE7BBG and WA6HXW. Activity spread to all continents — except South America. In July 1976, the Mt. Airy VHF Club of Philadelphia (Pack Rats) staged an expedition to Barranquilla, Colombia, which allowed K2UYH to become the first amateur to work all continents on 432 MHz.

Amateurs have even used the 2300-MHz band for EME work, starting with a QSO between W3GKP and W4HHK in 1970. There are presently active stations in half a dozen countries on that band.

Most of the components for an EME station on 144, 220, 432 or 1296 MHz are now commercially available. Whether a prospective EMEer chooses that route or builds all the gear, some design considerations must be taken because it is weak-signal work.

1) Transmissions must be made on CW

or SSB with as close to the maximum legal output as possible.

2) The antenna should have at least 20 dB of gain over a dipole.

3) As with an OSCAR antenna system, rotators are needed for both azimuth and elevation. Since the half-power beamwidth of a high-gain antenna is quite sharp, the rotators must have appropriate accuracy.

4) Transmission-line losses should be held to a minimum.

5) The receiving systems should have a very low noise figure.

Don't let these requirements scare you! Most EMEers started out as listeners. In the ARRL International EME Competition, operators with nothing more than a simple Yagi, preamplifier and multimode transceiver hear the stronger stations.

## Calculating EME Capabilities

EME path loss can be determined from Fig. 37. The received signal-to-noise ratio can be calculated from the formula:

$$S/N = P_o - L_t + G_t - P_l + G_r - P_n \quad (\text{Eq. 1})$$

where

$P_o$  = transmitter output power (dBW)

$L_t$  = transmitter feed-line loss (dB)

$G_t$  = transmitting antenna gain (dBi)

$P_l$  = total path loss (dB)

$G_r$  = receiving antenna gain (dBi)

$P_n$  = receiver noise power (dBW)

Receiver noise power,  $P_n$ , is determined by the following:

$$P_n = 10 \log_{10} K \times B \times T_s \quad (\text{Eq. 2})$$

where

$K = 1.38 \times 10^{-23}$  (Boltzmann's constant)

$B$  = bandwidth (Hz)

$T_s$  = receiving system noise temperature (K)

Receiving system noise temperature,  $T_s$ , can be found from:

$$T_s = T_a + (L_r - 1) T_l + L_r T_r \quad (\text{Eq. 3})$$

where

$T_a$  = antenna temperature (K)

$L_r$  = receiving feed-line loss (ratio)

$T_l$  = physical temperature of feed line (normally 290 K)

$T_r$  = receiver noise temperature (K)

The meaning of these formulas becomes clear if we substitute appropriate values and calculate S/N for a typical 432-MHz EME communications link:

$P_o = +30$  dBW (1000 W)

$L_t = 0.5$  dB

$G_t = 23.0$  dBi ( $8 \times 4.2 - \lambda$  NBS Yagi)

$P_l = 262$  dB

$G_r = 23.5$  dBi (15-ft parabolic)

$B = 100$  Hz

$T_a = 100$  K

$L_r = 1$  (0 dB, preamp at antenna)

$T_l = 290$  K

$T_r = 50.72$  K (NF = 0.7 dB)

S/N = +0.8 dB

It is obvious that there is no place for compromise in assembling the EME station. Even relatively sophisticated equipment gives marginal results.

## EME Scheduling

The best days to schedule are usually when the moon is at perigee (closest to the earth) since the path loss is typically 2 dB less than when the moon is at apogee (farthest from the earth). The moon's perigee and apogee dates may be determined from publications such as *The*

Fig. 37 — Variations in EME path loss can be determined from this graph. S.D. refers to the semi-diameter of the moon, which is indicated for each day of the year in *The Nautical Almanac*.

*Nautical Almanac*<sup>1</sup> by inspecting the section of the tables headed "S.D." (semi-diameter of the moon in minutes of arc). An S.D. of 16.53 equates to an approximate earth-to-moon distance of 225,000 miles, typical perigee, and an S.D. of 14.7 to an approximate distance of 252,500 miles, typical apogee. If the semi-diameters are located on Fig. 37, the EME path losses in decibels may be determined for the most popular amateur frequencies.

The moon's orbit is slightly elliptical. Hence, the day-to-day path-loss changes at apogee and perigee are minor. The greatest changes take place at the time when the moon is traversing between apogee and perigee. However, several other factors must be considered for optimum scheduling aside from the path losses.

If perigee occurs near the time of a new moon, one to two days will be unusable since the sun behind the moon will cause increased sun-noise pickup. Therefore, schedules should be avoided when the moon is within 10° of the sun (and farther if your antenna has a wide beam or strong side lobes). The moon's orbit follows a cycle of 18 to 19 years, so the relationships between perigee and new moon will not be the same from one year to the next.

Low moon declinations and low aiming elevations generally produce poor results and should be avoided if possible. Conversely, high moon declinations and high elevation angles should yield best results. Good results are usually obtained when both stations are using similar elevation angles, since then both stations are looking through comparable electron densities. Generally, low elevation angles increase antenna-noise pickup and increase tropospheric absorption, especially above 420 MHz, where the galactic noise is very low. This situation cannot be avoided when one station is unable to elevate the antenna above the horizon or when there is a great terrestrial distance between stations. Ground gain (gain obtained when the antenna is aimed at the horizon) has been used very effectively at 144 and 432 MHz. While potentially useful, ground gain is a complex phenomenon and difficult to predict.

Usually, signals are stronger in the fall and winter months and weaker in the summer. Also, signals are generally better at night than during the day. This may be attributable to decreased ionization or less Faraday rotation.

Whenever the moon crosses the galactic plane (twice a month for three to five days each occurrence), the sky temperature will be higher. Areas of the sky to avoid are the constellations Orion and Gemini at northern declinations and Scorpius and Sagittarius at southern declinations. Posi-

tions of the moon with respect to these constellations can be checked with *Sky and Telescope* magazine or *The Nautical Almanac*. The galactic plane is biased toward southern declinations, which will cause southerly declinations to be less desirable (with respect to noise) than are northern declinations.

Finally, the time of the day and the day of the week must be considered since most of us have to work for a living and cannot always be available for schedules. Naturally, weekends and evenings are preferred, especially when perigee occurs on a weekend.

### General Considerations

It helps to know your own EME window as accurately as possible. The term "window" means the period of time that a station can "see" the moon. This can be determined with the help of information contained in a later section of this chapter. Most EME operators determine their local window and translate it into GHA (Greenwich hour angle) and declination. This information is a constant, so once it is determined it is usable by other stations just as one would use UTC. Likewise, it helps to know the window of the station to be scheduled. Most EME stations are limited in some way by local obstructions, antenna-mounting constraints, geographical considerations, and the like. Therefore, the accuracy of each station's EME window is very important for locating common windows and setting schedule times.

A boresight of some type is practically mandatory in order to align your antenna accurately with the moon. Most antenna systems exhibit some pattern skewing which must be accounted for. A simple calibration method is to peak your antenna on received sun noise and then align the boresight tube on the sun. The boresight of the antenna is now calibrated and can be used to aim the antenna at the moon. Readers are cautioned against using a telescope or other device employing lenses as a boresight device! Even the best of optical filters will not eliminate the hazard from solar radiation when viewed directly. A simple piece of small diameter tubing, two or three feet long can serve this purpose. A symmetrical spot of light cast upon a piece of paper near the back end of the tube will indicate alignment.

A remote readout is a highly recommended convenience. Accuracies of  $\pm 2^\circ$  are usually necessary and can be attained with syncros. A remote readout is particularly important for scheduling when the moon is within 45° of the sun or when the sky is overcast. There are very few areas where the moon is not occasionally obscured by cloud cover. Aiming an antenna blindly seldom pays off.

### Locating the Moon

The moon orbits the earth once in approximately 28 days, a lunar month.

Because the plane of the moon's orbit is tilted from the earth's equatorial plane by approximately 23.5°, the moon swings in a sine-wave pattern both north and south of the equator. The angle of departure of the moon's position at a given time from the equatorial plane is termed declination. Declination angles of the moon, which are continually changing (a few degrees a day), indicate the latitude on the earth's surface where the moon will be at zenith. For this presentation, positive declination angles are used when the moon is north of the equator, and negative angles when south.

The longitude on the earth's surface where the moon will be at zenith is related to the moon's Greenwich Hour Angle, abbreviated G.H.A. or GHA. "Hour angle" is defined as the angle in degrees to the west of the meridian. If the GHA of the moon were zero degrees, it would be directly over the Greenwich meridian. If the moon's GHA were 15 degrees, the moon would be directly over the meridian which is designated as 15° W longitude on a globe. As one can readily understand, the GHA of the moon is continually changing, too, because of both the orbital velocity of the moon and the earth's rotation inside the moon's orbit. The moon's GHA changes at the rate of approximately 347° per day.

GHA and declination are terms that may be applied to any celestial body. *The Nautical Almanac* and other publications list the GHA and decl. of the sun and moon (as well as for other celestial bodies that may be used for navigation) for every hour of the year. This information may be used to point an antenna when the moon is not visible. Almanac tables for the sun may be useful for calibrating remote-readout systems.

### Using the Almanac

Books such as *The Nautical Almanac* and other almanacs show the GHA and declination of the sun or moon at hourly intervals for every day of the period covered by the book. Instructions are included in such books for interpolating the positions of the sun or moon for any time on a given date. The orbital velocity of the moon is not constant, and therefore precise interpolations are not linear.

Fortunately, linear interpolations from one hour to the next, or even from one day to the next, will result in data that is entirely adequate for Amateur Radio purposes. If linear interpolations are made from 0000 UTC on one day to 0000 UTC on the next, worse-case conditions exist when apogee or perigee occurs near mid-day on the next date in question. Under such conditions, the total angular error in the position of the moon may be as much as a sixth of a degree. Because it takes a full year for the earth to orbit the sun, the similar error for determining the position of the sun will be no more than a few hundredths of a degree.

If a polar mount (a system having one

<sup>1</sup>*The Nautical Almanac for the Year\*\*\*\**, where \*\*\*\* indicates the calendar year for the data. This annual publication is printed by the U.S. Printing Office, Washington, DC. It is available from the Superintendent of Documents and from many dealers of marine products.

axis parallel to the earth's axis) is used, information from the Almanac may be used directly to point the antenna array. The local hour angle (LHA) is simply the GHA plus or minus the observer's longitude (plus if east long., minus if west). The LHA is the angle west of the observer's meridian at which the celestial body is located. LHA and declination information may be translated to an EME window by taking local obstructions and any other constraints into account.

### Azimuth and Elevation

An antenna system that is positioned in azimuth (compass direction) and elevation (angle above the horizon) is called an az-el system. For such a system, some additional work will be necessary to convert the almanac data into useful information. The GHA and decl. information may be converted into azimuth and elevation angles with the mathematical equations that follow. An electronic calculator or computer that treats trigonometric functions may be used. CAUTION: Most almanacs list data in degrees, minutes, and either decimal minutes or seconds. Computer or calculator programs generally require this information in degrees and decimal fractions, so a conversion may be necessary before the almanac data is entered.

Determining az-el data from equations follows a procedure similar to calculating great-circle bearings and distances for two points on the earth's surface. There is one additional factor, however. Visualize two observers on opposite sides of the earth who are pointing their antennas at the moon. Imaginary lines representing the boresights of the two antennas will converge at the moon at an angle of approximately 2°. Now assume both observers aim their antennas at some distant star. The boresight lines now may be considered to be parallel, each observer having raised his antenna in elevation by approximately 1°. The reason for the necessary change in elevation is that the earth's diameter in comparison to its distance from the moon is significant. The same is not true for distant stars, or for the sun.

Equations for az-el calculations are:

$$\sin E = \sin L \sin D + \cos L \cos D \cos \text{LHA} \quad (\text{Eq. 4})$$

$$\tan F = \frac{\sin E - K}{\cos E} \quad (\text{Eq. 5})$$

$$\cos C = \frac{\sin D - \sin E \sin L}{\cos E \cos L} \quad (\text{Eq. 6})$$

where

E = elevation angle for the sun  
L = your latitude (negative if south)  
D = declination of the celestial body  
LHA = local hour angle = GHA  
plus or minus your longitude (plus if east long., minus if west long.)  
F = elevation angle for the moon  
K = 0.01657, a constant (see text that follows)

C = true azimuth from north if sin LHA is negative; if sin LHA is positive, then the azimuth = 360 minus C

Assume our location is 50° N. lat., 100° W. long. Further assume that the GHA of the moon is 140° and its declination is 10°. To determine the az-el information we first find the LHA, which is 140 minus 100 or 40°. Then we solve Eq. 4:

$$\sin E = \sin 50 \sin 10 + \cos 50 \cos 10 \cos 40$$

$$\sin E = 0.61795 \text{ and } E = 38.2^\circ$$

Solving Eq. 5 for F, we proceed. (The value for sin E has already been determined in Eq. 4.)

$$\tan F = \frac{0.61795 - 0.06175}{\cos 38.2} = 0.76489$$

From this, F, the moon's elevation angle, is 37.4°.

We continue by solving Eq. 6 for C. (The value of sin E has already been determined.)

$$\cos C = \frac{\sin 10 - 0.61795 \sin 50}{\cos 38.2 \cos 50} = -0.59308$$

C therefore equals 126.4°. To determine if C is the actual azimuth, we find the polarity for sin LHA, which is sin 40° and has a positive value. The actual azimuth then is 360 - C = 233.6°.

If az-el data is being determined for the sun, use of Eq. 5 must be omitted; Eq. 5 takes into account the nearness of the moon. The solar elevation angle may be determined from Eq. 4 alone. In the above example, this angle is 38.2°.

The mathematical procedure is the same for any location on the earth's surface. Remember to use negative values for southerly latitudes. If solving Eq. 4 or 5 yields a negative value for E or F, this indicates the celestial body is below the horizon.

These equations may also be used to determine az-el data for man-made satellites, but a different value for the constant, K, must be used. K is defined as the ratio of the earth's radius to the distance from the earth's center to the satellite.

The value for K as given above, 0.01657 is based on an average earth-moon distance of 239,000 miles. The actual earth-moon distance varies from approximately 225,000 to 253,000 mi. When this change in distance is taken into account, it yields a change in elevation angle of approximately 0.1° when the moon is near the horizon. For greater precision in determining the correct elevation angle for the moon, the moon's distance from the earth may be taken as:

$$D = -15,074.5 \times \text{S.D.} + 474,332$$

where

D = moon's distance in miles

S.D. = moon's semi-diameter, from the almanac.

### Calculator and Computer Programs

As has been mentioned, a calculator or computer may be used in solving the equations for azimuth and elevation. Tables in this section list suitable programs. The program of Table 9 is for Hewlett-Packard HP-25 and similar calculators using reverse Polish notation (RPN). With this program, the GHA and declination of a celestial body are entered for a particular time of day, and the calculator computes the azimuth and elevation for that time. Calculations must then be repeated for a different time of day, by using different GHA and declination values, as appropriate. For EME work, it is convenient to calculate az-el data at 30-minute intervals or so, and to keep the results of all calculations handy during the EME window. Necessary antenna-position corrections can then be made periodically.

Table 10 is a BASIC language program for the IBM PC. This program provides azimuth and elevation information for half-hour intervals during a UTC day when the celestial body is above the horizon. The program makes a linear interpolation of GHA and declination values (discussed earlier) during the period of the UTC day.

With the program of Table 10 in operation, the computer first asks for various data to be entered via the keyboard, including GHA and declination for 2400 UTC for the date of the calculations. This data, of course, will be the same as for 0000 UTC for the following day from the almanac. After all data is entered, the computer performs calculations for each half hour. Only those results for which the body is above the horizon are displayed, so there may be a period of 15 seconds or more during which nothing appears to be happening. This is normal. The program may be modified to print the results of calculations on paper if a line printer is available, or to adapt it for use on other computers with variations in BASIC language.

Either of these programs may be used for determining the azimuth and elevation for more distant bodies, by using program steps 26 and 27 for the sun in Table 9, or by entering SUN at the keyboard for statement 130 in Table 10. Further, Table 9 may be used for determining the positions of man-made satellites for a given time, if the appropriate value for the constant K is stored in register 3. For this application, the coordinates of the sub-satellite point are used in place of GHA and declination.

### Libration Fading of EME Signals

One of the most troublesome aspects of receiving a moonbounce signal, besides the enormous path loss and Faraday rotation fading, is libration fading. This section will deal with libration (pronounced lie-bray-shun) fading, its cause and effects, and possible measures to minimize it.

Table 9

#### Instructions

- 1) Load the program, selecting lines 26 and 27 for either the moon or for more distant bodies. Switch to RUN.
- 2) Initialize: f PRGM; f FIX 1; g DEG
- 3) Store constants: 360 STO 2; 0.01657 STO 3
- 4) Store data  
Your latitude (degrees and decimal; negative if east) STO 0  
Your longitude (degrees and decimal; negative if east) STO 1
- 5) Input data:  
Decl. of celestial body (degrees and decimal) Enter 1  
GHA of celestial body (degrees and decimal) R/S  
The result displayed after a few seconds is the azimuth or bearing in degrees clockwise from north.  
Depressing  $x \geq y$  displays the elevation angle above the horizon. (The body is below the horizon if a negative angle is displayed.)
- 6) For another az-el calculation from the same location, go to step 5.
- 7) For az-el calculations from a different location on the earth's surface, go to step 4 using new latitude and longitude.

Libration fading of an EME signal is characterized in general as fluttery, rapid, irregular fading not unlike that observed in tropospheric scatter propagation. Fading can be very deep, 20 dB or more, and the maximum fading will depend on the operating frequency. At 1296 MHz the maximum fading rate is about 10 Hz, and scales directly with frequency.

On a weak CW EME signal, libration fading gives the impression of a randomly keyed signal. In fact on very slow CW telegraphy the effect is as though the keying is being done at a much faster speed.

On very weak signals only the peaks of libration fading are heard in the form of occasional short bursts or "pings."

Fig. 38 shows samples of a typical EME echo signal at 1296 MHz. These recordings, made at W2NFA, show the wild fading characteristics with sufficient S/N ratio to record the deep fades. Circular polarization was used to eliminate Faraday fading; thus these recordings are of libration fading only. The recording bandwidth was limited to about 40 Hz to minimize the higher sideband-frequency components of libration fading that exist but are much smaller

Fig. 38 — Chart recording of moon echoes received at W2FNA on July 26, 1973, at 1630 UTC. Antenna gain 44 dBi, transmitting power 400 watts and system temperature 400 K.

in amplitude. For those who would like a better statistical description, libration fading is Raleigh distributed. In the recordings shown by Fig. 38, the average signal-return level computed from path loss and mean reflection coefficient of the moon is at about the +15 dB S/N level.

It is clear that enhancement of echoes far in excess of this average level is observed. This point should be kept clearly in mind when attempting to obtain echoes or receive EME signals with marginal equipment. The probability of hearing an occasional peak is quite good since random enhancement as much as 10 dB is possible. Under these conditions, however, the amount of useful information that can be copied will be near zero. Enthusiastic newcomers to EME communications will be stymied by this effect since they know they can hear the signal strong enough on peaks to copy but can't make any sense out of what they try to copy.

What causes libration fading? Very simply, multipath scattering of the radio waves from the very large (2000-mile diameter) and rough moon surface combined with the relative motion between earth and moon called librations.

To understand these effects, assume first that the earth and moon are stationary (no libration) and that a plane wave front arrives at the moon from your earth-bound station as shown in Fig. 39A.

The reflected wave shown in Fig. 39B consists of many scattered contributions from the rough moon surface. It is perhaps easier to visualize the process as if the scattering were from many small individual flat mirrors on the moon that reflect small portions (amplitudes) of the incident wave energy in different directions (paths) and with different path lengths (phase). Those paths directed toward the moon arrive at your antenna as a collection of small wave fronts (field vectors) of various amplitudes

and phases. The vector summation of all these coherent (same frequency) returned waves (and there is a near-infinite array of them) takes place at the feed point of your antenna (the collecting point in your antenna system). The level of the final summation as measured by a receiver can, of course, have any value from zero to some maximum. Remember that we assumed the earth and moon were stationary, which means that the final summation of these multipath signal returns from the moon will be one fixed value. The condition of zero relative motion between earth and moon is a rare event that will be discussed later in this section.

Consider now that the earth and moon are moving relative to each other (as they are in nature), so the incident radio wave "sees" a slightly different surface of the moon from moment to moment. Since the lunar surface is very irregular, the reflected wave will be equally irregular, changing in amplitude and phase from moment to moment. The resultant continuous summation of the varying multipath signals at your antenna feed point produces the effect called libration fading of the moon-reflected signal.

The term libration is used to describe small perturbations in the movement of celestial bodies. Each libration consists mainly of its diurnal rotation; moon libration consists mainly of its 28-day rotation, which appears as a very slight rocking motion with respect to an observer on earth. This rocking motion can be visualized as follows: Place a marker on the surface of the moon at the center of the moon disc, which is the point closest to the observer, as shown in Fig. 40. Over time, we will observe that this marker wanders around within a small area. This means the surface of the moon as seen from the earth is not quite fixed but changes slightly as different areas of the periphery are exposed because

Fig. 39 — How the rough surface of the moon reflects a plane wave as one having many field vectors.

Fig. 40 — The moon appears to "wander" in its orbit about the earth. Thus a fixed marker on the moon's surface will appear to move about in a circular area.

of this rocking motion. Moon libration is very slow (on the order of  $10^{-7}$  radians per second) and can be determined with some difficulty from published moon ephemeris tables.

Although the libration motions are very small and slow, the larger surface area of the moon has nearly an infinite number of scattering points (small area). This means that even slight geometric movements can alter the total summation of the returned multipath echo by a significant amount. Since the librations of the earth and moon are calculable, it is only logical to ask if there ever occurs a time when the total libration is zero or near zero. The answer is yes, and it has been observed and verified

**Table 11****Signal Reports Used on 144-MHz EME**

T — Signal just detectable  
 M — Portions of call copied  
 O — Complete call set has been received  
 R — Both "O" report and call sets have been received  
 SK — End of contact

experimentally on radar echoes that minimum fading rate (not depth of fade) is coincident with minimum total libration. Calculation of minimum total libration is at best tedious and can only be done successfully by means of a computer. It is a problem in extrapolation of rates of change in coordinate motion and in small differences of large numbers.

**EME Operating Techniques**

Many EME signals are near the threshold of readability, a condition caused by a combination of path loss, Faraday rotation and libration fading. This weakness and unpredictability of the signal has led to the development of techniques for exchange of EME information that differs from those used for normal VHF work — the usual RST reporting would be jumbled and meaningless for many EME contacts. Dashes are often chopped into pieces, a string of dots would be incomplete, and complicated words would make no sense at all.

Unfortunately, there is no universal agreement as to procedures for all the bands, although there is similarity. Two-meter operators generally use the "T M O R" system, while those on 432 MHz use a similar system but applied at somewhat different levels of readability. The meanings and typical use of each part of the sequence are given in Tables 11 through 14.

At the moment, there is no uniform system in use for EME operation on all bands. The 432-MHz procedure is used on 432 MHz and above. It has also become the preferred system on 220 MHz, although the 144-MHz procedure is sometimes used on this band.

In the schedule sequence for both 144 and 432 MHz, the initial period starts on the hour, but because of the difference in sequence lengths for the two bands, schedules starting on the half hour will not be the same. On 2 meters, there are 15 sequence periods to the half hour, which make the period 0030 to 0032 an "even" sequence. This could make a difference, depending on which operator was assigned an "odd" or "even" sequence. Note that odd or even refers to the sequence number, not the minutes designated within that sequence.

On 432 MHz, there are 12 sequence periods to the half hour. The eastern-most station from the international date line usually calls first, and since two 2½-minute periods fill a 5-minute space, it works out conveniently that the eastern (or first) station will call starting with every five minute mark, and start listening 2½-minutes later. Thus a schedule starting at 0030 would be an "odd" period, although operators on 432 MHz seldom label them as such. It is convenient for the operators simply to start with the eastern-most station calling on the hour or half hour, unless arranged otherwise.

Of course there is much room for change in these arrangements, but they do serve as vital guidelines for schedules. As signals become stronger, the rules can be relaxed to a degree, and after many contacts, stations can often ignore them completely, if the signals are strong enough.

Calls are often extremely difficult to hear in their entirety. A vital dot or dash can be missing, which can render a complex call unreadable. To copy both calls completely requires much patience and a good ear. Both calls must be copied, because even though most work is by timed schedules, there can be last-minute substitutions because of equipment trouble at one station, unexpected travel, changes in plans or the like, which make it impossible for the scheduled station to appear. Thus, rather than have one station spend the entire period listening, only to find that no one is there, a system of standby stations is becoming more popular. This is good, because nothing will demoralize a newcomer faster than several one-sided schedules.

An exchange of signal reports is a useful and required bit of information: useful because it helps in evaluating your station performance and the conditions at the time, required because it is a "non-prearranged" exchange, thereby requiring that you copy what was sent as part of the contact. Obviously, other things could be included in an "exchange of unknown information," and when conditions permit stronger signals, many operators do include names, elaborate on the signal reports, arrange next schedule times, and so on. Unfortunately, such exchanges are rare.

Confirmation is essential for completion of the exchange. There is no way that you can be sure that the other operator copies what you sent until you hear him say so. The final R or ROGER means that he has copied your information, and your two-way contact is complete.

Sending speed is usually in the 10- to 13-WPM range, although it can be adjusted according to conditions and operator skill. Characters sent too slowly tend to become chopped up and confusing. High-speed CW is hard to copy at marginal signal levels for most amateurs, and the fading that is typical of an EME path can make it nearly impossible to decipher the content.

**Other Modes**

Only a few stations have the capability of sending (and receiving) signals of a strength sufficient to allow experimentation with other than CW. SSB contacts are now common. In general, only the stations with large antennas try the more difficult modes for EME work. Such installations are often "borrowed" from some research program for the amateur endeavors.

**Frequencies**

EME contacts are generally made randomly or by prearranged schedule. Many stations, especially those with marginal capability, prefer to set up a specific time and frequency in advance so that they will have a better chance of finding each other. The larger stations, especially on 144 and 432 MHz where there is a good amount of activity, often call CQ during evenings and weekends when the moon is at perigee and listen for random replies. Most of the work on 220, 1296 and 2304 MHz, where activity is light, is done by schedule.

Most amateur EME work on 144 and 220 MHz takes place near the low edge of the band. Activity is found 50 kHz or higher in the band during peak hours. Generally, random activity and CQ calling take place in the lower 10 kHz or so, and schedules are run higher in the band.

Formal schedules (that is, schedules arranged well in advance and published in the *432 and Above EME Newsletter* published by Al Katz, K2UYH) are run on 432.000, 432.025 and 432.030 MHz. Other schedules are normally run on 432.035 and up to 432.070. For this band, the EME random calling frequency is 432.010 with random

activity spread out between 432.005 and 432.020. Random SSB CQ calling is at 432.015. Terrestrial activity is centered on 432.100 and is, by agreement, limited to 432.075 and above in North America.

Moving up in frequency, formal schedules are run on 1296.000 and 1296.025 MHz. The EME random calling frequency is 1296.010 with random activity spread out between 1296.005 and 1296.020. Terrestrial activity is centered at 1296.100. There is some EME activity on 2304 MHz. Specific frequencies are dictated by equipment availability and are arranged by the stations involved.

For EME SSB contacts on 144 and 432 MHz, contact is usually established on CW, and then the stations move up 100 kHz from the CW frequency. (This method was adopted because of the U.S. requirement for CW only below 144.1 MHz.)

Of course, it is obvious that as the number of stations on EME increases, the frequency spread must become greater. Since the moon is in convenient locations only a few days out of the month, and only a certain number of stations can be scheduled for EME during a given evening, the answer will be in the use of simultaneous schedules, spaced a few kilohertz apart. The time may not be too far away — QRM has already been experienced on each of our three most active EME frequencies.

#### EME Net Information

An EME net meets on weekends on 14.345 MHz for the purpose of arranging schedules and exchanging pertinent information. The net meets at 1600 UTC concerning EME operation on 432 MHz and above. At 1700 UTC the net is for 2-meter EME operation. Both nets carry information on 220-MHz EME operation.

#### Antenna Requirements

The tremendous path loss incurred over an EME circuit places stringent requirements on station performance. Low-noise receiving equipment, maximum legal power and large antenna arrays are required for successful EME operation. Although it may be possible to copy some of the better-equipped stations while using a single high-gain Yagi antenna, it is doubtful whether such an antenna could provide reliable two-way communication. Antenna gain of at least 20 dB is required for reasonable success. Generally speaking, more antenna gain will yield the most noticeable improvement in station performance, as the increased gain will aid both the received and transmitted signals.

Several types of antennas have become popular among EME enthusiasts. Perhaps the most popular antenna for 144-MHz work is an array of either four or eight long-boom (14- to 15-dB gain) Yagis. The four-Yagi array would provide approximately 20-dB gain, and the eight-antenna system would show an approximate 3-dB

Fig. 41 — The 2-meter EME antenna system used at DL8DAT — 16 x 24-element Yagis.

increase over the four-antenna array. At 432 MHz, eight or 16 long-boom Yagis are used. Yagi antennas are available commercially or can be constructed from readily available materials. Information on maximum-gain Yagi antennas is presented in Chapter 33. The dimensions presented are based on figures developed by the National Bureau of Standards for Yagi design. At least one manufacturer has used the NBS design information for their latest series of high-performance antennas.

A moderately sized Yagi array has the advantage that it is relatively easy to construct and can be positioned in azimuth and elevation with commercially available equipment. Matching and phasing lines present no particular problems. The main disadvantage of a Yagi array is that the polarization plane of the antenna cannot be conveniently changed. Polarization shift at 144 MHz is fairly slow, and the added complexity of the cross-polarized antenna

system may not be worth the effort. At 432 MHz, where the shift is at a somewhat faster rate, an adjustable polarization system offers a definite advantage over a fixed one.

Quagi antennas (made from both quad and Yagi elements) are also popular for EME work. Slightly more gain per unit boom length is possible as compared to the conventional Yagi. Additional information on the quagi is presented in Chapter 33.

The collinear is another popular type of antenna for EME work. A 40-element collinear array has approximately the same frontal area as an array of four Yagis. The collinear array would produce approximately 1- to 2-dB less gain. Of course the depth dimension of the collinear array is considerably less than for the long-boom Yagis. An 80-element collinear would be marginal for EME communications, providing approximately 19-dB gain. Many operators choosing this type of antenna use 160-element or larger systems. As with Yagi and quagi antennas, the collinear cannot be easily adjusted for polarity changes. From a constructional standpoint there may be little difference in complexity and material costs between the collinear and Yagi arrays.

The parabolic dish is another antenna used extensively for EME work. Unlike the other antennas described, the major problems associated with dish antennas are mechanical. Dishes 12 feet in diameter are required for successful EME operation on 432 MHz. With structures of this size, wind and ice loading place a severe strain on the mounting and positioning systems. Extremely rugged mounts are required for large dish antennas, especially when used in windy locations. Several aspects of the parabolic dish antennas make the extra mechanical problems worth the effort. For example, the dish antenna is inherently broadband and may be used on several different bands by simply changing the feed.

The graph at Fig. 42 relates antenna

Fig. 42 — Parabolic antenna gain versus size, frequency and surface errors. All curves assumed 60-percent aperture efficiency and 10-dB power taper. Reference: J. Ruze, British IEE.

Fig. 43 — A newcomer to EME stands in awe of the K2UYH 28-foot dish.

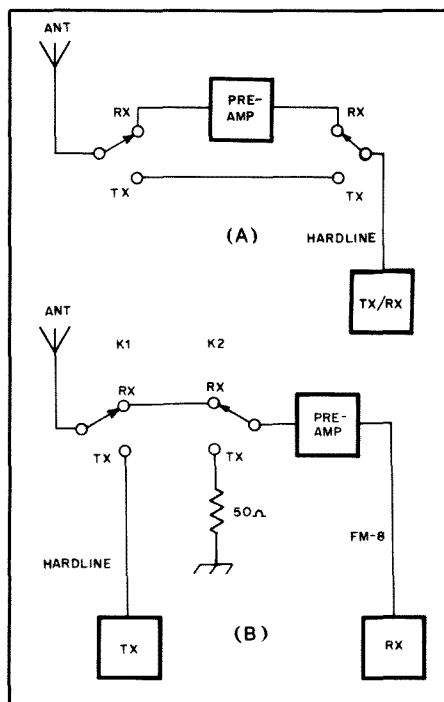

Fig. 44 — Two systems for switching a preamplifier in and out of the receive line. At A, a single length of cable is used for both the transmit and receive line. At B is a slightly more sophisticated system that uses two separate transmission lines. See text for details.

gain, frequency and size. As can be seen, an antenna that is suitable for 432-MHz work is also usable for each of the higher

amateur bands. Additional gain is available as the frequency of operation is increased. Another advantage of this antenna is in the feed system. The polarization of the feed, and therefore the polarization of the antenna, can be adjusted with little difficulty. It should be relatively easy to devise a system whereby the feed could be rotated remotely from the shack. Changes in polarization of the signal could be compensated for at the operating position! As polarization changes can account for as much as 30 dB of signal attenuation, the rotatable feed could make the difference between working a station and not. A photograph of the parabolic dish antenna used at K2UYH is shown in Fig. 43. More information on parabolic dish antennas is available in *The ARRL Antenna Book*.

Antennas suitable for EME work are by no means limited to the types described thus far. Rhombics, quad arrays, helices and others have not gained the popularity of the Yagi, quagi, collinear and parabolic dish, however.

### Receiver Requirements

A low-noise receiving setup is essential for successful EME work. Since many of the signals to be copied on EME are barely, but not always, out of the noise, a low-noise-figure receiver is a must. The mark to shoot for at 144 MHz is something under 0.5 dB, as the cosmic noise will then be the limiting factor in the system. Noise figures of this level are relatively easy to achieve, even with available inexpensive devices.

As low a noise figure as can be attained will be usable at 432 MHz. Noise figures on the order of 0.5 dB are possible with GaAsFETs. Other builders choose the rugged bipolar transistor, which offers a noise figure just under 1 dB.

The loss in the transmission line that connects the antenna to the preamplifier adds directly to the system noise figure. Not only does the line have loss, it also is a source of noise, which further deteriorates the system noise figure. For those reasons, most serious EME operators mount a preamplifier at the top of the tower or directly at the antenna. If an exceptionally good grade of transmission line is available, it is possible to obtain almost as good results with the preamplifier located in the shack.

Two relay/preamplifier switching systems are sketched in Fig. 44. The system at A makes use of two relays and a single transmission line for both transmit and receive. The preamplifier is simply switched "in" for receive and "out" for transmit.

The system outlined at Fig. 44B also uses two relays, but the circuit is somewhat more sophisticated. Two transmission lines are used, one for the receive line and one

for the transmit line. In addition, a 50-ohm termination is provided. Since relays with high isolation in the VHF/UHF range are difficult and expensive to obtain, two relays with a lower-isolation factor may be used.

When the relays are switched for the transmit mode, K1 connects the antenna to the transmit line, K2 switches the preamplifier into the 50-ohm termination. Hence, two relays provide the isolation between the transmitter connection and the preamplifier. If independent control of K2 is provided for, the preamplifier can be switched between the 50-ohm termination and the antenna during receive. This feature is especially useful when making sun-noise measurements to check system performance. For this measurement the antenna is directed toward the sun and the preamplifier is alternately switched between the 50-ohm load and the antenna. The decibel difference can be recorded and used as a reference when checking system improvements. A less convenient, but better, check is to compare sun noise with cold sky noise. The complete circuit for this relay system is presented later in this chapter.

As the preamplifier is mounted ahead of the transmission line to the receiver, a cable of mediocre performance can be used. The loss of the cable, as long as it is within reason, will not add appreciably to the system noise figure. Information contained in the Receiving chapter of this book explains how to calculate system noise figures. Foam-type RG-8 cable is acceptable for runs up to 100 feet at 144 MHz. See Chapter 31 for examples of practical preamplifiers and remote-mounted relay/preamp projects.

It is important to get as much transmitter power as possible to the antenna. For this reason rigid or semirigid low-loss cable is specified for the transmit line.

### Transmitter Requirements

In many EME installations the antenna gain is not much above the minimum required for communications. It is highly likely that the maximum legal limit of power will be required for successful EME work on up through 432 MHz. Since many contacts may require long, slow sending, the transmitter and amplifier should have adequate cooling. An amplifier with some power to spare rather than an amplifier running "flat out" is desirable. This is especially important should SSB communication be attempted. An amplifier run all out on SSB will likely produce large amounts of odd-order IMD products that fall within the band. While the splatter produced will not affect your communications, it will certainly affect that of others close in frequency!

# Construction Techniques

While a better job can be done with a variety of tools, by taking little care it is possible to turn out a fine piece of equipment with only a few common hand tools. A list of tools that are indispensable in the construction of electronic equipment is found on this page. With these tools it should be possible to prepare panels and metal chassis for assembly and wiring. It is an excellent idea for the amateur who builds gear to add tools from time to time as finances permit.

## RECOMMENDED TOOLS AND MATERIALS

Long-nose pliers, 6- and 4-inch  
 Diagonal cutters, 6- and 4-inch  
 Combination pliers, 6-inch  
 Screwdriver 6- to 7-inch, 1/4-inch blade  
 Screwdriver, 4- to 5-inch, 1/8-inch blade  
 Phillips screwdriver, 6- to 7-inch  
 Phillips screwdriver, 3- to 4-inch  
 Long-shank screwdriver with holding clip on blade  
 Scratch awl or scriber for marking metal  
 Combination square, 12-inch, for layout work  
 Hand drill, 1/4-inch chuck or larger  
 Soldering pencil, 30-watt, 1/8-inch tip  
 Soldering iron, 200-watt, 5/8-inch tip  
 Hacksaw and 12-inch blades  
 Hand nibbling tool, for chassis-hole cutting  
 Hammer, ball-peen, 1-lb head  
 Heavy-duty jackknife  
 File set, flat, round, half-round, and triangular. Large and miniature types recommended  
 High-speed drill bits, no. 60 through 3/8-inch diameter  
 Set of Spintite socket wrenches for hex nuts  
 Adjustable wrenches, 6- and 10-inch  
 Machine-screw taps, 4-40 through 10-32 thread  
 Socket punches, 1/2 in, 5/8 in, 3/4 in, 1-1/8 in, 1-1/4 in, and 1-1/2 in  
 Tapered reamer, T-handle, 1/2-inch maximum width  
 Bench vise, 4-inch jaws or larger  
 Medium-weight machine oil  
 Tin shears, 10-inch  
 Motor-driven emery wheel for grinding

Radio-supply houses, mail-order retail stores and most hardware stores carry the various tools required for building or servicing Amateur Radio equipment. While power tools (electric drill or drill press, grinding wheel, etc.) are very useful and will save a lot of time, they are not essential.

## Twist Drills

Twist drills are made of either high-speed steel or carbon steel. The latter type is more common and will usually be supplied unless a specific request is made for high-speed drills. The carbon drill will suffice for most equipment construction work and costs less than the high-speed type.

While twist drills are available in a number of sizes, those listed in bold type in Table 1 will be most commonly used in construction of amateur equipment. It is usually desirable to purchase several of each of the commonly used sizes rather than a standard set, most of which will be used infrequently, if at all.

Although Table 1 lists drills down to no. 54, the series extends to no. 80. No. 68 and no. 70 are useful for drilling printed-circuit boards for component leads.

## Care of Tools

The proper care of tools is not only a matter of pride to a good worker. Energy is saved and annoyance avoided by possessing a full kit of well-kept, sharp-edged tools.

Drills should be sharpened at frequent intervals so grinding is kept at a minimum each time. This makes it easier to maintain the rather critical surface angles required for best cutting with least wear. Occasional oilstoning of the cutting edges of a drill or reamer will extend the time between grindings.

The soldering iron can be kept in good condition by keeping the tip well tinned with solder and not allowing it to run at

Fig. 1 — A compact assembly of commonly available items, this soldering station sanitizes the electronics assembly process. Miniature toggle switches are used because of the minimal force required to manipulate them. The force required to operate standard-size switches could destabilize the unit.

Fig. 2 — View of the chassis underside with the bottom plate removed. No. 24 hookup wire is adequate for all connections. Use sleeving wherever the possibility of a short circuit exists. The diode may be installed in either direction.

full voltage for long periods when it is not being used. After each period of use, the tip should be removed and cleaned of any scale that may have accumulated. An oxidized tip may be cleaned by dipping it in sal ammoniac (ammonium chloride) while hot and then wiping it clean with a rag. If a copper tip becomes pitted, it should be filed until smooth and bright and then tinned immediately with solder. Most modern soldering iron tips are iron-clad and cannot be filed.

#### Useful Materials

Small stocks of various miscellaneous materials will be required in constructing radio apparatus. Most of these are available from hardware or radio-supply stores. A representative list follows:

Sheet aluminum, solid and perforated, 16 or 18 gauge, for brackets and shielding.

Aluminum angle stock,  $1/2 \times 1/2$ -inch  $1/4$ -inch-diameter round brass or aluminum rod for shaft extensions.

Machine screws: Round-head and flat head, with nuts to fit. Most useful sizes: 4-40, 6-32 and 8-32, in lengths from  $1/4$ -inch to 1-1/2 inches. (Nickel-plated steel will be found satisfactory except in strong RF fields, where brass should be used.)

Bakelite, Lucite, polystyrene and copper-clad PC-board scraps.

Soldering lugs, panel bearings, rubber grommets, terminal-lug wiring strips,

varnished-cambric insulating tubing, heat-shrinkable tubing.

Shielded and unshielded wire.

Tinned bare wire, nos. 22, 14 and 12.

Machine screws, nuts, washers, soldering lugs, etc., are most reasonably purchased in quantities of a gross. Many radio-supply stores sell small quantities and assortments that come in handy.

#### A DELUXE SOLDERING STATION

The simple device shown on this page can enhance the versatility and longevity of a soldering iron as well as make electronic

assembly more convenient. Fig. 1 depicts the obvious convenience features — a protective heat sink and case, and a tip-cleaning sponge rigidly attached to a sturdy base for efficient one-handed operation. Inside the chassis are some electrical refinements that justify the sophisticated name soldering station.

Soldering iron tips and heating elements last longer if operated at a lower-than-maximum temperature when idling. In the unit described here, temperature reduction is accomplished by halving the duty cycle of the applied ac voltage. D1 in Fig. 3 con-

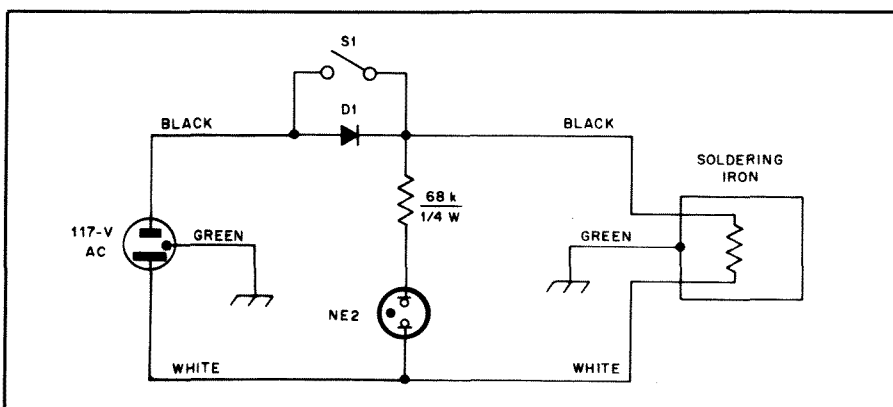

Fig. 3 — Schematic diagram of the soldering station. D1 is a silicon power rectifier, 1-A, 400-PIV. S1 is a miniature SPST toggle switch rated 3 at 125 V. This current is satisfactory for use with irons having power ratings up to 100 W.

ducts only when the hot ac line is positive with respect to neutral. If the diode were reversed, the soldering iron would be heated only on the negative half cycles, but the result would be the same. This is one of the rare applications of rectifier diodes where the polarity is not important. With current flowing only in one direction, only one electrode of the neon bulb will glow. Closing S1 short-circuits the diode and applies full power to the soldering iron, igniting both bulb electrodes brightly.

CMOS ICs are prone to damage by static charges, so they should be soldered with an iron having a grounded tip. This requirement is fulfilled by most irons having 3-wire power cords.

The base for the unit is a 2 × 6 × 4-inch (HWD) aluminum chassis (Bud AC-431 or equivalent). An Ungar model 8000 soldering iron fits neatly on the chassis top. The holder has two mounting holes in each foot. A sponge tray nests between the feet and the case. In this model, a sardine tin is used for the sponge tray. A suitable watertight enclosure can also be fabricated from strips of copper-clad circuit-board material. The tray and iron holder are secured to the chassis by 6-32 × 1/2-inch pan-head machine screws and nuts, with flat washers under the screw heads (sponge tray) and lock washers under the nuts (chassis underside). One of these nuts fastens a 6-lug tie point strip to the chassis bottom. Use the soldering iron holder base as a template for drilling the chassis and sponge tray. The floor of the sponge tray must be sealed around the screw heads to prevent moisture from leaking into the electrical components below the chassis. RTV compound was used for this purpose in the unit pictured.

Purchase a separate 3-wire cord for the power input. Merely splicing the soldering station into existing soldering iron cord will shorten the operating radius of the iron and make it awkward to use. Heyco bushings were used to anchor both cords in the unit described. If these aren't available, grommets and cable clamps will work as well. Knotting the cords inside the chassis is a simple expedient that normally provides adequate strain relief.

The underchassis assembly is shown in Fig. 2. The neon bulb is forced through a 3/16-inch-ID grommet. The leads are sleeved to prevent short circuits. If you mount the bulb in a fixture or socket, use a clear lens to ensure that the electrodes are distinctly visible. Fit a cover to the bottom of the chassis to prevent accidental contact with the live ac wiring. Stick-on rubber feet will ensure a skid-free unit that won't mar your work surface.

## SOLDERING-IRON TEMPERATURE CONTROL

Greater flexibility can be realized by installing a temperature rather than an idle control for your soldering iron. An incandescent-light dimmer can be used to

Fig. 4 — An incandescent-light dimmer controls soldering iron tip temperature. Only one of the duplex outlets is connected through the dimmer.

control the working temperature of the tip. Shown in Fig. 4 is a temperature control that can be built into an electrical box. A dimmer and a duplex outlet are mounted in the box; the wiring diagram is shown in Fig. 5. Be sure to break the link that connects the two hot terminals of the duplex outlet. The hot terminal is narrower than the neutral one. Neutral terminals may remain interconnected.

The dimmer shown in Fig. 4 was purchased at Radio Shack. It looks like a switch but it is really a variable control. Finer adjustment could be realized with a knob-controlled unit, but this one works fine.

When soldering static-sensitive devices, two or three jumpers can be used to ground you, the work and the iron. If the iron does not have a ground wire in the power cord, clip a jumper from the metal part of the iron near the handle to the metal box that houses the temperature control. Another jumper connects from the box to the work. Finally, a jumper goes from the box to your metal watch band. 3M makes an elastic wrist band for static grounding. This wrist band is equipped with a snap-on ground lead. Also, a 1-MΩ resistor is built into the snap of the strap to protect the user should a live circuit be contacted while using the strap. A similar resistor should be built into any homemade ground strap to protect the operator. It's not good practice to work on live circuits, however. This resistor will pro-

Fig. 5 — Schematic diagram of the soldering-iron temperature control.

tect you, but you should make sure that all power is removed from a circuit before working on it. Remember: even 24 V can be lethal! This technique works well for soldering CMOS ICs and GaAsFETs.

## Chassis Working

With a few essential tools and proper procedure, building radio gear on a metal chassis is a relatively simple matter. Aluminum is preferred to steel, not only because it is a superior shielding material, but because it is much easier to work and provides good chassis contacts.

The placement of components on the chassis is shown clearly in the photographs in this *Handbook*. Aside from certain essential dimensions, which usually are given in the text, exact duplication is not necessary.

Fig. 6 — Method of measuring the heights of capacitor shafts. If the square is adjustable, the end of the scale should be set flush with the face of the head.

Much trouble and energy can be saved by spending sufficient time in planning the job. When all details are worked out beforehand, the actual construction is greatly simplified.

Cover the top of the chassis with a piece of wrapping paper, or, preferably, cross-section paper. Fold the edges down over the sides of the chassis and fasten with adhesive tape. Then assemble the parts to be mounted on top of the chassis and move them about until a satisfactory arrangement has been found, keeping in mind any parts to be mounted underneath, so interference in mounting can be avoided. Place capacitors and other parts with shafts extending through the panel first, and arrange them so the controls will form the desired pattern of the panel. Be sure to line up the shafts squarely with the chassis front. Locate any partition shields and panel brackets next, and then sockets and any other parts. Mark the mounting-hole centers of each accurately on the paper. Watch out for capacitors whose shafts are off center and do not line up with the mounting holes. Do not forget to mark the centers of socket holes and holes for wiring leads. The small holes for socket-mounted screws are best located and center-punched, using the socket itself as a template, after

the main center hole has been cut.

Use the square to indicate the centers of shafts. These should be extended to the chassis front and marked on the panel at the chassis line, the panel being fastened on temporarily. The hole centers may then be punched in the chassis with the center punch. After drilling, the parts that require mounting underneath may be located and the mounting holes drilled, making sure by trial that no interferences exist with parts mounted on top. Mounting holes along the front edge of the chassis should be transferred to the panel by once again fastening the panel to the chassis and marking it from the rear.

Next, mount on the chassis the capacitors and any other parts with shafts extending to the panel, and measure accurately the height of the center of each shaft above the chassis, as illustrated in Fig. 6. The horizontal displacement of shafts having already been marked on the chassis line on the panel, the vertical displacement can be measured from this line. The shaft centers may now be marked on the back of the panel, and the holes drilled. Holes for any other panel equipment coming above the chassis line may then be marked and drilled, and the remainder of the apparatus mounted. Holes for terminals and other parts of the rear edge of the chassis should also be marked at this time.

#### Drilling and Cutting Holes

When drilling holes in metal with a hand drill it is important that the centers first be located with a center punch, so the drill point will not "walk" away from the center when starting the hole. When the drill starts to break through, special care must be used. Often it is an advantage to shift a two-speed drill to low gear at this point. Holes more than  $\frac{1}{4}$ -inch in diameter should be started with a smaller drill and reamed out with the larger drill.

The chuck on the usual type of hand drill is limited to  $\frac{1}{4}$ -inch drills. The  $\frac{1}{4}$ -inch hole may be filed out to larger diameters with a round file. Another method possible with limited tools is to drill a series of small holes with the hand drill along the inside of the circumference of the large hole, placing the holes as close together as possible. The center may then be knocked out with a cold chisel and the edges smoothed with a file.

Taper reamers which fit into the carpenter's brace will make the job easier. A large rat-tail file clamped in the brace makes a good reamer for holes up to the diameter of the file.

For socket holes and other large holes in an aluminum chassis, socket-hole punches should be used. They require first drilling a guide hole to pass the bolt that is turned to squeeze the punch through the chassis. The threads of the bolt should be oiled occasionally.

Large holes in steel panels or chassis are best cut with an adjustable circle cutter ("flycutter"). Occasional application of machine oil in the cutting groove will help. The cutter first should be tried out on a block of wood or scrap material to make sure it is set for the right diameter.

The burrs or rough edges that usually result after drilling or cutting holes may be removed with a file, or sometimes more conveniently with a sharp knife or chisel. It is a good idea to keep an old wood chisel sharpened and available for this purpose.

#### Rectangular Holes

Square or rectangular holes may be cut out by making a row of small holes as previously described, but is more easily done by drilling a  $\frac{1}{2}$ -inch hole inside each corner, as illustrated in Fig. 7, and using these holes for starting and turning the hacksaw. The socket-hole punch and the square punches that are now available also may be of considerable assistance in cutting out large openings.

#### Semiconductor Heat Sinks

Homemade heat sinks can be fashioned from brass, copper or aluminum stock with ordinary workshop tools. The dimensions of the heat sink will depend on the type of device used and the amount of heat that must be conducted away from the body of the semiconductor.

Fig. 8 shows the order of progression for forming a large heat sink from aluminum or brass channels of near-equal height and depth. The width is lessened in parts B and C so each channel will fit into the preceding one as shown in the completed model at D. The three pieces are bolted together with 8-32 screws and nuts. Dimensions given are for illustrative purposes only.

Heat sinks for smaller transistors can be

Fig. 7 — To cut rectangular holes in a chassis corner, holes may be filed out as shown in the shaded portion of B, making it possible to start the hacksaw blade along the cutting line. A shows how a single-ended handle may be constructed for a hacksaw blade.

Fig. 8 — Details for forming channel-type heat sinks.

fabricated as shown in Fig. 9. Select a drill bit that is one size smaller than the diameter of the transistor case and form the heat sink from 1/16-inch-thick brass, copper or aluminum stock as shown in steps A, B and C. Form the stock around the drill bit by compressing it in a vise (A). The completed heat sink is press-fitted over the body of the semiconductor as illustrated at D. The larger the heat sink area, the greater the amount of heat conducted away from the transistor body. In some applications, such as power transistor stages, the heat sinks shown in Fig. 9 may be 2 or 3 inches in height.

Another technique for making heat sinks for TO-5 type transistors and larger models is shown in Fig. 10. This style of heat sink will dissipate considerably more heat than will the type shown in Fig. 9. The main body of the sink is fashioned from a piece of 1/8-inch-thick aluminum angle bracket — available from most hardware stores. A hole is bored in the angle stock to allow the transistor case to fit *snugly* into it. The transistor is held in place by a small metal plate whose center hole is slightly smaller in diameter than the case of the transistor. Details are given in Fig. 10.

A thin coating of silicone grease, available from most electronic supply houses, can be applied between the case of the transistor and the part of the heat sink with which it comes in contact. The silicone grease will aid the transfer of heat from the transistor to the sink. Electrically conductive and nonconductive grease is available. Do not use conductive grease for applications where the device is insulated from the heat sink. This practice can be applied to all models shown here. In the example given in Fig. 8, the grease should be applied between the three channels before they are bolted together, as well as between the transistor and the channel it contacts.

### Construction Notes

If a control shaft must be extended or insulated, a flexible shaft coupling with adequate insulation should be used. Satisfactory support for the shaft extension, as well as electrical contact for safety, can be provided by means of a metal panel bushing made for the purpose. These can be obtained singly for use with existing shafts, or they can be bought with a captive extension shaft included. In either case the panel bushing gives a solid feel to the control. The use of fiber washers between ceramic insulation and metal brackets, screws or nuts will prevent the ceramic parts from breaking.

### Cutting and Bending Sheet Metal

If a metal sheet is too large to be cut conveniently with a hacksaw, it may be marked with scratches as deep as possible along the line of the cut on both sides of the sheet, and then clamped in a vise and worked back and forth until the sheet breaks at the line. Do not carry the bending too far until

Fig. 9 — Steps used in constructing heat sinks for small transistors.

Fig. 10 — Layout and assembly details of another homemade heat sink. The completed assembly can be insulated from the main chassis of the transmitter by using insulating washers.

the break begins to weaken; otherwise the edge of the sheet may become bent. A pair of iron bars or pieces of heavy angle stock, as long or longer than the width of the sheet, to hold it in the vise, will make the job easier. C clamps may be used to keep the bars from spreading at the ends. Bends may be made similarly. The rough edges may be smoothed with a file or by placing a large piece of emery cloth or sandpaper on a flat surface and running the edge of the metal back and forth over the sheet.

Much of the tedium of sheet metal work can be relieved by using copper-clad printed-circuit board material wherever possible. Copper-clad stock is manufac-

tured with phenolic, FR-4 fiberglass and Teflon base materials in thicknesses up to 1/8 inch. While it is manufactured in large sheets for industrial use, some hobby electronics stores and surplus outlets market usable scraps at reasonable prices. PC-board stock is easily cut with a small hacksaw. Because the nonmetallic base material isn't malleable, it can't be bent in the usual way. However, corners are easily formed by holding two pieces at right angles and soldering the seam. Excellent RF-tight enclosures can be fabricated in this manner. Many projects in this Handbook were constructed using this technique. If mechanical rigidity is required of a large

copper-clad surface, stiffening ribs may be soldered at right angles to the sheet.

### Finishing Aluminum

Aluminum chassis, panels and parts may be given a sheen finish by treating them in a caustic bath. An enameled or plastic container, such as a dishpan or infant's bathtub, should be used for the solution. Dissolve ordinary household lye in cold water in a proportion of one-quarter to one-half can of lye per gallon of water. The stronger solution will do the job more rapidly. Stir the solution with a stick of wood until the lye crystals are completely dissolved. Be very careful to avoid skin contact with the solution. It is also harmful to clothing. Sufficient solution should be prepared to cover the piece completely. When the aluminum is immersed, a very pronounced bubbling takes place and ventilation should be provided to disperse the escaping gas. A half hour to two hours in the bath should be sufficient, depending on the strength of the solution and the desired surface.

Fig. 11 — State diagram for tin-lead solder alloys. Courtesy of Litton Industries, Inc., Kester Solder Co.

Raw aluminum can be prepared for painting by abrading the surface with medium-grade sandpaper, making certain the strokes are applied in the same direction (not circular or random). This process will create tiny grooves on the otherwise smooth surface. As a result, paint or lacquer will adhere well. Before painting, wash the abraded aluminum with alcohol or soap and hot water, then dry thoroughly. Avoid touching the prepared surface before painting it. One or two coats of zinc chromate primer applied before the finish paint will ensure good adherence.

### Soldering

The secret of good soldering is to use the right amount of heat. Solders have different melting points, depending on the ratio of tin to lead. Tin melts at 450°F and lead at 621°F (see Fig. 11). Solder with 63% tin and 37% lead melts at 361°F, the lowest melting point for a tin and lead mixture. Called 63-37, this ratio also provides the most rapid solid to liquid transition and best stress resistance.

As shown in Fig. 11, solder that is not 63-37 goes through a *plastic* state. If the solder is deformed while it is in the plastic state, that deformation will remain when the solder freezes into the solid state. Any stress or motion applied to "plastic solder" will result in poor solder joint.

A 60-40 solder has the best *wetting* qualities. Wetting is the ability to spread rapidly and alloy uniformly. Soldering is not like glueing. The solder does more than bind pieces of metal together and provide an electrically conductive path between them. In the soldering process, the materials being joined and the solder combine to form an alloy. This effect is illustrated in Fig. 12. Because of its low melting point, small plastic area and excellent wetting characteristics, 60-40 solder is the most commonly used alloy in electronics.

Fig. 12 — An alloy layer exists in a good solder joint.

Various solder alloys are used for special purposes. Other tin-lead alloys are 50-50 and 40-60. A low-melting-point solder, 50-32-18 (tin-lead-cadmium) has a melting temperature of under 300°F. This alloy is used for heat sensitive components.

Some connections carrying very high current can't be made with ordinary tin-lead solder because the heat generated by the joint resistance would melt the solder. Automotive starter brushes and UHF transmitter tank circuits are two cases in which this situation can occur. High-melting-point silver solder prevents this condition. A typical alloy contains 5-93.5-1.5 (tin-lead-silver) and the melting point is about 600°F.

To prevent the silver plating on some components from leaching into the solder, some silver is added to the solder. A typical alloy contains 62-36-2 (tin-lead-silver) and melts at 354°F. Another silver solder is 96.3-3.7 (tin-silver); it contains no lead and melts at 430°F.

Always use rosin-core solder; never acid-core. The rosin is a flux. Flux removes oxide by suspending it in solution and floating it to the top. Flux is not a cleaning agent! The work must be cleaned before soldering. Flux is not a part of a soldered connection — it merely aids the soldering process. After soldering, any remaining flux should be removed. Alcohol is a good

solvent for the job. A toothbrush is an excellent tool for applying the alcohol and scrubbing the excess flux away.

The two key factors in quality soldering are time and temperature. Generally, rapid heating is desired. If heat is applied too long, the flux may become used up and surface oxidation can become a problem. Further, thin coating may dissolve from leads and components, or components may be harmed. The soldering-iron tip should be hot enough to readily melt the solder without burning, charring or discoloring components, PC boards or wires. Usually, a tip temperature about 100°F above the solder melting point is about right for mounting components on PC boards.

When soldering, apply the solder to the joint — not to the iron. A small amount of solder on the tip will improve heat transfer. The iron and the solder should be applied simultaneously to the joint. Keep the iron clean by brushing the tip with a cloth towel or a moist sponge. Allow the joints to cool in air at room temperature. Make sure there is no movement or stress on joints during cooling and solidification of the solder.

When you solder transistors, crystal diodes or small resistors, the lead should be gripped with a pair of pliers up close to the unit so that the heat will be conducted away. Overheating of a transistor or diode while soldering can cause permanent damage. Also, mechanical stress will have a similar effect. Therefore, a small unit should be mounted so there is no appreciable mechanical strain on the leads.

Trouble is sometimes experienced soldering to the pins of coil forms or male cable plugs. It helps if the pins are first cleaned on the inside with a suitable twist drill and then tinned by flowing rosin-core solder into them. Immediately clear the surplus solder from each hot pin by a whipping motion or by blowing through the pin from the inside of the form or plug. Before inserting the wire in the pin, file the nickel plate from the pin tip. After soldering, remove excess solder with a file.

When soldering to the pins of polystyrene coil forms, hold the pin to be soldered with a pair of heavy pliers to form a heat sink and ensure that the pin does not heat enough in the coil form to loosen and become misaligned.

Just as important as soldering is desoldering to remove components. Commercially made wicking material (braid) will soak up excess solder from a joint. Another useful tool is an air-suction solder remover. Or, you can heat the joint and "flick" the wet solder off. Keep a large cardboard box handy to flick the solder into, or you'll get solder splashes everywhere.

## Wiring

The wire used in connecting amateur equipment should be selected by considering both the maximum current it will be

called on to handle and the voltage its insulation must stand without breakdown. Also, from the consideration of TVI, the power wiring of all transmitters should be done with wire that has a braided shielding cover. Receiver and audio circuits may also require the use of shielded wire at some points for stability or the elimination of hum.

No. 20 stranded wire is commonly used for most receiver wiring (except for the high-frequency circuits) where the current does not exceed 2 or 3 amperes. For higher-current heater circuits, no. 18 is available. Wire with cellulose acetate insulation is good for voltages up to about 500. For higher voltages, Teflon-insulated or other special HV wire should be used. Teflon insulation has the additional advantage of not melting when a soldering iron is applied. This makes it particularly helpful in tight places or large harnesses. Although Teflon-insulated wire is more expensive, it is often available from industrial surplus houses. Inexpensive wire strippers make the removal of insulation from hookup wire an easy job.

When power leads have several branches in the chassis, it is convenient to use fiber-insulated multiple tie points as anchorages of junction points. Strips of this type are also useful as insulated supports for resistors, RF chokes and capacitors. Exposed points of high-voltage wiring should be held to a minimum; those that cannot be avoided should be made as inaccessible as possible to accidental contact or short-circuit.

Where shielded wire is called for and capacitance to ground is not a factor, Belden type 8885 shielded grid wire may be used. If capacitance must be minimized, it may be necessary to use a piece of car radio low-capacitance lead-in wire or coaxial cable.

For wiring high-frequency circuits, rigid wire is often used. Bare soft-drawn tinned wire, size 22 to 12 (depending on mechanical requirements) is suitable. Kinks can be avoided by stretching a piece 10 or 15 feet long and then cutting it into short lengths that can be handled conveniently. RF wiring should be run directly from point to point with a minimum of sharp bends and the wire kept well spaced from the chassis or other grounded metal surfaces. Where the wiring must pass through the chassis or a partition, a clearance hole should be cut and lined with a rubber grommet. If insulation is necessary, varnished cambric tubing (spaghetti) can be slipped over the wire.

In transmitters in which the peak voltage does not exceed 2500, the shielded grid wire mentioned above should be satisfactory for power circuits. For higher voltages, Belden type 8656, Birnbach type 1820, or shielded ignition cable can be used. In the case of filament circuits carrying heavy current, it may be necessary to use no. 10 or 12 bare or enameled wire, slipped through

Fig. 13 — Methods of lacing cables. The method shown at C is more secure, but takes more time than the method of B. The latter is usually adequate for most amateur requirements.

Fig. 14 — Plastic products are used to form and secure wires into a cable.

Fig. 15 — Adhesive-backed blocks and plastic wraps used to make wiring cables. Some wraps are reusable.

spaghetti, and then covered with copper braid pulled tightly over the spaghetti. If the shielding is simply slid back over the insulation and solder flowed into the end of the braid, the braid usually will stay in place without the necessity for cutting it back or binding it in place. The braid should be cleaned first so solder will take with a minimum of heat. RF wiring in transmitters usually follows the methods described above for receivers with due respect to the voltages involved.

Where power or control leads run together for more than a few inches, they will present a better appearance when bound together in a single cable. The correct technique is illustrated in Fig. 13; both

Fig. 16 — Pictorial diagram of a heavy-duty plate choke for the HF bands. No. 26 enameled wire is used for the winding. Low-loss material should be used for the form.

plastic and waxed-linen lacing cords are available. A variety of plastic devices are available to bundle wires into cables and to clamp or secure them in place. Figs. 14 and 15 show some of the products and techniques that you might use. Check with your local electronic parts supplier for items that are in stock.

To give a commercial look to the wiring of any unit, run any cabled leads along the edge of the chassis. If this isn't possible, the cabled leads should then run parallel to an edge of the chassis. Further, the generous use of the tie points mounted parallel to an edge of the chassis, for the support of one or both ends of a resistor or fixed capacitor, will add to the appearance of the finished unit. In a similar manner, arrange the small components so that they are parallel to the panel or sides of the chassis.

### Winding Coils

Close-wound coils are readily wound on the specified form by anchoring one end of the length of wire (in a vise or to a doorknob) and the other end to the coil form. Straighten any kinks in the wire and then pull to keep the wire under slight tension. Wind the coil to the required number of turns while walking toward the anchor,

always maintaining a slight tension on the wire.

To space-wind the coil, wind the coil simultaneously with a suitable spacing medium (heavy thread, string or wire) in the manner described above. When the winding is complete, secure the end of the coil to the coil-form terminal and then carefully unwind the spacing material. If the coil is wound under suitable tension, the spacing material can be easily removed without disturbing the winding. Finish the space-wound coil by judicious applications of Duco cement to hold the turns in place.

The cold end of a coil is the end at or close to chassis or ground potential. Coupling links should be wound on the cold end of a coil to minimize capacitive coupling.

RF chokes must often present a high impedance over a broad frequency range. This requirement calls for the avoidance of series resonances within the range. Such resonances can be avoided in single-layer solenoids by separating the winding into progressively shorter sections. A practical choke suitable for HF amateur service at plate impedances up to 51-k $\Omega$  and currents up to 600 mA is shown in Fig. 16.

Another way to build a broadband choke is to wind a small number of turns on a high-permeability ferrite rod (such as the type used for antennas in some portable radios). The magnetic core supplies a large inductance with a small winding. Keeping the number of turns small reduces the distributed capacitance and raises the self-resonant frequency of the choke. Ferrite chokes are best suited to low-impedance applications. A bifilar (this term is explained in the following paragraphs) filament choke for grounded-grid kilowatt HF amplifiers appears in Fig. 17.

Toroidal inductors and transformers are specified for many projects in this *Handbook*. The advantages of this type of winding include compactness and a self-shielding property. Figs. 18 and 19 illustrate the proper way to wind and count the turns on a toroidal core.

A *bifilar* winding is one that has two identical lengths of wire, which when placed on the core result in the same number of turns for each wire. The two wires can be put on the core side by side at the same time, just as if a single winding were being applied. An easier and more popular method is to twist the two wires (8 to 15 times per inch will suffice), then

Fig. 18 — The suggested winding method for a single-layer toroid as shown at A. A 30° gap is recommended (see text). Wrong methods are shown at B and C. At D is a method for placing a tap on the coil.

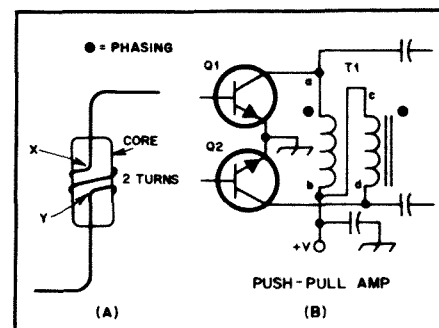

Fig. 19 — The view at A shows how the turns on a toroid should be counted. The large black dots in the diagram at B are used to indicate the polarity (phasing) of the windings.

Fig. 20 — Schematic and pictorial presentation of a bifilar-wound toroidal transformer.

wind the pair on the core. The wires can be twisted handily by placing one end of the length of two wires in a bench vise. The remaining wire-pair ends are tightened into the chuck of a small hand drill, and the twisting is done.

A *trifilar* winding has three wires, and a *quadri-filar* winding has four. The procedure for preparation and winding is otherwise the same as for a bifilar winding. Fig. 20 shows a bifilar type of toroid in schematic and pictorial form. The wires have been twisted together prior to placing them on the core. It is helpful, though by no means essential, to use wires of different color when multifilar-winding a core. The more wires used, the more perplexing it is

Fig. 17 — Bifilar filament choke wound on a ferrite rod. Heat-shrink tubing will help anchor the winding. If enameled wire is used, the form should be insulated before winding.

to identify the end of the windings correctly once the core has been wound. There are various colors of enamel insulation available, but it is not easy for amateurs to find this wire locally or in small-quantity lots. This problem can be solved by taking lengths of wire (enameled magnet wire), cleaning them to remove dirt and grease, then spray-painting them. Ordinary aerosol-can spray enamel works fine. Spray lacquer is not as satisfactory because it is brittle when dry and tends to flake off the wire.

The winding sense of a multifilar toroidal transformer is important in most circuits. Fig. 19B illustrates this principle. The black dots (called phasing dots) at the top of the T1 windings indicate polarity. That is, points a and c are both start or finish ends of their respective windings. In this example, points a and d are of opposite phase ( $180^\circ$  phase difference) to provide push-pull voltage feed to Q1 and Q2.

## CIRCUIT-BOARD FABRICATION

Modern-day builders prefer the neatness and miniaturization made possible by the use of etched printed-circuit boards. There are additional benefits to be realized from the use of circuit boards: Low lead inductances, excellent physical stability of the components and interconnecting leads, and good repeatability of the basic layout of a given project. The repeatability factor makes the use of circuit boards ideal for group projects.

### Planning and Layout

The constructor should first plan the physical layout of the circuit by sketching a pictorial diagram on paper, drawing it to scale. Once this has been done, the interconnecting leads can be inked in to represent the copper strips that will remain on the etched board. The Vector Company sells layout paper for this purpose. It is marked with the same patterns used on their perforated boards.

After the basic etched-circuit design has been completed, the designer should go over the proposed layout several times to insure against errors. When that has been done, the pattern can be painted on the copper surface of the board to be etched. Etch-resistant solutions are available from commercial suppliers and can be selected from their catalogs. Some builders prefer to use India ink for this purpose. Perhaps the most readily available material for use in etch-resist applications is ordinary exterior enamel paint. The portions of the board to be retained are covered with a layer of paint applied with an artist's brush, duplicating the pattern that was drawn on the layout paper. The job is made a bit easier by tracing over the original layout with a ballpoint pen and carbon paper while the pattern is taped to the copper side of the unetched circuit board. The carbon paper is placed between the pattern and the

Fig. 21 — A homemade stand for processing etched-circuit boards. The heat lamp maintains the etchant-bath temperature between  $90$  and  $115^\circ\text{F}$  ( $32$  and  $46^\circ\text{C}$ ) and is mounted on an adjustable arm. The tray for the bath is raised and lowered at one end by the action of a motor-driven eccentric disc, providing the necessary agitation of the chemical solution. A darkroom thermometer monitors the temperature of the bath.

Fig. 22 — Schematic diagram of an audio amplifier.

circuit board. After the paint has been applied, it should be allowed to dry for at least 24 hours prior to the etching process. The Vector Company produces a rub-on transfer material that can also be used as etch-resist when laying out circuit-board patterns. Thin strips of ordinary masking tape, cut to size and firmly applied, serve nicely as etch-resist material too.

To make a single PC board, it is convenient to cover the copper surface with masking tape, transfer the circuit pattern by means of carbon paper, then cut out and remove the sections of masking tape where the copper is to be etched away. An X-acto® hobby knife is excellent for the purpose. Masking tape, securely applied, serves as a fine etch-resist material.

Many magazine articles feature printed-circuit layouts. The more-complex patterns (those containing ICs and high component densities) are difficult to duplicate accurately by hand. A photographic pro-

cess is the most efficient way to transfer a layout from a magazine page to a circuit board. A Thermofax transparency-producing machine (most schools have these) will copy the circuit on a clear plastic sheet for use as a negative. Pressing this negative against a photosensitive copper-clad board with a piece of glass and exposing the assembly to sunlight for about 90 seconds will deactivate the etchant resist on the exposed part of the board. The portion of the copper that is shielded from the light by the negative will resist etching. Photosensitive PC-board material is manufactured by Kepro Company.

### The Etching Process

Almost any strong acid bath will serve as an etchant, but the two chemical preparations recommended here are the safest to use. A bath can be prepared by mixing one part ammonium persulphate crystals with two parts clear water. A normal quantity of working solution for most Amateur Radio applications is composed of one cup of crystals and two cups of water. To this mixture add  $\frac{1}{4}$  teaspoon of mercuric chloride crystals; this serves as an activator for the bath. Ready-made etchant kits that use these chemicals are available from Vector. Complete kits that contain circuit boards, etchant powders, etch-resist transfers, layout paper, and plastic etchant bags are also available from Vector at moderate prices.

Another chemical bath that works satisfactorily for copper etching is made up from one part ferric chloride crystals and two parts water. No activator is required with this bath. Ready-made solutions (one-pint and one-gallon sizes) are available through some mail-order houses at low cost. They are manufactured by Kepro Company and carry stock numbers E-1PT and E-1G, respectively.

Etchant solutions become exhausted after a certain amount of copper has been processed. Therefore, it is wise to keep a quantity of the bath on hand if frequent use is anticipated. With either chemical bath, the working solution should be maintained at a temperature between  $90$  and  $115^\circ\text{F}$ . A heat lamp can be directed toward the bath during the etching period, its distance set to maintain the required temperature. A darkroom thermometer is handy for monitoring the temperature of the bath.

While the circuit is immersed in the solution, it should be agitated continuously to permit uniform reaction to the chemicals. This action will also speed up the etching process somewhat. Normally, the circuit board should be placed in the bath with the copper side facing down, toward the bottom of the tray. The tray should be nonmetallic, preferably a Pyrex dish or a photographic darkroom tray.

Fig. 21 shows a homemade etching stand made up from a heat lamp, some lumber,

and an 8-r/min motor. An eccentric disc has been mounted on the motor shaft and butts against the bottom of the etchant tray. As the motor turns, the eccentric disc raises and lowers one end of the tray, thus providing continuous agitation of the solution. The heat lamp is mounted on an adjustable, slotted wooden arm. Its height above the solution tray is adjusted to provide the desired bath temperature. Because the etching process takes between 15 minutes and one hour — dependent on the strength and the temperature of the bath — such an accessory is convenient.

After the etching process is completed, the board is removed from the tray and washed thoroughly with fresh, clear water. The etch-resist material can then be rubbed off by applying a few brisk strokes with medium-grade steel wool. **WARNING: Always use rubber gloves when working with etchant powders and solutions. Should the acid bath come in contact with the body, immediately wash the affected area with clear water. Protect the eyes when using acid baths.**

#### No-Etch PC Boards

Some would-be builders express revulsion at the prospect of PC-board fabrication. The distaste for chemical processes should not deter a person, however, for several alternatives exist.

A construction technique that is practically indistinguishable from true printed circuitry is excavating a copper-clad board with hand-held grinding tool, such as the Moto-tool manufactured by the Dremel Company. The simpler circuits can be cut out of the board with an X-acto knife. Unwanted copper can be removed by heating it with a soldering iron and lifting it off with a knife while it is still hot.

#### Alternative Construction Methods

Many methods can be used to construct a circuit. Say, for example, you wish to build the audio amplifier shown in Fig. 22. What construction method would you use? Many possibilities exist — some of them will be covered in this section.

You can build the audio amplifier on an etched PC board. That technique was described earlier. The results might look like the board shown in Fig. 23. For a complicated project, a lot of work can go into getting one perfect PC board. However, after that first one is perfected, dozens more can be made with relative ease.

#### Solderless Prototyping Board

An etched PC board is not always the best way to construct a circuit. That is especially true when you are developing a circuit. It can be frustrating to have to make another PC board for every circuit variation you want to try. A better method for experimental circuit construction is to use a solderless prototyping board. Several models are available from many sources. One of these is illustrated in Fig. 24.

(A)

(B)

Fig. 23 — Audio amplifier built on a PC board. Top view at A; bottom view at B.

Fig. 24 — The audio amplifier of Fig. 22 has been built on this solderless prototyping board.

Metal strips inside the board grip inserted component leads and hookup wire. The strips are arranged in short columns along the center of the board and in long rows at the top and bottom. Circuit components and hookup wire are used to interconnect the strips and make the circuit. This is a fast and easy way to test an idea and work on modifications. Component and interconnection changes can be readily made.

There are some minor disadvantages to these solderless boards. Because of the capacitance between the finger-stock strips, the boards are not good for building RF circuits. Also, to prevent deforming the

finger stock when using components with heavy leads, you must add short lead extensions of small diameter wire.

#### Perforated Construction Board

Perhaps the least complicated approach to circuit-board fabrication is the use of unclad perforated board. Perforated board is available with many different hole patterns. Your choice will depend on your needs.

A great deal of time can be spent laying out and etching a single PC board. Circuit construction on perforated board is much easier. Start by placing the components on the board and moving them about until a satisfactory layout is obtained. Component leads are then pushed through the holes, connected with bus or hookup wire and soldered. The audio amplifier of Fig. 22 is shown constructed with this technique in Fig. 25.

Perforated boards and accessories are manufactured by several companies. Accessories include mounting hardware and a variety of connection terminals for solder and solderless construction. These products are widely available.

#### Utility PC Boards

Utility PC boards offer a hybrid alternative to the custom-designed etched PC board. They offer the flexibility of perforated board construction and the mechanical and electrical advantages of etched circuit connection pads. Utility PC boards can be used to build anything from simple passive filter circuits to computers.

(A)

(B)

Fig. 25 — Audio amplifier built on perforated board. Top view at A; bottom view at B.

Fig. 26 — Etching pattern for the universal breadboard. Black represents copper; the pattern is shown actual size. You can etch your own from this pattern or purchase a board from Circuit Board Specialists, P.O. Box 969, Pueblo, CO 81002.

Fig. 27 — Utility PC boards like these are available from Oak Hills Research, 4061 N. Douglas Rd., Luther, MI 49656.

Circuits can be built on boards on which the copper cladding has been divided into connection pads. Power supply voltages can be distributed on bus strips. The etching pattern for a board of this type can be found in Fig. 26. Boards like those shown in Fig. 27 are commercially available.

The example audio amplifier is shown in Fig. 28. This time the amplifier was built on a Radio Shack board that is designed for building circuits with ICs. Component leads are inserted into the etched pads. Wire jumpers connect the pads together to complete the circuit.

Utility boards with one or more etched plugs for use in computer-bus, interface and general purpose applications are widely available. Connectors, mounting hardware and other accessories are also available. Check with your parts supplier for details.

Plug-in boards facilitate maintenance and repair.

#### Wire Wrap

Wire-wrap construction can be used to construct a circuit quickly and without solder. Low- and medium-speed digital circuits are often assembled on a wire-wrap board. The technique is not limited to digital circuits, however. Fig. 29 shows the example audio amplifier built using wire wrap. Circuit changes can be easily made, and yet the method is suitable for permanent assemblies.

Wire wrap basically consists of twisting or wrapping a wire around a post to make each connection. The wrapping tool resembles a thick pencil. Powered wire-wrap guns are used when many connections must be made. The wire is almost always no. 30 and has a thin insulation on it. Two wire-wrap methods are used: the standard

(A)

(B)

Fig. 28 — Audio amplifier built on a multipurpose PC breadboard. Top view at A; bottom view at B.

and the modified wrap (Fig. 30). The modified wrap is more secure and should be used for no. 30 wire. The wrap-post terminals are usually square; they should be long enough for at least two connections. For proper wire-wrap technique, see Figs. 30 and 31.

When wire wrapping, small components can be mounted on an IC header plug. The plug is then inserted into a wire-wrap IC socket, as shown in Fig. 29. The large capacitor in that figure has its leads soldered to Y-shaped wrap posts. Wire wrap works only on posts with sharp corners!

#### Ugly or Dead-Bug Construction

The term "ugly construction" was coined by Wes Hayward, W7ZOI. "Dead-bug construction" gets its name from the appearance of an IC with its leads sticking up in the air. This technique uses copper-clad circuit-board material as a foundation and ground plane on which to build a circuit using point-to-point wiring.

This method is flexible. The builder may use the parts on hand, something that is often difficult to do with the projects that use etched boards. The circuit may be changed easily; that aids experimentation. Speed is the greatest virtue of ugly construction. A moderately complex project (like a QRP transmitter) can be built in half the time, or less, than that required for the

Fig. 29 — Audio amplifier built using wire-wrap techniques.

Fig. 30 — Wire-wrap connections. Standard wrap is shown at A; modified wrap at B. The modified wrap should be used with no. 30 wire.

same project using boards that have to be etched and drilled.

Components are mounted just above the copper-clad board. (See Fig. 32.) Copper on the board becomes the circuit ground. Ground connections are made directly, thereby minimizing component lead lengths. Short lead lengths and a low-impedance ground conductor help prevent circuit instability. For that reason, ugly construction is particularly good for RF circuits — and for sensitive circuits, better than etched circuit boards.

High-ohmage resistors can be used as

Fig. 31 — Improper wire-wrap connections. Insufficient insulation for modified wrap is shown at A; a spiral wrap at B; an open wrap at C and an over wrap at D.

Fig. 32 — Audio amplifier built using ugly or dead bug construction.

Fig. 34 — Cordwood modules make compact subassemblies. This broad-band amplifier consists of two transistors, two capacitors and six resistors.

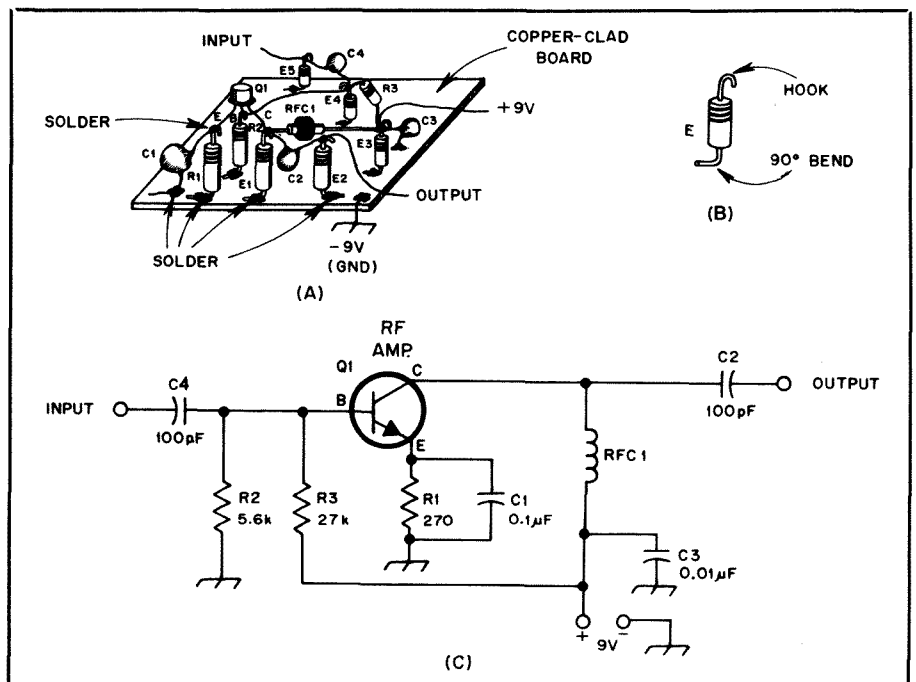

Fig. 33 — Pictorial view of a circuit board that uses ugly construction is shown at A. A closeup view of one of the standoff resistors is shown at B. Note how the pigtails are bent. The schematic diagram at C shows the assembled circuit displayed at A.

soldered to the PC-board material. Components E1 through E5 are resistors that are used as stand-off insulators. They do not appear in the schematic diagram. The base circuitry at Q1 of Fig. 33A is stretched out excessively. This was done to reduce clutter in the drawing. In a practical circuit all of the signal leads should be kept as short as possible. E4 would, therefore, be placed much closer to Q1 than the drawing indicates.

R1 and R2 of Fig. 33 actually serve two purposes: They are not only the normal circuit resistances, but function as stand-off posts as well. This practice should be followed wherever a capacitor or resistor can be employed in the dual role.

#### *Space Savers.*

Compact assemblies can be made using cordwood modules. A cordwood module resembles a sandwich. On the outside are the end pieces. In the center are the circuit

Fig. 35 — Surface-mounted components take up little space on this thick-film module. (Courtesy Tactical RF Inc., Norfolk, Massachusetts.)

components. The end pieces have holes for the component leads to pass through. Etched traces or point-to-point wiring can be used for circuit connections. Component leads can be used to make connections to the module. This construction method is particularly useful for making small

subassemblies. A broad-band amplifier with two transistors, two capacitors and six resistors built with this technique is shown in Fig. 34.

Another space-saving technique is the use of surface-mounted or chip components. Most UHF and microwave enthusiasts know about chip resistors and capacitors. Other devices, such as transistors and diode arrays, are also available in this space-saving format.

Surface-mounted components take up very little space on a PC board. Even less space is required when circuit traces and components are placed on a piece of ceramic substrate material to make a thick-film module. It is possible for the advanced amateur builder to construct thick-film modules at home. The techniques used today are beyond the scope of this book. Fig. 35 shows what can be done using thick-film technology for making miniature circuits.

# Test Equipment and Measurements

**M**easurement and testing go hand in hand, but it is useful to make a distinction between measuring and testing. Measurement is commonly considered to give a meaningful quantitative result, while for testing a simple indication of satisfactory or unsatisfactory may suffice. In any event, the accurate calibration associated with real measuring equipment is seldom necessary

for simple test apparatus.

Certain items of measuring equipment that are useful to amateurs are readily available in kit form, at prices that represent a genuine saving over the cost of identical parts. Included are volt-ohm-milliammeter combinations, vacuum-tube and transistor voltmeters, oscilloscopes and the like. The coordination of electrical and mechanical design, components and appearance make it far preferable to pur-

chase such equipment than to attempt to build one's own.

However, some test gear can easily be built at home. This chapter considers the principles of the more useful types of measuring equipment and concludes with the descriptions of several pieces that not only can be built satisfactorily at home but also will facilitate operation of the amateur station.

## The Direct-Current Instrument

In measuring instruments and test equipment suitable for amateur purposes, the ultimate readout is generally based on a measurement of direct current. A meter for measuring dc uses electromagnetic means to deflect a pointer over a calibrated scale in proportion to the current flowing through the instrument.

In the D'Arsonval type, a coil of wire to which the pointer is attached is pivoted between the poles of a permanent magnet. When current flows through the coil, it sets up a magnetic field that interacts with the field of the magnet to cause the coil to turn. The design of the instrument normally makes the pointer deflect in direct proportion to the current.

A less expensive type of instrument is the moving-vane type, in which a pivoted soft-iron vane is pulled into a coil of wire by the magnetic field set up when current flows through the coil. The farther the vane extends into the coil, the greater the magnetic pull on it for a given change in current. This type of instrument thus does not have linear deflection. The intervals of equal current change are crowded together at the low-current end and spread out at the high-current end of the scale.

### Current Ranges

The sensitivity of an instrument is usually expressed in terms of the current required for full-scale deflection of the pointer.

Fig 1—Use of a shunt to extend the calibration range of a current-reading instrument.

Although a very wide variety of ranges is available, the meters of interest in amateur work have basic movements that will give maximum deflection with currents measured in microamperes or milliamperes. They are called microammeters and milliammeters, respectively.

Thanks to the relationships between current, voltage and resistance expressed by Ohm's Law, it becomes possible to use a single low-range instrument—e.g., 1 milli-ampere or less full-scale pointer deflection—for a variety of direct-current measurements. Through its ability to measure current, the instrument can also be used indirectly to measure voltage. Likewise, a

measurement of both current and voltage will obviously yield a value of resistance. These measurement functions are often combined in a single instrument—the volt-ohm-milliammeter or VOM, a multirange meter that is one of the most useful pieces of measuring and test equipment an amateur can possess.

### Accuracy

The accuracy of a dc meter of the D'Arsonval type is specified by the manufacturer. A common specification is 2 percent of full scale, meaning that a 0-100 microammeter, for example, will be correct to within 2 microamperes at any part of the scale. There are very few cases in amateur work where accuracy greater than this is needed. However, when the instrument is part of a more complex measuring circuit, the design and components can all cause error, reducing the overall accuracy of the complete device.

### Extending the Current Range

Because of the way current divides between two resistances in parallel, it is possible to increase the range (more specifically, to decrease the sensitivity) of a dc microammeter or milliammeter. The meter itself has an inherent resistance—its internal resistance—which determines the full-scale current passing through it when its rated voltage is applied. (This rated voltage is on

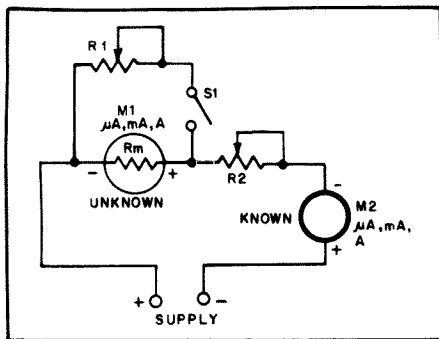

Fig 2—A safe method for determining the internal resistance of a meter.

Fig 3—A voltmeter is a current-indicating instrument in series with a high resistance, the "multiplier."

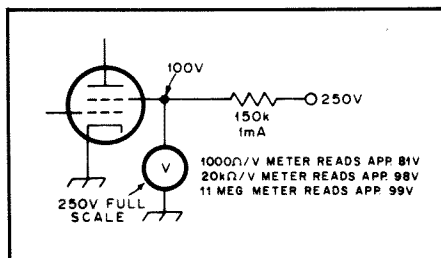

Fig 4—Effect of voltmeter resistance on accuracy of readings. It is assumed that the dc resistance of the screen circuit is constant at 100 kilohms. The actual current and voltage without the voltmeter connected are 1 mA and 100 volts. The voltmeter readings will differ because the different types of meters draw different amounts of current through the 150-kΩ resistor.

the order of a few millivolts.) By connecting an external resistance in parallel with the internal resistance, as in Fig 1, the current will divide between the two, with the meter responding only to that part of the current that flows through the internal resistance of its movement. Thus, it reads only part of the total current; the effect is to make more total current necessary for a full-scale meter reading. The added resistance is called a shunt.

It is necessary to know the meter's internal resistance before the required value for a shunt can be calculated. It may vary from a fraction of an ohm to a few thousand ohms, with the higher resistance values associated with higher sensitivity. When this resistance is known, it can be used in the formula below to determine the re-

quired shunt for a given multiplication:

$$R = \frac{R_m}{n - 1}$$

where

$R$  = the shunt

$R_m$  = internal resistance

$n$  = the factor by which the original meter scale is to be multiplied.

Often the internal resistance of a particular meter will be unknown. This is usually the case when the meter is purchased at a flea market or is obtained from a commercial piece of equipment. Unfortunately, the internal resistance of the meter can not be measured directly with a VOM or VTVM without risk of damage to the meter movement.

Most modern digital multimeters *can* be used to measure the internal resistance of a meter directly.

Fig 2 shows another method that can be used safely to determine the internal resistance of a meter. A calibrated meter capable of measuring the same current as the unknown meter is required. The system works as follows: S1 is placed in the open position and R2 is set for maximum resistance. A supply of constant voltage is connected to the terminals + and - (a battery will work fine) and R2 is adjusted so that the unknown meter reads exactly full scale. Note the current shown on M2. Close S1 and alternately adjust R1 and R2 so that the unknown meter (M1) reads exactly half scale and the known meter (M2) reads the same value as in the step above. At this point the current in the circuit flows through M1 and half through R1. To determine the internal resistance of the meter, simply open S1 and read the resistance of R1 with a VTVM, VOM or digital voltmeter.

The values of R1 and R2 will depend on the meter sensitivity and the supply voltage. The maximum resistance value for R1 should be approximately twice the expected internal resistance of the meter. For highly sensitive meters (10  $\mu$ A and less) 1 kilohm should be adequate. For less sensitive meters 100 ohms should suffice. Use no more supply voltage than necessary.

The value for minimum resistance at R2 can be calculated using Ohm's Law. For example, if the meter is a 0-1 mA type and the supply is a 1.5-volt battery, the minimum resistance required at R2 will be

$$R2 = \frac{1.5}{0.001}$$

$$R2(\text{min}) = 1500 \text{ ohms}$$

In practice a 2- or 2.5-kΩ potentiometer would be used.

### Making Shunts

Homemade shunts can be constructed from any of various special kinds of resistance wire, or from ordinary copper wire if no resistance wire is available. The copper wire table in this handbook gives

the resistance per 1000 feet for various sizes of copper wire. After computing the resistance required, determine the smallest wire size that will carry the full-scale current (250 circular mils per ampere is a satisfactory figure for this purpose). Measure off enough wire to provide the required resistance. A high-resistance 1- or 2-watt carbon-composition resistor makes an excellent form on which to wind the wire. It is recommended that you use the largest size copper wire that is practical to keep the effects of the temperature coefficient of copper to a minimum.

### The Voltmeter

If a large resistance is connected in series with a current-reading meter, as in Fig 3, the current multiplied by the resistance will be the voltage drop across the resistance. This is known as a multiplier. An instrument used in this way is calibrated in terms of the voltage drop across the multiplier resistor and is called a voltmeter.

### Sensitivity

Voltmeter sensitivity is usually expressed in ohms per volt, meaning that the meter full-scale reading multiplied by the sensitivity will give the total resistance of the voltmeter. For example, the resistance of a 1-kΩ-per-volt voltmeter is 1000 times the full-scale calibration voltage, and by Ohm's Law the current required for full-scale deflection is 1 milliampere. A sensitivity of 20 kΩ per volt, a commonly used value, means that the instrument is a 50-microampere meter.

The higher the resistance of the voltmeter, the more accurate the measurements, especially in high-resistance circuits. Current flowing through the voltmeter will cause a change in the voltage between the points where the meter is connected, compared with the voltage with the meter absent. This is illustrated in Fig 4.

### Multipliers

The required multiplier resistance is found by dividing the desired full-scale voltage by the current, in amperes, required for full-scale deflection of the meter alone. Strictly, the internal resistance of the meter should be subtracted from the calculated value but this is seldom necessary (except perhaps for very low ranges), since the meter resistance will be negligible compared with the multiplier resistance. An exception is when the instrument is already a voltmeter and is provided with an internal multiplier, in which case the multiplier resistance required to extend the range is

$$R = R_m (n - 1)$$

where

$R_m$  = total resistance of the instrument

$n$  = factor by which the scale is to be multiplied

For example, if a 1-kΩ-per-volt voltmeter

having a calibrated range of 0-10 volts is to be extended to 1000 volts,  $R_m$  is  $1000 \times 10 = 10 \text{ k}\Omega$ ,  $n$  is  $1000/10 = 100$ , and  $R = 10,000 (100 - 1) = 990 \text{ k}\Omega$ .

When extending the range of a voltmeter or converting a low-range meter into a voltmeter, the rated accuracy of the instrument is retained only when the multiplier resistance is precise. Precision wire-wound resistors are used in the multipliers of high-quality instruments. These are relatively expensive, but the home constructor can do quite well with 1-percent-tolerance composition resistors. They should be derated when used for this purpose—that is, the actual power dissipated in the resistor should not be more than  $\frac{1}{4}$  to  $\frac{1}{2}$  the rated dissipation—and care should be used to avoid overheating the body of the resistor when soldering to the leads. These precautions will help prevent permanent change in the resistance of the unit.

Ordinary composition resistors are generally furnished in 10- or 5-percent-tolerance ratings. If possible errors of this order can be accepted, resistors of this type may be used as multipliers. They should be operated below the rated power dissipation figure, in the interest of long-term stability.

## DC MEASUREMENT CIRCUITS

### The Voltmeter

A current-measuring instrument should have very low resistance compared with the resistance of the circuit being measured; otherwise, inserting the instrument will cause the current to differ from its value with the instrument out of the circuit. The resistance of many circuits in radio equipment is high and the circuit operation is affected little, if at all, by adding as much as a few hundred ohms in series. In such cases the voltmeter method of measuring current, shown in Fig 5, is frequently convenient. A voltmeter (or low-range milliammeter provided with a multiplier and operating as a voltmeter) having a full-scale voltage range of a few volts is used to measure the voltage drop across a suitable value of resistance acting as a shunt.

The value of shunt resistance must be calculated from the known or estimated maximum current expected in the circuit (allowing a safe margin) and the voltage required for full-scale deflection of the meter with its multiplier.

### Power

Power in direct-current circuits is determined by measuring the current and voltage. When these are known, the power is equal to the voltage in volts multiplied by the current in amperes. If the current is measured with a milliammeter, the reading of the instrument must be divided by 1000 to convert it to amperes.

The setup for measuring power is shown in Fig 6, where  $R$  is any dc load, not necessarily an actual resistor.

## Resistance

Obviously, if both voltage and current are measured in a circuit such as that in Fig 6, the value of resistance  $R$  (in case it is unknown) can be calculated from Ohm's Law. For accurate results, the internal resistance of the ammeter or milliammeter,  $mA$ , should be very low compared with the resistance,  $R$ , being measured. This is because the voltage read by the voltmeter,  $V$ , is the voltage across  $mA$  and  $R$  in series. The instruments and the dc voltage should be chosen so that readings are in the upper half of the scale, if possible, since the percentage error is less in this region.

### The Ohmmeter

Although Fig 6 suffices for occasional resistance measurements, it is inconvenient when frequent measurements over a wide range of resistance are to be made. The device generally used for this purpose is the ohmmeter. This consists fundamentally of a voltmeter (or milliammeter, depending on the circuit used) and a small battery, the meter being calibrated so the value of an unknown resistance can be read directly from the scale. Typical ohmmeter circuits are shown in Fig 7. In the simplest type, Fig 7A, the meter and battery are connected in series with the unknown resistance. If a given deflection is obtained with terminals A-B shorted, inserting the resistance to be measured will cause the meter reading to decrease. When the resistance of the voltmeter is known, the following formula can be applied.

$$R = \frac{eR_m}{E} - R_m$$

where

$R$  = resistance to be found

$e$  = voltage applied (A-B shorted)

$E$  = voltmeter reading with  $R$  connected, and

$R_m$  = resistance of the voltmeter.

The circuit of Fig 7A is not suited to measuring low values of resistance (below a hundred ohms or so) with a high-resistance voltmeter. For such measurements the circuit of Fig 7B can be used. The unknown resistance is

$$R = \frac{I_2 R_m}{I_1 - I_2}$$

where

$R$  = the unknown resistance

$R_m$  = the internal resistance of the milliammeter

$I_1$  = current with  $R$  disconnected from terminals A-B

$I_2$  = current with  $R$  connected

The formula is based on the assumption that the current in the complete circuit will be essentially constant whether or not the

Fig 7—Ohmmeter circuits. Values are discussed in the text.

Fig 5—Voltmeter method of measuring current. This method permits using relatively large values of resistance in the shunt, standard values of fixed resistors frequently being usable. If the multiplier resistance is 20 (or more) times the shunt resistance, the error in assuming that all the current flows through the shunt will not be of consequence in most practical applications.

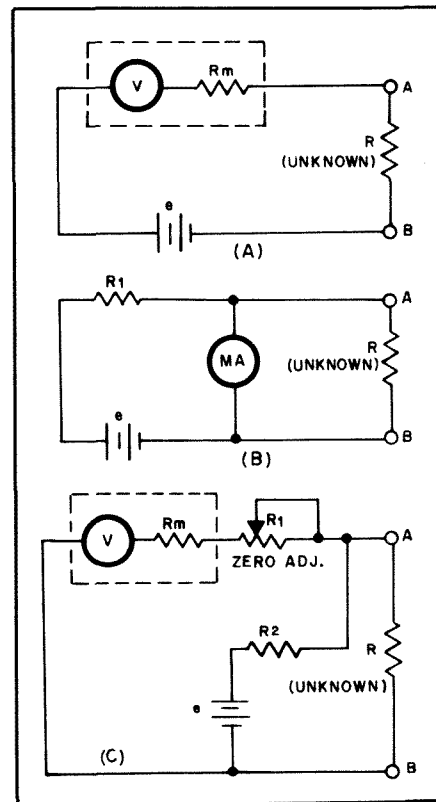

Fig 6—Measurement of power requires both current and voltage measurements; once these values are known, the power is equal to the product  $P = EI$ . The same circuit can be used for measurement of an unknown resistance.

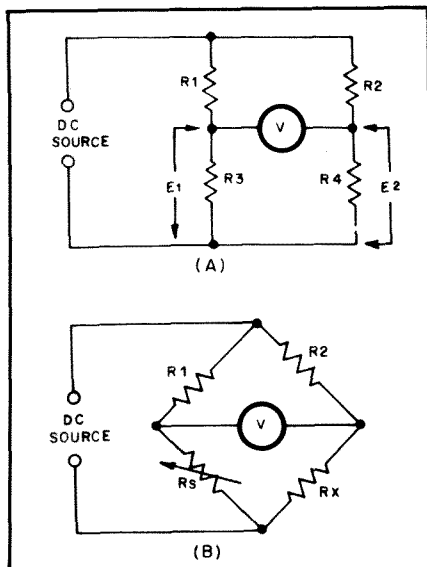

Fig 8—The Wheatstone bridge circuit. It is frequently drawn as at B for emphasizing its special function.

**unknown** terminals are short-circuited. This requires that  $R_1$  be very large compared with  $R_m$ , e.g., 3000 ohms for a 1-mA meter having an internal resistance of perhaps 50 ohms. A 3-volt battery would be necessary in this case in order to obtain a full-scale deflection with the **unknown** terminals open.  $R_1$  can be an adjustable resistor, to permit setting the open-terminal current to exact full scale.

A third circuit for measuring resistance

Fig 9—The IC voltmeter mounted in a small plastic case. This basic instrument measures only dc voltages, but with an RF probe as described later in this chapter, it can be used for RF measurements as well. It may also be used for resistance measurements, by using techniques described in the previous section. DS1, mounted between the binding posts, is a power-on indicator.

is shown in Fig 7C. In this case a high-resistance voltmeter is used to measure the voltage drop across a reference resistor,  $R_2$ , when the unknown resistor is connected so that current flows through it,  $R_2$  and the battery in series. By suitable choice of  $R_2$  (low values for low-resistance, high values for high-resistance unknowns), this circuit will give equally good results on all resistance values in the range from one ohm to several megohms. That is provided that the voltmeter resistance,  $R_m$ , is always very high (50 times or more) compared with the resistance of  $R_2$ . A 20-k $\Omega$ -per-volt instrument (50- $\mu$ A movement) is generally used. Assuming that the current through

the voltmeter is negligible compared with the current through  $R_2$ , the formula for the unknown is

$$R = \frac{eR_2}{E} - R_2$$

where

$R$  and  $R_2$  are shown in Fig 7C

$e$  = the voltmeter reading with A-B open circuited

$E$  = voltmeter reading with  $R$  connected.

The zero adjuster,  $R_1$ , is used to set the voltmeter reading exactly to full scale when the meter is calibrated in ohms. A 10-k $\Omega$  variable resistor is suitable with a 20-k $\Omega$ -per-volt meter. The battery voltage is usually 3 volts for ranges up to 100 k $\Omega$  or so and 6 volts for higher ranges.

### Bridge Circuits

An important class of measurement circuits is the bridge. A desired result is obtained by balancing the voltages at two different points in the circuit against each other so there is zero potential difference between them. A voltmeter bridged between the two points will read zero (null) when this balance exists, but will indicate some definite value of voltage when the bridge is not balanced.

Bridge circuits are useful both on direct current and on ac of all frequencies. The majority of amateur applications are at radio frequencies, as shown later in this chapter. However, the principles of bridge operation are most easily introduced in

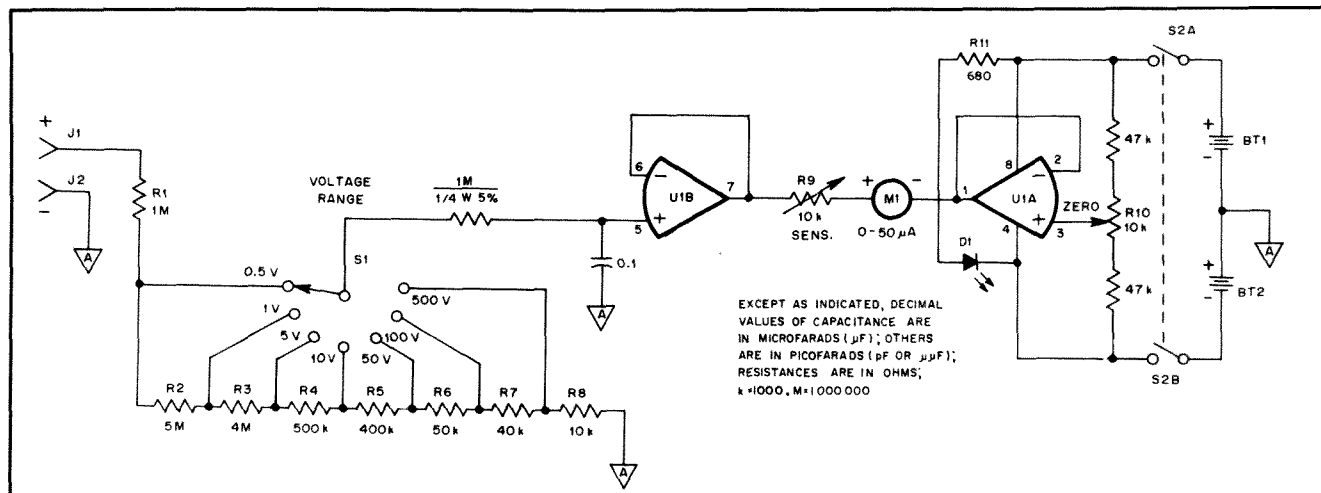

Fig 10—A high impedance voltmeter need not be complex. This circuit uses a single IC. BT1 and BT2 can be 2 AAA (or AA) cells in a holder or 9-V transistor radio batteries (see text).

terms of dc, where the bridge takes its simplest form.

### The Wheatstone Bridge

The simple resistance bridge, known as the Wheatstone bridge, is shown in Fig 8. All other bridge circuits—some of which are rather elaborate, especially those designed for ac—derive from this. The four resistors, R1, R2, R3 and R4 shown in A, are known as the bridge arms. For the voltmeter reading to be zero, the voltages across R3 and R4 in series must add algebraically to zero; that is, E1 must equal E2. R1 with R3 and R2 with R4 form voltage dividers across the dc source, so if

$$\frac{R1}{R3} = \frac{R2}{R4} \quad \text{then}$$

$$E1 = E2$$

The circuit is customarily drawn as shown at Fig 8B when used for resistance measurement. The equation above can be rewritten

$$R_x = R_s \frac{R2}{R1}$$

to find  $R_x$ , the unknown resistance. R1 and R2 are frequently made equal; then the calibrated adjustable resistance (the standard),  $R_s$ , will have the same value as  $R_x$  when  $R_s$  is set to show a null on the voltmeter.

Note that the resistance *ratios*, rather than the actual resistance values, determine the voltage balance. However, the values do have important practical effects on the sensitivity and power consumption. The bridge sensitivity is the readiness with which the meter responds to small amounts of unbalance about the null point; the sharper the null the more accurate the setting of  $R_s$  at balance.

The Wheatstone bridge is rarely used by amateurs for resistance measurement, the ohmmeter being the favorite instrument for that purpose. However, it is worthwhile to understand its operation because it is the basis of more complex bridges.

### Electronic Voltmeters

It has been pointed out that for many purposes the resistance of a voltmeter must be extremely high in order to avoid "loading" errors caused by the current that necessarily flows through the meter. The use of high-resistance meters tends to cause difficulty in measuring relatively low voltages (under perhaps 1000 volts) because progressively smaller multiplier resistance is needed as the voltage range is lowered.

The voltmeter resistance can be made independent of the voltage range by using vacuum tubes or field-effect transistors as electronic dc amplifiers between the circuit being measured and the indicator, which may be a conventional meter movement or a digital display. As the input resistance of the electronic devices is extremely high—hundreds of megohms—they have essen-

tially no loading effect on the circuit to which they are connected. They do, however, require a closed dc path in their input circuits (although this path can have very high resistance). They are also limited in the amplitude of voltage that their input circuits can handle. Because of this, the device actually measures a small voltage across a portion of a high-resistance voltage divider connected to the circuit being measured. Various voltage ranges are obtained by appropriate taps on the voltage divider.

In the design of electronic voltmeters it has become standard practice to use a voltage divider having a resistance of 10 megohms, tapped as required, in series with a 1-megohm resistor incorporated in the meter. The total voltmeter resistance, including probe, is therefore 11 megohms. The 1-megohm resistor serves to isolate the voltmeter circuit from the active circuit.

### Hybrid Digital Meters

Over the years since digital meters (DMMs) came in to the price range of experimenters, the one argument against DMMs has been the lack of a facility for peaking and nulling circuits. The conversion and display times of most digital meters are slow enough that slight peaks and dips are almost impossible to observe without going to ridiculous extremes. Because of this, most experimenters still have a good old VOM or VTVM on the bench. In the past few years, manufacturers have taken various steps to make the digital meter more attractive to the user who needs peaking and nulling facilities. Three approaches have come into use:

- 1) Putting a small analog meter on the front panel of the DMM to give trends indication. This meter tends to be coarsely calibrated. This method allows the user to see the peaks and nulls and still have the accuracy of the digital display available in one package. Examples of this type of meter are the Heath IM-2264 and the Simpson 460-3.

- 2) Addition of a bar graph on the display. This bar graph usually takes the form of 20 to 40 dots in a row which are lit in proportion to the percentage of the range that is inputted. For example, if the meter had a 2-V range and a 20-dot bar graph, a dot would light for every 0.1-V increase. So if this meter has an input of 0.6 V on its leads, the six left-hand dots would light. This may seem a bit coarse, but it is useful in practice. Examples of this type of meter are the Fluke 70 series (sold by Heath as the SM77) and the Simpson 467.

- 3) The third method is using peak and null LEDs. In this case, there are two LEDs: one is for peaking and one is for nulling. As a signal is peaked, the peaking LED will glow brighter. When the peak occurs, both LEDs will glow equally. As the peak is passed, the null LED will brighten. This is probably the most difficult to interpret of the three methods. An

example of this type of meter is the Sencore DVM56A.

The individual will have to decide which method best suits his or her personal taste and budget, when selecting this type of meter. But, with the steady improvement in measurement technology, the day may not be far off when mechanical meter movements may completely disappear from electrical and electronic applications.

### AN IC VOLTMETER

One of the fundamental troubleshooting techniques is to check the voltage present at various points in the circuit. The measured voltage is compared with the voltage we expect to find at that point. Knowing what to expect is important. If we don't have some idea of what the voltage should be, measuring it won't tell us very much. Often the voltages we measure in a circuit will not agree exactly with our expected values. Small variations are normal and do not mean the circuit is not operating as it should. Component tolerance and meter errors are the primary causes for these variations.

Shown in Figs 9 through 12 is an easy-to-build, high-impedance dc voltmeter, first described by George Collins, KC1V, in January 1982 *QST*. All of the parts for the voltmeter are readily available. Calibration is simple and the cost is low. Construction of this meter can be considered as an easy weekend project. The input-impedance is 11 MΩ, and accuracy is better than 15%. With the RF probe shown later in this chapter, this meter can be used to make reasonably accurate RF voltage measurements at frequencies up to 30 MHz.

### Circuit Details

The input impedance of the meter is determined by the total resistance of the range-selector voltage divider (R1 through R8). The values of the individual resistors have been selected to provide the desired full-scale voltage ranges and a total resistance of 11 MΩ. Some of the resistance values needed for the divider are not found in the standard series of 5%-tolerance resistor values. To avoid having to buy expensive (and hard to find) 1% resistors, two 5% units are used in series for each of the nonstandard values.

To keep the meter movement from loading the 11-MΩ divider, an operational amplifier (op amp) with JFET inputs is used to drive the meter. The LF353N IC (U1) contains two of these op amps in the same package. U1B drives the meter movement, while U1A serves as an adjustable voltage reference point. Both of the op amps are connected as voltage followers. This means that the input and output voltages are the same (a gain of 1). What makes the voltage follower useful is that the output can supply several milliamperes of current while the input draws a very small current (the input impedance is high).

Fig 11—Inside view of the IC voltmeter. This version was built from an available parts kit. Other components and construction styles can be used as well.

By varying the voltage at pin 3 of U1 with R10, the zero setting of the meter can be adjusted to compensate for changes in battery voltage and room temperature. The fact that both op amps are in the same package helps reduce drift caused by temperature changes. R10 is mounted on the front panel so the operator can adjust it easily. R9 is the calibration control; it adjusts the meter sensitivity. R9 does not require frequent adjustment, so it is mounted inside the case.

Two batteries are used to power the meter circuit. Any battery potential between 3 and 9 V can be used without changes in the circuit. In the unit shown, four AAA penlight cells are used. These give the needed 3 V and have long life. Two 9-V transistor radio batteries will also be suitable.

### Construction

Almost any type of case can be used to house the voltmeter. The exact size needed will depend on the dimensions of the batteries, meter movement and switches used. A plastic case, only  $2\frac{7}{8} \times 4 \times 1\frac{5}{8}$  inches, houses the meter shown in the photographs. If a larger meter movement is used, an enclosure measuring  $2\frac{5}{8} \times 5\frac{1}{6} \times 1\frac{5}{8}$  inches will be more satis-

factory. If you use a case with a metal panel, it is best if the negative jack (J2) is not connected to the panel. This permits voltage measurements below ground potential without having a voltage on the meter case.

The voltage-divider resistors are mounted on the range selector switch S1, as shown in Fig 11. If the switch has any spare lugs, they can be used as tie points for the series-connected resistors. If no lugs are available, simply solder the leads together; the remaining leads will support the resistors. The other components can be mounted on a small printed-circuit board,\* although any method of wiring can be used. A quick and simple way of wiring the IC is to use a general-purpose IC-prototyping board, such as the Radio Shack 276-159.

The builder should be aware that very minute leakage currents between pins of the op-amp IC can cause improper operation

\*A printed-circuit board and parts for the voltmeter, including a small circuit board for an RF probe, are available from Circuit Board Specialists, P.O. Box 951, Pueblo, CO 81002-0951.

Fig 12—Parts-placement guide for the FET voltmeter. Parts are placed on the nonfoil side of the board; the shaded area represents an X-ray view of the copper pattern. A full-size etching pattern can be found at the back of this book.

of the instrument. If a circuit board is used, be sure to clean the rosin flux from around these pins after soldering is completed. Use a suitable solvent, such as denatured alcohol. Further, the circuit board should not be allowed to rest on any type of supporting material; even nonconducting foam may yield unexpected results.

With the resistor values shown in Fig 10, the highest full-scale range is 500 V. If this range is included, be sure the input connectors (J1 and J2) and the range switch (S1) are rated for 500 V or more. J1 and J2 should also be able to handle 500 volts safely. Only thin, fiber washers are used to insulate some type of jacks from the panel. These are fine for up to 100 V, but are not recommended for higher voltages. If the 500-V range is not needed, R7 and R8 can be connected in series or replaced by a 50-k $\Omega$  resistor (the same as R6).

### Calibration

Only the sensitivity control, R9, needs to be adjusted before the meter can be used. A good method of calibration is to use two fresh carbon-zinc batteries in series to form a source of known potential. Each cell, when new, should produce 1.54 V. To adjust R9, turn the meter on, and set it to the 5-V range. With the meter leads shorted together, adjust the zero control (R10) so that the meter shows zero. Connect the two cells to the meter, and adjust R9 so the meter reads 3.1 V. This completes the voltmeter, and it is ready to use.

# AC Instruments and Circuits

Although purely electromagnetic instruments that operate directly from alternating current are available, they are seen infrequently in present-day amateur equipment. For one thing, their use is not feasible above power-line frequencies.

Common instruments for audio and radio frequencies generally use a dc meter movement in conjunction with a rectifier. Voltage measurements suffice for nearly all test purposes. Current, as such, is seldom measured in the AF range. When RF current is measured the instrument used is a thermocouple milliammeter or ammeter.

## The Thermocouple Meter

In a thermocouple meter the alternating current flows through a low-resistance heating element. The power lost in the resistance generates heat that warms a thermocouple, a junction of certain dissimilar metals that has the property of developing a small dc voltage when heated. This voltage is applied to a dc milliammeter calibrated in suitable ac units. The heater-thermocouple-dc meter combination is usually housed in a regular meter case.

Thermocouple meters can be obtained in ranges from about 100 mA to many amperes. Their useful upper frequency limit is in the neighborhood of 100 MHz. Their principal value in amateur work is in measuring current into a known load resistance for calculating the RF power delivered to the load.

## Rectifier Instruments

The response of a rectifier-type meter is proportional (depending on the design) to either the peak amplitude or average amplitude of the rectified ac wave, and never directly responsive to the RMS value. The meter therefore cannot be calibrated in RMS without preknowledge of the relationship that happens to exist between the real reading and the RMS value. This relationship, in general, is not known, except in the case of single-frequency ac (a sine wave). Many practical measurements involve nonsinusoidal wave forms, so it is necessary to know what kind of instrument you have, and what it is actually reading, in order to make measurements intelligently.

### Peak and Average with Sine-Wave Rectification

Fig 13 shows the relative peak and average values in the output of half- and full-wave rectifiers (see Chapter 6 for further details). As the positive and negative half cycles of the sine wave have the same shape, A, half-wave rectification of either the positive half, B or the negative half, C, gives exactly the same result. With full-wave rectification, D, the peak is still the same, but the average is doubled, since

Fig 13—Sine-wave alternating current or voltage, A, with half-wave rectification of the positive half cycle, B, and negative half cycle, C. At D—full-wave rectification. Average values are shown with relation to a peak value of 1.

there are twice as many half cycles per unit of time.

## Unsymmetrical Wave Forms

A nonsinusoidal waveform is shown in Fig 14A. When the positive half cycles of this wave are rectified, the peak and average values are shown at B. If the polarity is reversed and the negative half cycles are rectified, the peak value is different but the average value is unchanged. The fact that the average of the positive side is equal to the average of the negative side is true of all ac waveforms, but different waveforms have different averages. Full-wave rectification of such a lopsided wave doubles the average value, but the peak reading is always the same as it is with the half cycle that produces the highest peak in half-wave rectification.

## Effective-Value Calibration

The actual scale calibration of commercially made rectifier-type voltmeters is very often (almost always, in fact) in terms of RMS values. For sine waves this is satisfactory, and useful since RMS is the standard measure at power-line frequency. It is also useful for many RF applications where the waveform is often close to sinusoidal. But in other cases, particularly in the AF range, the error may be considerable when the waveform is not pure.

## Turn-Over

From Fig 14 it is apparent that the calibration of an average-reading meter will

Fig 14—Same as Fig 13 for an unsymmetrical waveform. The peak values are different with positive and negative half-cycle rectification.

be the same whether the positive or negative sides are rectified. A half-wave peak-reading instrument, however, will indicate different values when its connections to the circuit are reversed (turn-over effect). Very often readings are taken both ways, in which case the sum of the two is the peak-to-peak (P-P) value, a useful figure in much audio and video work.

## Average- and Peak-Reading Circuits

The basic difference between average- and peak-reading rectifier circuits is that the output is not filtered for averaged readings, while a filter capacitor is charged up to the peak value of the output voltage for measuring peaks. Fig 15A shows typical average-reading circuits, one half-wave and the other full-wave. In the absence of dc filtering the meter responds to wave forms such as are shown at B, C and D in Figs. 14 and 15, and since the inertia of the pointer system makes it unable to follow the rapid variations in current, it averages them out mechanically.

In Fig 15A, D1 actuates the meter; D2 provides a low-resistance dc return in the meter circuit on the negative half cycles. R1 is the voltmeter multiplier resistance. R2 forms a voltage divider with R1 (through D1), which prevents more than a few ac volts from appearing across the rectifier-meter combination. A corresponding resistor can be used across the full-wave bridge circuit.

In these two circuits no provision is made for isolating the meter from any dc voltage that may be on the circuit under measurement. The error caused by this can be avoided by connecting a large capacitor (not electrolytic!) in series with the hot lead. The reactance must be low compared with the meter impedance (see next section) in order for the full ac voltage to be applied

Fig 15—At A, half-wave and full-wave rectification for an instrument intended to operate on average values. At B, half-wave circuits for a peak-reading meter.

to the meter circuit. As much as  $1\ \mu\text{F}$  may be required at line frequencies with some meters. The capacitor is not usually included in a VOM.

Series and shunt peak-reading circuits are shown in Fig 15B.  $C_1$  isolates the rectifier from dc voltage on the circuit under measurement. In the series circuit (which is seldom used) the time constant of the  $C_2$ - $R_1$ - $R_2$  combination must be very large compared with the period of the lowest ac frequency to be measured; similarly with  $C_1$ - $R_1$ - $R_2$  in the shunt circuit. The reason is that the capacitor is charged to the peak value of voltage when the ac wave reaches its maximum, and then must hold the charge (so it can register on a dc meter) until the next maximum of the same polarity. If the time constant is 20 times the ac period, the charge will have decreased by about five percent by the time the next charge occurs. The average drop will be smaller, so the error is appreciably less. The error will decrease rapidly with increasing frequency, assuming no change in the circuit values, but will increase at lower frequencies.

In Fig 15B,  $R_1$  and  $R_2$  form a voltage divider that reduces the peak dc voltage to 71 percent of its actual value. This converts the peak reading to RMS on sine-wave ac. Since the peak-reading circuits are incapable of delivering appreciable current without considerable error,  $R_2$  is usually the 11-megohm input resistance of an electronic voltmeter.  $R_1$  is therefore approximately 4.7 megohms, making the total resistance approach 16 megohms. A capacitance of  $0.05\ \mu\text{F}$  is sufficient for low audio frequencies under these conditions. Much smaller values of capacitance suffice for radio frequencies, obviously.

#### Voltmeter Impedance

The impedance of the voltmeter at the frequency being measured may have an effect on the accuracy similar to the error

caused by the resistance of a dc voltmeter, as discussed earlier. The ac meter acts like a resistance in parallel with a capacitance, and since the capacitive reactance decreases with increasing frequency, the impedance also decreases with frequency. The resistance is subject to some variation with voltage level, particularly at very low voltages (on the order of 10 volts or less) depending on the sensitivity of the meter movement and the kind of rectifier used.

The ac load resistance represented by a diode rectifier is approximately equal to one-half its dc load resistance. In Fig 15A the dc load is essentially the meter resistance, which is generally quite low compared with the multiplier resistance  $R_1$ , so the total resistance will be about the same as the multiplier resistance. The capacitance depends on the components and construction, test lead length and disposition, and other such factors. In general, it has little or no effect at lower line and low audio frequencies, but the ordinary VOM loses accuracy at the high audio frequencies and is of little use at RF. For radio frequencies it is necessary to use a rectifier having very low inherent capacitance.

Similar limitations apply to the peak-reading circuits. In the parallel circuit the resistive component of the impedance is smaller than in the series circuit because the dc load resistance,  $R_1/R_2$ , is directly across the circuit being measured, and is therefore in parallel with the diode ac load resistance. In both peak-reading circuits the effective capacitance may range from 1 or 2 to a few hundred picofarads. Values of the order of 100 pF are to be expected in electronic voltmeters of customary design and construction.

#### Linearity

Fig 16, a typical current/voltage characteristic of a small semiconductor rectifier, indicates that the forward dynamic

Fig 16—Typical semiconductor diode characteristic. Actual current and voltage values vary with the type of diode, but the forward-current curve would be in its steep part with only a volt or so applied. Note the change in the current scale for reverse current. Breakdown voltage, again depending on diode type, may range from 15 or 20 volts to several hundred.

resistance of the diode is not constant, but rapidly decreases as the forward voltage is increased from zero. The transition from high to low resistance occurs at considerably less than 1 volt, but is in the range of voltage required by the associated dc meter. With an average-reading circuit the current tends to be proportional to the square of the applied voltage. This crowds the calibration points at the low end of the meter scale. For most measurement purposes, however, it is far more desirable for the output to be linear; that is, for the reading to be directly proportional to the applied voltage.

To obtain linearity it is necessary to use a relatively large load resistance for the diode—large enough so this resistance, rather than the diode's own resistance, will govern the current flow. A linear or equally spaced scale is thus gained at the expense of sensitivity. The amount of resistance needed depends on the type of diode; 5000 to 50,000 ohms usually suffices for a germanium rectifier, depending on the dc meter sensitivity, but several times as much may be needed for silicon. The higher the resistance, the greater the meter sensitivity required; i.e., the basic meter must be a microammeter rather than a low-range milliammeter.

#### Reverse Current

When voltage is applied in the reverse direction there is a small leakage current in semiconductor diodes. This is equivalent to a resistance connected across the rectifier, allowing current to flow during the half cycle that should be completely non-conducting and causing an error in the dc meter reading. This back resistance is so high as to be practically unimportant with silicon diodes, but may be less than 100 k $\Omega$  with germanium.

The practical effect of semiconductor back resistance is to limit the amount of resistance than can be used in the dc load. This in turn affects the linearity of the

Fig 17—RF probe for use with an electronic voltmeter. The case of the probe is constructed from a seven-pin ceramic tube socket and a 2¼-inch tube shield. A half-inch grommet at the top of the tube shield prevents the output lead from chafing. A flexible copper-braid grounding lead and alligator clip provide a low-inductance return path from the test circuit.

meter scale. The back resistance of vacuum-tube diodes is infinite, for practical purposes.

#### RF Voltage

Special precautions must be taken to minimize the capacitive component of the voltmeter impedance at radio frequencies. If possible, the rectifier circuit should be installed permanently at the point where the RF voltage is to be measured, using the shortest possible RF connections. The dc meter can be remotely located, however.

For general RF measurements an RF probe is used in conjunction with an 11-M $\Omega$  electronic voltmeter, substituted for the dc probe mentioned earlier. The circuit of Fig 18, essentially the peak-reading shunt circuit of Fig 15B, is generally used. The series resistor, installed in the probe close to the rectifier, prevents RF from being fed through the probe cable to the electronic voltmeter. RF is further reduced from reaching the voltmeter by the cable capacitance. This resistor, in conjunction with the 10-M $\Omega$  divider resistance of the electronic voltmeter, also reduces the peak rectified voltage to a dc value equivalent to the RMS of the RF signal, to make the RF readings consistent with the regular dc calibration.

Of the diodes readily available to amateurs, the germanium point-contact or Schottky type is preferred for RF applications. It has low capacitance (on the

order of 1 pF) and in the high-back-resistance types the reverse current is not serious. The principal limitation is that its safe reverse voltage is only about 50-75 volts, which limits the RMS applied voltage to 15 or 20 volts. Diodes can be connected in series to raise the overall rating.

Fig 19—Inside the probe. The 1N34A diode, calibration resistor and input capacitor are mounted tight to the terminal strip with the shortest possible leads. Spaghetti tubing is placed on the diode leads to prevent accidental short circuits. The tube-shield spring and flexible copper grounding lead are soldered to the cable braid (the cable is RG-58 coax). The tip can be either a phone tip or a short pointed piece of stiff wire.

#### AN RF PROBE FOR ELECTRONIC VOLTMETERS

The isolation capacitor, C1, crystal diode and filter/divider resistor are mounted on a bakelite five-lug terminal strip, as shown in Fig 20. One end lug should be rotated 90 degrees so it extends off the end of the strip. All other lugs should be cut off flush with the edge of the strip. Where the inner conductor connects to the terminal lug, unravel the shield three-quarters of an inch, slip a piece of spaghetti tubing over it and then solder the braid to the ground lug on the terminal strip. Remove the spring from the tube shield, slide it over the cable, and crimp it to the remaining quarter inch of shield braid. Solder both the spring and a 12-inch length of flexible copper braid to the shield.

Fig 20—Component mounting details.

Next, cut off the pins on a seven-pin miniature shield-base tube socket. Use a socket with a cylindrical center post. Crimp the terminal lug previously bent out at the end of the strip and insert it into the center post of the tube socket from the top. Insert the end of a phone tip or a pointed piece of heavy wire into the bottom of the tube

socket center post, and solder the lug and tip to the center post. Insert a half-inch grommet at the top of the tube shield, sliding it over the cable and flexible braid down into the tube socket. The spring should make good contact with the tube shield to assure that the tube shield (probe case) is grounded. Solder an alligator clip to the other end of the flexible braid and mount a phone plug on the free end of the shielded wire.

Mount components close to the terminal strip, to keep lead lengths as short as possible and minimize stray capacitance. Use spaghetti tubing over all wires to prevent accidental shorts.

The phone plug on the probe cable plugs into the dc input jack of the electronic voltmeter and RMS voltages are read on the voltmeter negative dc scale.

The accuracy of the probe is within  $\pm 10$  percent from 50 kHz to 250 MHz. The approximate input impedance is 6000 ohms shunted by 1.75 pF (at 200 MHz).

#### RF Power

Power at radio frequencies can be measured by means of an accurately calibrated RF voltmeter connected across the load in which the power is being dissipated. If the load is a known pure resistance, the power, by Ohm's Law, is equal to  $E^2/R$ , where E is the RMS value of the voltage.

If the load is not a pure resistance, the above method indicates only apparent power. The load can be a terminated transmission line, tuned with the aid of bridge circuits such as are described in the next section to act as a known resistance. An alternative load is a dummy antenna, a known pure resistance capable of dissipating the RF power safely.

#### AC Bridges

In its simplest form, the ac bridge is exactly the same as the Wheatstone bridge discussed earlier. However, complex impedances can be substituted for resistances, as suggested by Fig 21A. The same bridge equation holds if Z is substituted for R in each arm. For the equation to be true, however, the phase angles as well as the numerical values of the impedances must balance; otherwise, a true null voltage is impossible to obtain. This means that a bridge with all "pure" arms (pure resistance or reactance) cannot measure complex impedances; a combination of R and X must be present in at least one arm aside from the unknown.

The actual circuits of ac bridges take many forms, depending on the type of measurement intended and on the frequency range to be covered. As the frequency is raised, stray effects (unwanted capacitances and inductances) become more pronounced. At radio frequencies, special attention must be paid to minimizing them.

Most amateur-built bridges are used for

Fig 18—The RF probe circuit.

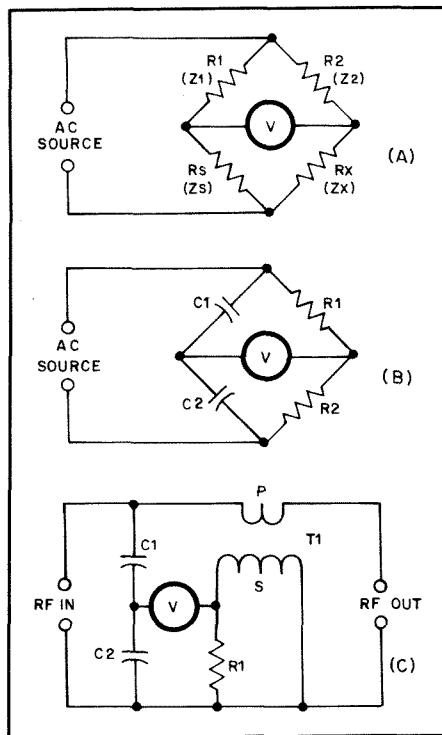

Fig 21—(A) Generalized form of bridge circuit for either ac or dc. (B) One form of ac bridge frequently used for RF measurements. (C) SWR bridge for use in transmission lines. This circuit is often calibrated in watts rather than volts.

RF measurements, especially SWR measurements on transmission lines. The circuits at Fig 21B and C are favorites for this purpose.

Fig 21B is useful for measuring both transmission lines and lumped constant components. Combinations of resistance and capacitance are often used in one or more arms; this may be required for eliminating the effects of stray capacitance.

The bridge shown in Fig 21C is used only on transmission lines, and only on those lines having the characteristic impedance for which the bridge is designed.

#### SWR Measurement—the Reflectometer

In measuring the standing-wave ratio, advantage is taken of the fact that the voltage on a transmission line consists of two components traveling in opposite directions. The power going from the transmitter to the load is represented by one voltage (designated incident or forward) and the power reflected from the load by the other. Because the relative amplitudes and phase relationships are definitely established by the line's characteristic

impedance, its length and the load impedance in which it is terminated, a bridge circuit can separate the incident and reflected voltages for measurement. This is sufficient for determining the SWR. Bridges designed for this purpose are frequently called reflectometers.

Refer to Fig 21A. If R1 and R2 are made equal, the bridge will be balanced when  $R_x = R_s$ . This is true whether  $R_x$  is an actual resistor or the input resistance of a perfectly matched transmission line, provided  $R_s$  is chosen to equal the characteristic impedance of the line. Even if the line is not properly matched, the bridge will still be balanced for power traveling outward on the line, since outward-going power sees only the  $Z_0$  of the line until it reaches the load. However, power reflected back from the load does not see a bridge circuit, and the reflected voltage registers on the voltmeter. From the known relationship between the incident and reflected voltages the SWR is easily calculated:

$$SWR = \frac{V_o + V_r}{V_o - V_r}$$

where

$V_o$  = incident voltage

$V_r$  = reflected voltage

#### The Reflected Power Meter

Fig 21C makes use of mutual inductance between the primary and secondary of T1 to establish a balancing circuit. C1 and C2 form a voltage divider in which the voltage across C2 is in the same phase as the voltage at that point on the transmission line. The relative phase of the voltage across R1 is determined by the phase of the current in the line. If a pure resistance equal to the design impedance of the bridge is connected to the RF OUT terminals, the voltages across R1 and C2 will be out of phase and the voltmeter reading will be minimum. If the amplitudes of the two voltages are also equal (they are made so by bridge adjustment) the voltmeter will read zero. Any other value of resistance or impedance connected to the RF OUT terminals will result in a finite voltmeter reading. When used in a transmission line this reading is proportional to the reflected voltage. To measure the incident voltage, the secondary terminals of T1 should be reversed. To function as described, the secondary-winding reactance of T1 must be very large compared to the resistance of R1.

Instruments of this type are usually designed for convenient switching between forward and reflected power, and are often calibrated to read watts in the specified characteristic impedance. As the power

calibration is made at an SWR of 1:1, the actual power transmitted to the load must be calculated from the difference between the forward and reflected readings when the SWR is other than 1:1. A reading of 400 watts forward and 300 watts reflected means that  $400\text{ W} - 300\text{ W} = 100\text{ W}$  has been delivered to the load. The SWR can be calculated from the formula

$$SWR = \frac{1 + \sqrt{\frac{\text{reflected power}}{\text{forward power}}}}{1 - \sqrt{\frac{\text{reflected power}}{\text{forward power}}}}$$

$$SWR = \frac{1 + \sqrt{\frac{300}{400}}}{1 - \sqrt{\frac{300}{400}}} = 13.9$$

Both of these calculations assume that the loss in the transmission line is very small; information on correcting for line loss is given in Chapter 16.

#### Sensitivity and Frequency

In all of the circuits in Fig 21 the sensitivity is independent of the applied frequency, within practical limits. Stray capacitances and couplings generally limit the performance of all three at the high-frequency end of the useful range. Fig 21A will work right down to dc, but the low-frequency performance of Fig 21B is degraded when the capacitive reactances become so large that voltmeter impedance becomes low in comparison. (In all these bridge circuits, it is assumed that the voltmeter impedance is high compared with the impedance of the bridge arms.) In Fig 21C the performance is limited at low frequencies by the fact that the transformer reactance decreases with frequency, so that eventually the reactance is not very high in comparison with the resistance of R1.

#### The Monimatch

A type of bridge that is simple to make, but in which the sensitivity rises directly with frequency, is the Monimatch and its various offspring. The circuit cannot be described in terms of lumped constants, as it makes use of the distributed mutual inductance and capacitance between the center conductor of a transmission line and a wire placed parallel to it. The wire is terminated in a resistance approximating the characteristic impedance of the transmission line at one end and feeds a diode rectifier at the other.

# Frequency Measurement

The regulations governing amateur operation require that the transmitted signal be maintained inside the limits of certain bands of frequencies.<sup>1</sup> The exact frequency need not be known, as long as it is not outside the limits. On this last point there are no tolerances: It is up to the individual amateur to see that he stays safely inside.

This is not difficult to do, but requires some simple apparatus and the exercise of some care. The apparatus commonly used is the frequency-marker generator, and the method involves use of the station receiver, as shown in Fig 22.

Fig 22—Setup for using a frequency standard. It is necessary that the transmitter signal be weak in the receiver—of the same order of strength as the marker signal from the standard. This requirement can usually be met by turning on just the transmitter oscillator, leaving all power off any succeeding stages. In some cases it may also be necessary to disconnect the antenna from the receiver.

## The Frequency Marker

The marker generator in its simplest form is a high-stability oscillator generating a series of signals which, when detected in the receiver, mark the exact edges of the amateur assignments. It does this by oscillating at a low frequency that has harmonics falling on the desired frequencies.

Most US amateur band limits are exact multiples of 25 kHz, whether at the extremes of a band or at points marking the subdivisions between types of emission, license privileges, and so on. A 25-kHz fundamental frequency therefore will produce the desired marker signals if its harmonics at the higher frequencies are strong enough. But since harmonics appear at 25-kHz intervals throughout the spectrum, along with the desired markers, the problem of identifying a particular marker arises. This is easily solved if the receiver has a reasonably good calibration. If not, most marker circuits provide for a choice of fundamental outputs of 100 and 50 kHz as well as 25 kHz, so the question can be narrowed down to initial identification of 100-kHz intervals. From these, the desired

25-kHz (or 50-kHz) points can easily be spotted. Coarser frequency intervals are rarely required; there are usually signals available from stations of known frequency, and the 100-kHz points can be counted off from them.

## Transmitter Checking

In checking one's own transmitter frequency, the signal from the transmitter is first tuned in on the receiver and the dial setting at which it is heard is noted. Then the nearest marker frequencies above and below the transmitter signal are tuned in and identified. The transmitter frequency is obviously between these two known frequencies.

If the marker frequencies are accurate, this is all that needs to be known—except that the transmitter frequency must not be so close to a band (subband) edge that sideband frequencies, especially in phone transmission, will extend over the edge.

If the transmitter signal is inside a marker at the edge of an assignment, to the extent that there is an audible beat note with the receiver BFO turned off, normal CW sidebands are safely inside the edge. (This statement does not take into account abnormal sidebands such as those caused by clicks and chirps.) For phone the safety allowance is usually taken to be about 3 kHz, the nominal width of one sideband. A frequency difference of this order can be estimated by noting the receiver dial settings for the two 25-kHz markers that bracket the signal and dividing 25 by the number of dial divisions between them. This will give the number of kilohertz per dial division.

## Transceivers

The method described above is applicable when the receiver and transmitter are separate pieces of equipment. When a transceiver is used and the transmitting frequency is automatically the same as that to which the receiver is tuned, setting the tuning dial to a spot between two known marker frequencies is all that is required. The RIT control must be turned off.

The proper dial settings for the markers are those at which, with the BFO on, the signal is tuned to zero beat—the spot where the beat disappears as the tuning makes the beat tone progressively lower. Exact zero beat can be determined by a very slow rise and fall of background noise, caused by a beat of a cycle or less per second. In receivers with high selectivity it may not be possible to detect an exact zero beat, because low audio frequencies from beat notes may be prevented from reaching the speaker or headphones.

## Frequency-Marker Circuits

The basic frequency-determining element in most amateur frequency markers is a

100-kHz or 1-MHz crystal. Although the marker generator should produce harmonics at 25-kHz and 50-kHz intervals, crystals (or other high-stability devices) for frequencies lower than 100 kHz are expensive and difficult to obtain. However, there is really no need for them, since it is easy to divide the basic frequency down to whatever one desires; 50 and 25 kHz require only two successive divisions, each by two. In the division process, the harmonic output of the generator is greatly enhanced, making the generator useful at frequencies well into the VHF range.

## Simple Crystal Oscillators

Fig 23 illustrates two of the simpler circuits. CI in both circuits is used for exact adjustment of the oscillating frequency to 100 kHz, which is done by using the receiver for comparing one of the oscillator's harmonics with a standard frequency transmitted by WWV, WWVH or a similar station.

Fig 23A shows a field-effect transistor analog of a vacuum-tube circuit. However, it requires a 10-mH coil to operate well, and since the harmonic output is not strong at the higher frequencies the circuit is given principally as an example of a simple transistor arrangement. A much better oscillator is shown at B. This is a cross-connected pair of transistors forming a multivibrator of the free-running or asynchronous type, locked at 100 kHz by using the crystal as one of the coupling elements. While it can use two separate bipolar transistors as shown, it is much simpler to use an integrated-circuit dual gate, which contains all necessary parts except the crystal and capacitors. Further, it is considerably less expensive and more compact than the separate components.

## Frequency Dividers

Electronic division is accomplished by a bistable flip-flop or cross-coupled circuit that produces one output change for every two impulses applied to its input circuit, thus dividing the applied frequency by two. All division therefore must be in terms of some power of two. In practice this is no handicap since with modern integrated-circuit flip-flops, circuit arrangements can be worked out for division by any desired number.

As flip-flops and gates in integrated circuits come in compatible series—meaning that they work at the same supply voltage and can be directly connected together—a combination of a dual-gate version of Fig 23B and a dual flip-flop makes an attractive simple combination for the marker generator. A circuit using a similar arrangement appears in Chapter 34.

There are several different basic types of flip-flops, the variations having to do with methods of driving (dc or pulse operation)

<sup>1</sup>These limits depend on the type of emission and class of license held, as well as on international agreements. See the latest edition of *The FCC Rule Book* for current status.

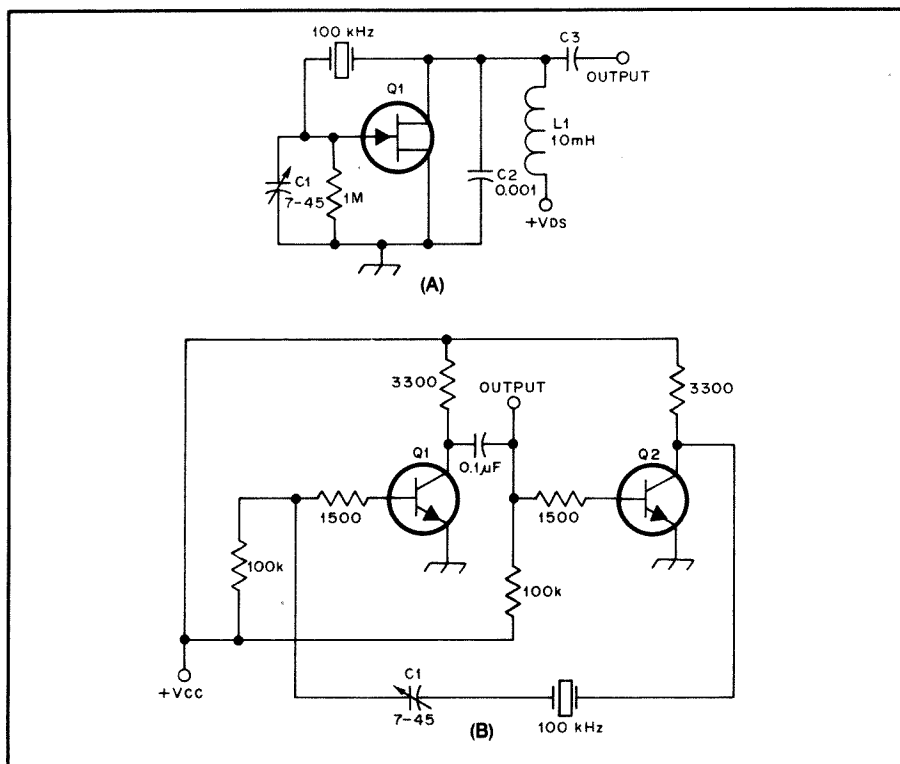

Fig 23—Two simple 100-kHz oscillator circuits. B is the most suitable of available transistor circuits (for marker generators) and is recommended where solid-state construction is to be used. In both circuits C1 is for fine frequency adjustment. The output coupling capacitor, C3 is generally small—20 to 50 pF—a compromise to avoid loading the oscillator by the receiver antenna input while maintaining adequate coupling for good harmonic strength.

and control of the counting function. Information on the operating principles and ratings of a specific type usually can be obtained from the manufacturer. The counting-control functions are not needed in using the flip-flop in a simple marker generator, although they come into play when dividing by some number other than a power of two.

#### Other Methods of Frequency Checking

The simplest possible frequency-measuring device is an absorption frequency-meter—a parallel LC circuit, tunable over a desired frequency range, with its tuning dial calibrated in frequency. It can be used only for checking circuits in which at least a small amount of RF power is present, because the energy required to give a detectable indication is not available in the LC circuit itself; it has to be extracted from the circuit being measured. Hence the name absorption frequency meter. What is actually measured is the frequency of the RF energy, not the frequency to which the circuit under test may be tuned.

The measurement accuracy of such an instrument is low, compared with the accuracy of a marker generator, because the Q of a practicable LC circuit is not high enough to make precise dial readings possible. Also, any two circuits coupled together react on each other's tuning. (This can be minimized by using the loosest

coupling that will give an adequate indication.)

The absorption frequency meter has one useful advantage over the marker generator—it will respond only to the frequency to which it is tuned, or to a band of frequencies very close to it. Thus there is no harmonic ambiguity, as there sometimes is with a marker generator.

#### Absorption Circuit

A typical absorption frequency-meter circuit is shown in Fig 24. In addition to the adjustable tuned circuit, L1-C1, it includes a pickup coil, L2, wound over L1, a high-frequency semiconductor diode, D1, and a microammeter or low-range (usually not more than 0.1 mA) milliammeter. A phone jack is included so the device can be used for listening to the signal.

Fig 24—Absorption frequency-meter circuit. The closed-circuit phone jack may be omitted if listening is not wanted, in which case the positive terminal of M1 goes to common ground.

The sensitivity of the frequency meter depends on the sensitivity of the dc meter movement and the size of L2 in relation to L1. There is an optimum size for this coil that must be found by experimentation. An alternative is to make the rectifier connection to an adjustable tap on L1, in which case there is an optimum tap point. In general, the rectifier coupling should be a little below (that is, less tight than) the point that gives maximum response, since this will make the indication sharper.

#### Calibration

The absorption frequency meter must be calibrated by taking a series of readings from circuits carrying RF power at known frequencies. The frequency of the RF energy may be determined by means such as a marker generator and receiver. The setting of the dial that gives the highest meter indication is the calibration point for that frequency. This point should be determined by tuning through it with loose coupling to the circuit being measured.

#### Frequency Standards

The difference between a marker generator and a frequency standard is that special pains are taken to make the frequency-standard oscillator frequency as stable as possible. Variations in temperature, humidity, line voltage and other factors can cause a small change in frequency.

While there are no definite criteria that distinguish the two in this respect, a circuit designated as a standard for amateur purposes should be capable of maintaining frequency within at least a few parts per million in ambient conditions, without adjustment. Commercially made receivers that employ synthesizers use frequency standards with a tolerance of 1 part in 100,000,000. A simple marker generator using a 100-kHz crystal can be expected to have frequency variations 10 times (or more) greater under similar conditions. It can of course be adjusted to exact frequency at any time the WWV (or equivalent) signal is available.

The design considerations of high-precision frequency standards are outside the scope of this chapter, but information is available from time to time in periodicals.

#### Frequency Counters

One of the most accurate means of measuring frequency is the frequency counter. This instrument is capable of numerically displaying the frequency of the signal supplied to its input. For example, if an oscillator operating at 8.244 MHz is connected to the counter input, 8.244 would be displayed. At present, there are counters that are usable well up into the gigahertz range. Most counters that are used at high frequencies make use of a prescaler ahead of a basic low-frequency counter. Essentially, the prescaler divides the high-frequency signal by 10, 100, 1000 or some other amount so the low-frequency

counter can display the operating frequency.

The accuracy of the counter depends on an internal crystal reference. The more accurate the crystal reference, the more accurate the readings will be. Crystals for frequency counters are manufactured to close tolerances. Most counters have a trimmer capacitor so the crystal can be set exactly on frequency. Crystal frequencies of 1 MHz, 5 MHz or 10 MHz have become more or less standard. Harmonics of the crystal can be compared to WWV or WWVH signals at 5, 10, 15 MHz, etc., and adjusted for zero beat.

Many frequency counters offer options to increase the accuracy of the counter's timebase; this directly increases the counter's accuracy. These options usually employ temperature-compensated crystal oscillators (TCXOs) or crystals mounted in constant temperature ovens that keep the crystal from being affected by changes in ambient (room) temperature. Counters with these options are capable of obtaining accuracies of 0.1 ppm (part per million) or better. For example, a counter with a timebase with an accuracy of 5.0 ppm and a second counter with a TCXO with an accuracy of 0.1 ppm are available to check a 436-MHz CW transmitter for satellite use. The counter with the 5-ppm timebase could have a frequency error of as much as 2.18 kHz, while the possible error of the counter with the 0.1-ppm timebase is only 0.0436 kHz.

## A 500-MHz FREQUENCY COUNTER

The advent of LSI (large-scale-integration) integrated-circuit technology has reduced the construction costs of many electronic products. The frequency counter shown in Figs 25 through 34 was designed and built in the ARRL lab by Ed Hare, KA1CV and Tom Miller, NK1P. It uses an Intersil ICM7216C 10-MHz frequency counter to obtain a lot of performance for relatively little cost. With some careful shopping it can be built for about \$125.00, including the cabinet. It is usable from audio through UHF, and its sensitivity of 15 mV makes it a useful station accessory and troubleshooting tool.

Two input connectors are provided. The 10-MHz input has a high impedance, with a usable range of 20 Hz to over 10 MHz. The sensitivity is reduced to about 50 mV at the low-frequency end. The 500-MHz input has a 50-ohm impedance, and it is used for frequencies from 400 kHz to over 500 MHz. A sensitivity control allows this input to accommodate signals of up to 2 V RMS.

The project incorporates a prescaler that works with the range switch to automatically select a divide-by-10 or divide-by-100 function. This prescaler can also be built as a separate project to extend the range of an existing frequency counter. The  $\frac{1}{2}$ -inch digital readout is easy to read in almost any lighting conditions; a GATE

Fig 25—Exterior view of the 500-MHz frequency counter. Clear red plastic has been put in front of the LED display to make it easier to read in bright light.

LED is included for those who like to watch “das-blinkenlights.”

### Technical Details

This project was designed in modules. Fig 26 shows the schematic of the prescaler. The 10 MHz input uses Q1 and its associated circuitry as a high-input impedance preamplifier, with input protection provided by D1 and D2. U1 is a high-speed comparator used to obtain fast rising square waves from the output of Q1. The output of this stage is coupled into Q2 to obtain the TTL voltage levels that are required by U5.

U2 is an MMIC preamplifier stage for the 500-MHz input. Other MMICs were tried successfully at U2, requiring only a change in the value of R10. (For more information on MMIC devices, see February and March 1987 QST). An 11C90 is used at U3 as a high-speed divide-by-10 stage. R12, R13 and R14 are optional components; they allow a fine adjustment of the VREF voltage output from U3, increasing the counter sensitivity. If the resistors are left out of the circuit the sensitivity will decrease to about 50 mV.

The output of U3 feeds U4 and U5, another divide-by-10 stage. A 74LS160 binary counter is used in this stage. A 74LS160 can be substituted here, but this limits the counter response to 350 MHz.

U5 selects either the 10-MHz direct input or the 500-MHz input divided by 10 or 100. This selection is accomplished through the appropriate A, B or C inputs of the 74LS151. If the prescaler is built as a separate module these signals must be provided. Table 1 shows a truth table for this stage. The output of this stage is a TTL voltage level.

The prescaler module requires +4.75 to +5.25 V at 450 mA and +12 to +18 V at 120 mA. The +12 to +18 V is regulated to +10 V by D5. Extensive power-supply bypassing has been used throughout.

The power-supply schematic is shown in Fig 27. A full-wave bridge rectifier is used to generate +12 to +18 V. This is regulated to +5 V by U1. The builder has quite a bit of latitude when selecting components for the power-supply circuit. Any

12.6-V transformer with at least a 450 mA current rating may be used at T1. U2 can be rated at 50 V or higher, 1 A or better. The values for C1 and C3 are approximate and could easily vary by 50%. The capacitor voltage ratings shown are the minimum that should be used, however.

The 10-MHz counter section has been designed to make full use of the features available in the Intersil ICM7216C frequency counter IC. The schematic for this module is shown on Fig 28. The internal 10-MHz oscillator can be adjusted to zero-beat with WWV. It is important to use a high-quality capacitor at C103; a mica or polystyrene capacitor is best. If a ceramic capacitor is used, the oscillator frequency is apt to be fairly sensitive to temperature changes, and this degrades counter accuracy. C102 can be any small trimmer capacitor that has a capacitance of at least 50 pF (a 6 to 70 pF unit was used in the ARRL counter). The RESET switch allows the user to restart the counter, a useful feature on longer gate times. The HOLD feature stops the counting and maintains the last reading on the LED display. The display uses GI MAN6710 dual displays, and the display PC board is designed to accommodate this (or an equivalent) display. Experienced builders could substitute a different LED display, but the ICM7216C is specified to sink a maximum of 20 mA, so the substitution must be made accordingly. The gate LED (DS101) lights when the counter is sampling the input signal.

The counter features six ranges. Gate times are 10 s, 1 s, 100 ms and 10 ms, with 100 ms used on the two prescaled ranges. Ultimate resolution is 0.1 Hz. The left decimal point indicates that the input signal is over-range. The external decimal point mode of the ICM7216C is used, automatically switching the decimal point to accommodate Hz, kHz and the two prescaled MHz ranges.

The ICM7216C accomplishes range and decimal point changes by connecting the RANGE and DP IN inputs to the various digit-multiplex outputs and internally evaluating the multiplex relationship. The TTL circuitry of U102, U103 and U104 is

designed to automatically generate the signals required to switch the prescaler into its various modes. U102 is configured as a flip-flop, changing state as the range switch is set to the 100-MHz or 500-MHz range by detecting a simultaneous occurrence of DP IN and digit 6 for divide-by-10 or digit 5 for divide-by-100. U103 and U104 set the 10 MHz output high on all other ranges. U102 and U103 must be CMOS, 74C00 or 74HC00. The use of a low-power Schottky device here will result in excessive loading of the multiplexing lines. C104 and

**Table 1**

component-side parts-placement diagram for the counter/prescaler board. Use insulated wire jumpers at the places marked W on the component-placement diagram.

Some additional components must be mounted on the bottom side of the board, and it is easier to do this after all of the component-side parts have been installed. U2 is a surface-mount MMIC, and the bypass capacitors are installed on pads on the PC board. Refer to Fig 30 for the solder-side parts-placement diagram. Fig 31 shows how the bypass capacitors have been mounted using heat-shrink tubing to keep the component leads from shorting to any of the PC board traces.

A 16-pin DIP socket may be installed in the socket for J101 if the builder wishes to use the dip header and ribbon cable seen in Fig 33. Sockets are recommended for all of the DIP ICs because it is a good idea to verify proper voltages at the power pins of the ICs before they are installed. Sockets also make IC replacement easier.

If the PC board is used for the power supply, the parts should be installed in the board as shown in the power-supply component-placement diagram, Fig 32. Pay close attention to the orientation of U1 (mount it with the tab flush against the PC board—part number facing up) and to the polarity markings on the electrolytic capacitors and the bridge rectifier. U1 requires a small heat sink similar to that shown in Fig 33.

The component-placement diagram for the display board is shown in Fig 34. A socket may be installed at J201 if desired, or the wires from J101 may be directly soldered through the appropriate holes. Pin 1 on J101 should be connected to pin 1 on J201. Install wire jumpers at the places marked W on the parts-placement diagram.

The display board mounts directly to the front panel. If ½-inch spacers are used to mount the display board, the LEDs will be flush with the front panel. For those builders who wish to exactly duplicate the ARRL version of the counter, a dimensional diagram and actual-size layout of the front panel lettering are available from the ARRL Technical Department secretary for an SASE and \$1.00.

The ARRL version of the counter was built in a Bud AC-406 chassis (2 × 9 × 7 inches HWD) with a BPA-1593 bottom plate. The HOLD and RESET switches and the gate LED are mounted between the display board and the front panel, so these must be mounted before the display board is installed. It is probably easier to install the wires on the PC board and solder them to the front-panel components after they are mounted. C6, C7, D3 and D4 are mounted off-board, and should be installed directly at J2 using short leads. Short pieces of RG-174 coaxial cable are used to connect J1 and J2 to the appropriate points on the PC board. The sensitivity control should be wired so that clockwise rotation

decreases the resistance. The remainder of the layout is not critical, so the builder can easily determine the layout best suited to the components used. The interior photograph, Fig 33 shows the arrangement used in the ARRL version.

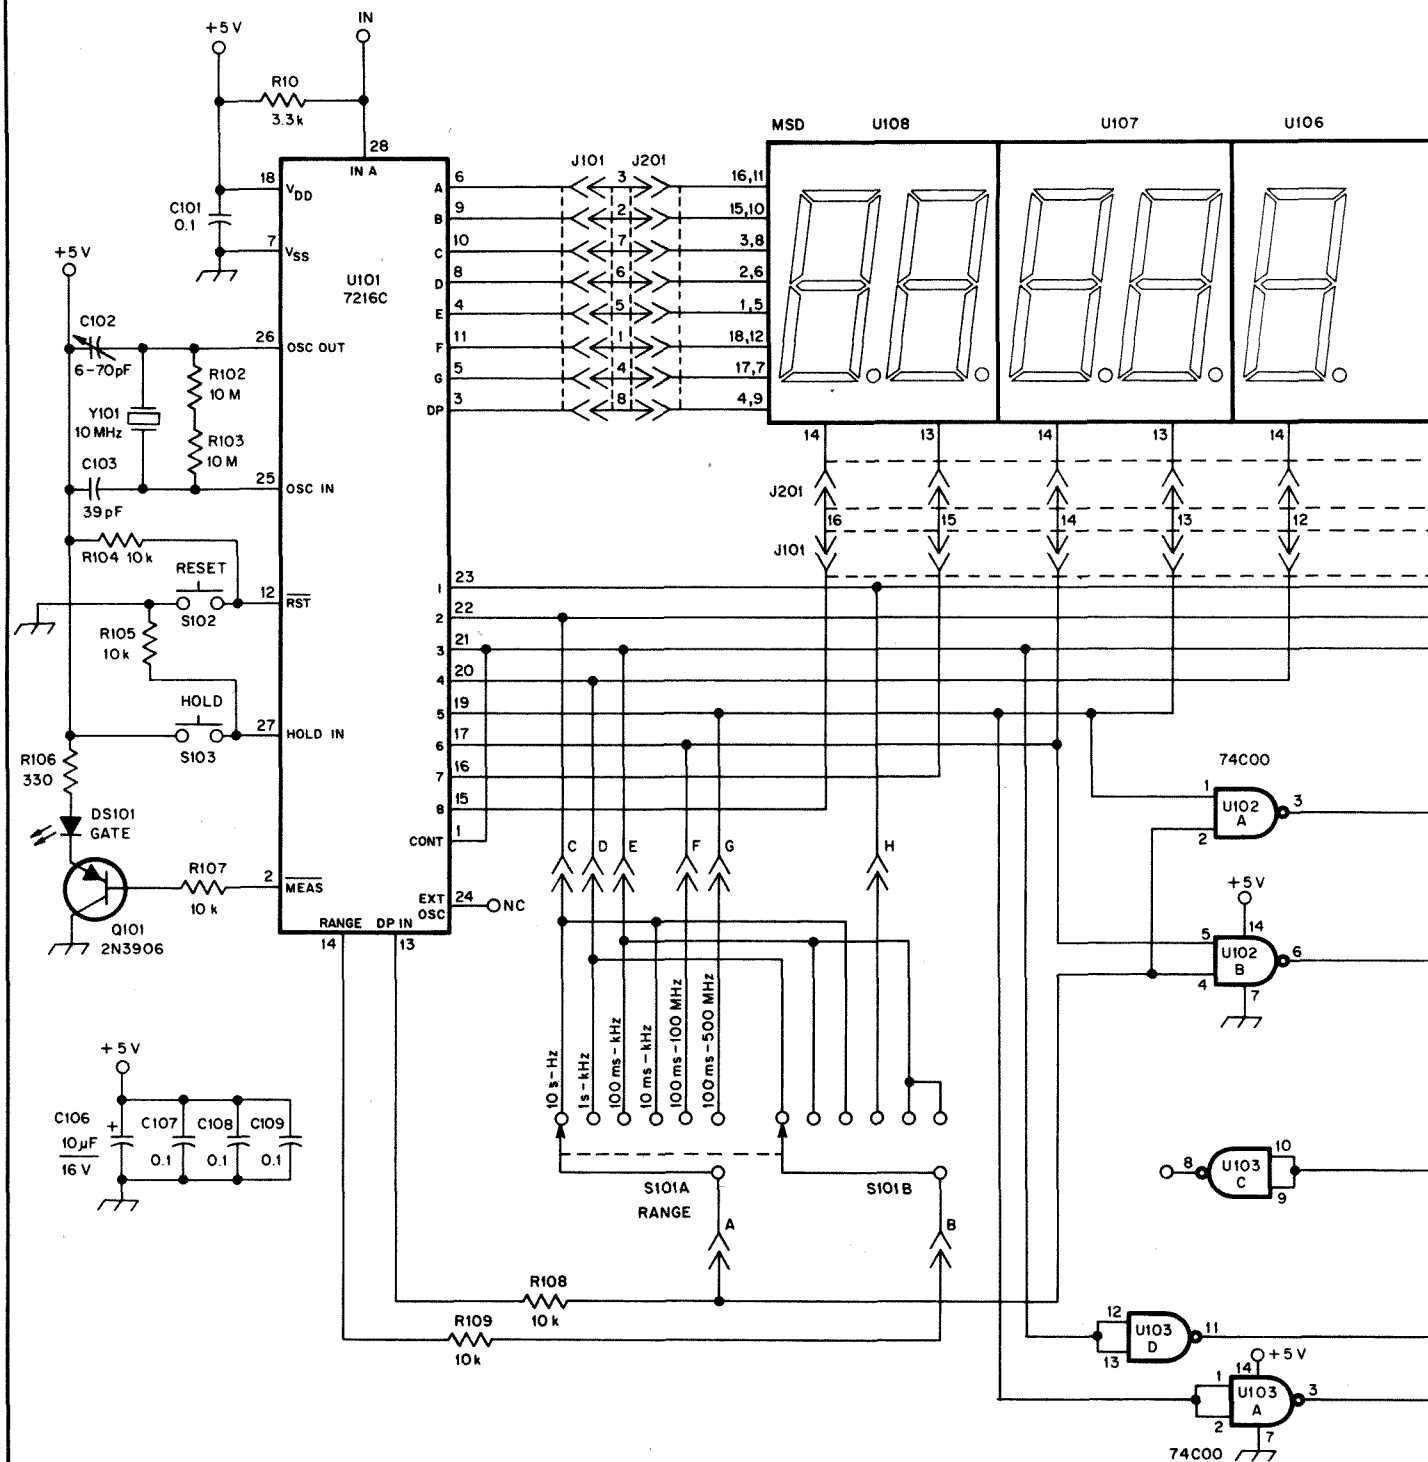

### Alignment and Troubleshooting

There is little alignment that needs to be performed on this circuit. Lab tests indicate that the counter has completely stabilized after a warmup time of 60 minutes, showing 170 Hz drift at 10 MHz during the warmup period. To align the counter, allow an hour for warmup and tune in WWV (10 MHz or 20 MHz) on a general-coverage receiver. Next, tune in the signal from the counter's internal oscillator on the receiver. It may be necessary to use an external antenna placed near the counter circuitry to pick up enough signal from the ICM7216C oscillator. Adjust C102 so that the oscillator is zero-beat with the WWV carrier.

A second calibrated frequency counter could also be used to set the 10-MHz oscillator if desired. Couple a signal from the ICM7216 10-MHz oscillator by placing the second counter's probe near the oscillator components. Adjust C102 for a 10-MHz reading on the second counter.

If a variable-output VHF/UHF generator is available, the prescale sensitivity control (R12), may be adjusted for maximum sensitivity. Set the front-panel sensitivity control fully clockwise and start with about 100 mV at 500 MHz into the 500 MHz input. Gradually decrease the output from the signal generator while adjusting R12 to maintain an accurate reading. With somewhere around 20 mV input the prescale sensitivity control will not give further improvement. R12 may be left at this setting; it should not require any further adjustment. It is best to use an external attenuator to reduce strong signals to about 100 mV or so, but the front-panel sensitivity control can be used for input signals up to 2 V RMS. The 10-MHz input can withstand input voltages of about 20 V RMS. The front-panel sensitivity control has no effect on the 10 MHz input.

If the circuit fails to function refer to Chapter 26 for general troubleshooting information. The signals are divided by 10 at U3 and U4; keep this in mind if signal tracing is being performed.

## Other Instruments and Measurements

Many measurements require a source of ac power of adjustable frequency (and sometimes adjustable amplitude) in addition to what is already available from the transmitter and receiver. RF and AF test oscillators, for example, provide signals for purposes such as receiver alignment, testing of phone transmitters, and so on. Another valuable adjunct to the station is the oscilloscope, essential for checking waveforms.

### RF Oscillators for Circuit Alignment

Receiver testing and alignment, covered in an earlier chapter, uses equipment common to ordinary radio service work. Inexpensive RF signal generators are available, both complete and in kit form. However, any source of signal that is weak enough to avoid overloading the receiver usually will serve for alignment work. The frequency marker generator is a satisfactory signal source. In addition, its frequencies, although not continuously adjustable, are known far more precisely, since the usual signal-generator calibration is not highly accurate. For rough work a gate-dip or grid-dip meter is sufficient.

### AUDIO-FREQUENCY OSCILLATORS

Tests requiring an audio-frequency signal generally call for one that is a reasonably good sine wave. The best oscillator circuits for this use are RC-coupled, operating as close to a class-A amplifier as possible. Variable frequencies covering the entire audio range are needed for determining frequency response of audio amplifiers.

For most phone-transmitter testing, and for simple trouble shooting in AF amplifiers, an oscillator generating one or two frequencies with good waveform is adequate. A two-tone (dual) oscillator is particularly useful for testing sideband transmitters and adjusting them for on-the-air use.

The circuit of a simple RC oscillator that is useful for general test purposes is given in Fig 35. This Twin-T arrangement gives a waveform that is satisfactory for most purposes, and by choice of circuit constants the oscillator can be operated at any frequency in the audio range. R1, R2 and C1 form a low-pass type network, while C2, C3 and R3 form a high-pass network. As the phase shifts are opposite, there is only one frequency at which the total phase shift from collector to base is 180 degrees; oscillation will occur at this frequency. Optimum operation results when C1 is approximately twice the capacitance of C2 or C3, and R3 has a resistance about 0.1 that of R1 or R2 ( $C2 = C3$  and  $R1 = R2$ ). Output is taken across C1, where the harmonic distortion is least. A relatively high impedance load should be used—100 k $\Omega$  or more.

A small-signal AF transistor is suitable for Q1. Either NPN or PNP types can be

Fig 35—Twin-T audio oscillator circuit. Representative values for R1-R2 and C1 range from 18 k $\Omega$  and 0.05  $\mu$ F for 750 Hz to 15 k $\Omega$  and 0.02  $\mu$ F for 1800 Hz. For the same frequency range, R3 and C2-C3 vary from 1800 ohms and 0.02  $\mu$ F to 1500 ohms and 0.01  $\mu$ F. R4 should be approximately 3300 ohms. C4, the output coupling capacitor, can be 0.05  $\mu$ F for high-impedance loads.

used, with due regard for supply polarity. R4, the collector load resistor, must be large enough for normal amplification, and may be varied somewhat to adjust the operating conditions for best waveform.

### A WIDE-RANGE AUDIO OSCILLATOR

A wide-range audio oscillator that will provide a moderate output level can be built from a single 741 operational amplifier (Fig 36). Power is supplied by two 9-volt batteries, from which the circuit draws 4 mA. The frequency range is selectable from 8 Hz to 150 kHz. Distortion is approximately one percent. The output level under a light load (10 k $\Omega$ ) is 4 to 5 volts. This can be increased by using higher battery voltages, up to a maximum of plus and minus 18 volts, with a corresponding adjustment of R<sub>f</sub>.

Pin connections shown are for the TO-5 case. If another package configuration is used, the pin connections may be different. R<sub>f</sub> (220 ohms) is trimmed for an output level about five percent below clipping. This should be done for the temperature

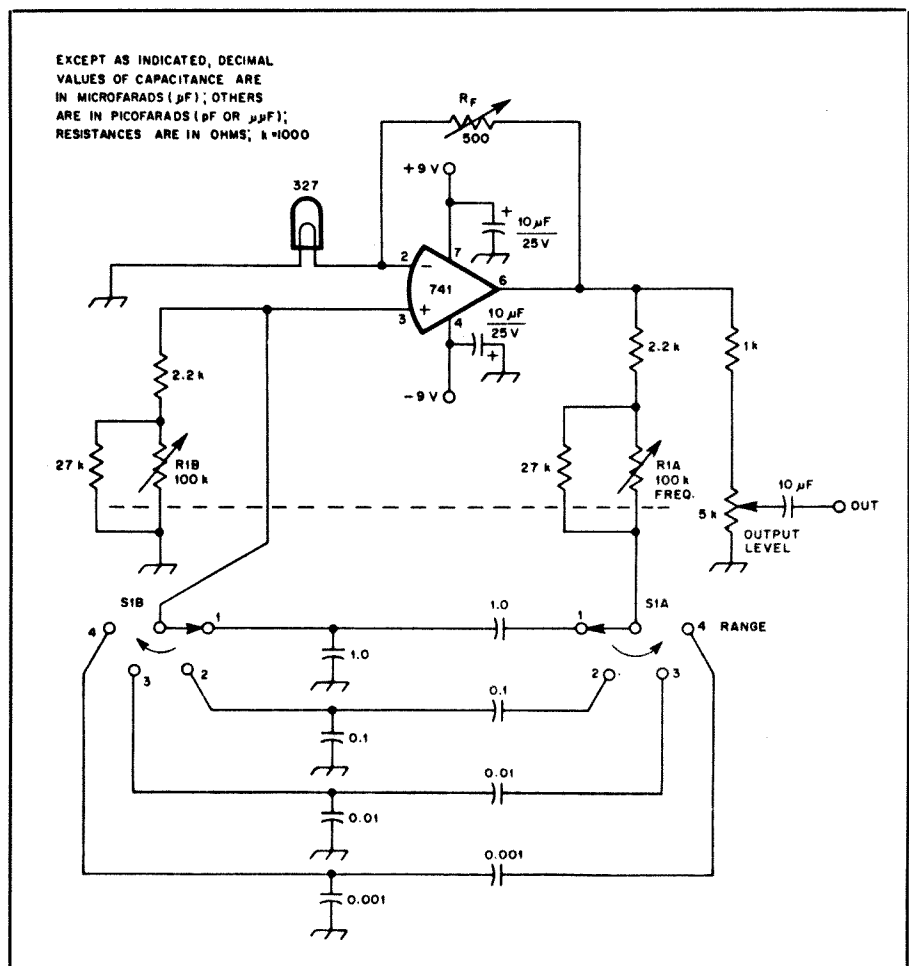

Fig 36—A simple audio oscillator that provides a selectable frequency range.

at which the oscillator will normally operate, as the lamp is sensitive to ambient temperature. This unit was originally described by Schultz in November 1974 *QST*; it was later modified by Neben as reported in June 1983 *QST*.

## A TWO-TONE AUDIO GENERATOR

The audio frequency generator shown in Figs. 37 and 38 makes a very convenient signal source for testing the linearity of a single-sideband transmitter. To be suitable for transmitter evaluation, a generator of this type must produce two nonharmonically related tones of equal amplitude. The level of harmonic and intermodulation distortion must be sufficiently low so as not to confuse the measurement. The frequencies used in this generator are 700 and 1900 Hz, both well inside the normal audio pass-band of an SSB transmitter. Spectral analysis and practical application with many different transmitters has shown this generator to meet all of the requirements mentioned above. While designed specifically for transmitter testing, it is also useful any time a fixed-frequency, low-level audio tone is needed. Details on distortion measurement and the two-tone test can be found in Chapter 18.

### Circuit Details

Each of the two tones is generated by a separate Wein bridge oscillator, U1B and U2B. The oscillators are followed by RC active low-pass filters, U1A and U2A. Because the filters require nonstandard capacitor values, provisions have been made on the circuit board for placing two capacitors in parallel in those cases where standard values cannot be used. The oscillator and filter capacitors should be polystyrene or Mylar film types if available. Two tones are combined at op amp U3A. This amplifier has a variable resistor, R4, in its feedback loop which serves as the output LEVEL control. While R4 varies both tones together, R3, the BALANCE control, allows the level of tone A to be changed without affecting the level of tone B. This is necessary because some transmitters do not have equal audio response at both frequencies. Following the summing amplifier is a step attenuator; S3 controls the output level in 10-dB steps. The use of two output level controls, R4 and S3, allows the output to cover a wide range and still be easy to set to a specific level. The remaining op amp, U3B, is connected as a voltage follower and serves to buffer the output while providing a high-impedance load for the step attenuator. Either a high or a low output impedance can be selected by S4.

Fig 37—Exterior view of the two-tone audio generator.

The values shown are suitable for most transmitters using either high- or low-impedance microphones.

### Construction and Adjustment

Component layout and wiring are not critical, and any type of construction can be used with good results. For those who wish to use a printed-circuit board, a parts-placement guide is shown in Fig 39. Because the generator will normally be used near a transmitter, it should be enclosed in some type of metal case for shielding. Battery power was chosen to reduce the possibility of RF entering the unit through the ac line. With careful shielding and filtering, the builder should be able to use an ac power supply in place of the batteries.

The only adjustment required before use is the setting of the oscillator feedback trimmers, R1 and R2. These should be set so that the output of each oscillator, measured at pin 7 of U1 and U2, is about 0.5 volt RMS. A VTVM or oscilloscope can be used for this measurement. If neither of these is available, the feedback should be adjusted to the minimum level that allows the oscillators to start reliably and stabilize quickly. When the oscillators are first turned on, they take a few seconds before they will have a stable output amplitude. This is caused by the lamps, DS1 and DS2, used in the oscillator feedback circuit. This is normal and should cause no difficulty. The connection to the transmitter should be through a shielded cable.

### Resistors at Radio Frequencies

Measuring equipment often requires essentially pure resistance in some part of its circuit—that is, resistance exhibiting only negligible reactive effects on the fre-

quencies at which measurement is intended. Of the resistors available to amateurs, this requirement is met only by small composition (carbon) resistors. The inductance of wire-wound resistors makes them useless for amateur frequencies.

The reactances to be considered arise from the inherent inductance of the resistor itself and its leads, and from small stray capacitances from one part of the resistor to another and to surrounding conductors. Although both the inductance and capacitance are small, their reactances become increasingly important as the frequency is raised. Small composition resistors, properly mounted, show negligible capacitive reactance up to 100 MHz or so in resistance values up to a few hundred ohms; similarly, the inductive reactance is negligible in values higher than a few hundred ohms. The optimum resistance region in this respect is 50 to 200 ohms.

Proper mounting includes reducing lead length as much as possible, and keeping the resistor separated from other resistors and conductors. Care must also be taken in some applications to ensure that the resistor, with its associated components, does not form a closed loop into which a voltage could be induced magnetically.

So installed, the resistance is essentially pure. In composition resistors the skin effect is very small, and the RF resistance up to VHF is nearly the same as the dc resistance.

### Dummy Antennas

A dummy antenna is simply a resistor that can be substituted for an antenna or transmission line for test purposes. The dummy must exhibit the same resistance as the antenna or line it is to replace. It permits leisurely transmitter testing without radiating a signal. (Amateur regulations strictly limit the amount of on-the-air testing that may be done.) A dummy antenna is useful in testing receivers, in that electrically it resembles an antenna, but does not pick up external noise and signals, a desirable feature in some tests.

For transmitter tests the dummy antenna must be capable of dissipating safely the entire power output of the transmitter. For most testing it is desirable that the dummy simulate a perfectly matched transmission line; it should be a pure resistance of approximately 50 or 75 ohms. This is a severe limitation in home construction, because nonreactive resistors rated at more than a few watts' safe dissipation are very difficult to obtain. Tubular carborundum non-reactive resistors can often be found in military surplus transmitters and antenna tuners. These resistors usually are rated at

50 to 100 W. Check surplus catalogs. (There are, however, dummy antenna kits available that can handle up to a kilowatt.)

For receiver and minipower transmitter testing an excellent dummy antenna can be made by installing a 51- or 75-ohm composition resistor in a PL-259 fitting, as shown in Fig 40. Sizes from one-half to two watts are satisfactory. The disc at the end helps reduce lead inductance and completes the shielding. Dummy antennas made in this way have good characteristics through the VHF bands as well as at all lower frequencies.

### Increasing Power Ratings

More power can be handled by using a number of 2-watt resistors in parallel, or series-parallel, but at the expense of introducing some reactance. Nevertheless, if some departure from the ideal impedance characteristics can be tolerated, this is a practical method for getting increased dissipation in a dummy antenna. The principal problem is stray inductance, which can be minimized by mounting the resistors on flat copper strips or sheets, as indicated in Fig 41.

The power rating on resistors is a continuous rating in free air. In practice, the maximum power dissipated can be increased in proportion to the reduction in duty cycle. Thus with keying, which has a duty cycle of about one half, the rating can be doubled. With sideband the duty cycle is usually not over about one-third. The best way of judging is to feel the resistors occasionally (with power off); if too hot to touch, they may be dissipating more power than they are rated for.

Fig 40—Dummy antenna made by mounting a composition resistor in a PL-259 coaxial plug. Only the inner portion of the plug is shown; the cap screws on after assembly is completed.

Fig 41—Use of resistors in series-parallel to increase the power rating of a small dummy antenna. Mounted in this way on pieces of flat copper, inductance is reduced to a minimum. Eight 100-ohm, 2-watt composition resistors in two groups, each four resistors in parallel, can be connected in series to form a 50-ohm dummy. The open construction shown permits free air circulation.

The dummy load shown in Fig 42 was constructed to test the feasibility of using a large number of 2-watt resistors to form a high-power load. This example uses 66 carbon resistors of 3.3 k $\Omega$ . The load will handle power levels up to 100 watts for reasonable lengths of time, and the SWR is less than 1.3 to 1 at frequencies up to 30 MHz. Because variations in construction may affect the stray reactances, it is recommended that the builder follow the general layout shown in the photograph. Complete details can be found in January 1981 *QST*.

### A SIMPLE INDUCTANCE METER

The inductance meter shown in Figs 43 through 47 measures the relative Q of a coil as well as its inductance. The Q/L meter is based on a design by Doug DeMaw, W1FB; this version was built by Zachary Lau, KH6CP, in the ARRL Lab. Simple LC Hartley oscillators replace the crystal oscillators used in the original design, eliminating the need for low-pass filters and reducing circuit complexity and cost. The accuracy of the meter is approximately  $\pm 10$  percent using the dial layout shown. Greater accuracy can be obtained by calibrating the meter against known high-accuracy standards.

### Circuit Details

The schematic of the Q/L meter is shown in Fig 43. A low-level RF signal is generated using an oscillator and an amplifier (Q1 through Q5). This signal is then applied to a tuned circuit consisting of the inductor under test and a calibrated capacitor. The voltage across the tuned circuit is measured using Q6 and displayed on M1, a 200- $\mu$ A meter. When the capacitor is adjusted for resonance at the frequency of the RF signal, the voltage across the tuned circuit is maximized, resulting in a peak indication on the meter.

The crystal oscillators used in the original versions were replaced with Hartley LC oscillators as a cost-cutting measure. While the Hartley oscillators do not have the great stability of crystal oscillators, they are adequate for this application. The output of the LC oscillators is relatively clean, and no additional filtering is needed. The potentiometers from source to ground

 T1—23t no. 26 enam wire on an Amidon FT-50-43 core. 1 turn no. 22 hookup wire secondary.

allow control of the power to the buffer amplifier.

The buffer amplifier is a broadband class-A amplifier with shunt and emitter feedback. T1 is used to match the 0.33-ohm load to the amplifier, as the load tends to swamp out the frequency dependence of the circuit.

A voltage-to-current amplifier (Q6) is used to determine the amount of RF present at J1. For best sensitivity, a small amount of current should always flow through the meter. Two meter shunts are used to select different Q ranges, and the 78L05 voltage regulator supplies Q6 with a constant voltage.

### Construction

Construction of the Q/L meter is fairly straightforward. The parts-placement diagram is shown in Fig 45. The toroids must be wound carefully; the total number of turns on the coils is determined by counting the number of times the wire passes through the hole in the toroid.

Fig 44—This inductance meter features a direct readout over an inductance range from 0.12  $\mu$ H to 1.8 mH.

Fig 46—Interior view of the inductance meter. An L-shaped bracket supports the variable capacitor.

Fig 45—Parts-placement diagram for the inductance meter.

The most critical construction detail is the mounting of the capacitor and the terminals for the test inductor. See Fig 46. The ungrounded capacitor lead is connected to J1 with a piece of no. 14 wire.

The distance from the capacitor to J1 in the version shown here is 2¼ inches, and the dial layout shown in Fig 47 may be used if this terminal spacing is duplicated. It may be possible to position the capacitor and

test inductor closer together and use the given dial layout if a series compensation inductor is used. The accuracy of the dial shown here may differ because of minor differences in construction and components.

The capacitor is mounted three inches from the terminals on an L-shaped mounting bracket below a vernier drive. The 6-to-1 vernier drive is used to prevent the tuning rate from being too fast for high Q inductors. A piece of plastic scored with a sharp knife is used as a dial pointer. The cabinet used is a Ten-Tec SE-7.

### Testing

An RF probe or oscilloscope should be used to verify that the oscillators are working. The peak-to-peak voltage at the input of the buffer amplifier should not exceed 0.40 V to allow the buffer amplifier to operate linearly. The potentiometers in the oscillator circuit, (R3, R5, R7 and R9), are used to adjust the oscillator output levels. They can be adjusted while measuring the oscillator output, or simply adjusted for an adequate meter deflection while measuring an inductor. If multiple peak indications are noted, the potentiometer is set too high and should be adjusted for less meter deflection. The oscillator output voltage depends somewhat on the FETs used; it may be as low as 0.20 V. R19, the high-Q shunt, should be set for a much lower meter reading than the low-Q shunt, R20.

### Operation

After connecting the unknown inductor to the test jacks, the sensitivity control is adjusted for a small quiescent meter current between 5 and 25 microamperes. If this

is not done, it may be impossible to find a peak, as the detector may be essentially turned off! The low-Q setting is most useful in finding the value of an unknown inductor. The capacitor is then adjusted for a peak meter reading. If no peak can be found, a different range should be tried.

### Limitations

The meter will not be very accurate for inductances below  $0.3 \mu\text{H}$ ; at inductances this low, the measurements are greatly affected by lead length and parts layout. It may be possible to calibrate the unit in terms of  $Q$ ; the meter is most useful as a measure of *relative*  $Q$ , however. The unit shown here was not calibrated for  $Q$ , as the meter reading is affected by the setting of the quiescent point. In addition,  $Q$  should always be measured at the frequency of interest, as it varies markedly with frequency. The inductance measurements are not absolute; it is not unusual for the inductance of a ferrite-core inductor to vary with frequency. Despite these limitations, this  $Q/L$  meter is quite useful in obtaining approximate inductance values.

## OSCILLOSCOPES

Most engineers and technicians will tell you that the most useful single piece of test and design equipment is the modern triggered-sweep oscilloscope (commonly called just a "scope"). This is because not only can the oscilloscope measure voltage, but it can display voltage relative to time, showing the waveform pictures we are all familiar with from electronics textbooks. Over the past 10 years, the advances in semiconductor technology have brought the price of a good high-frequency scope within the affordable price range for most hams.

Fig 48 shows a simplified diagram of a triggered-sweep oscilloscope. The heart of the scope is the cathode ray tube (CRT) display. The CRT allows the visual display of an electronic signal by taking two electric signals and using them to deflect a beam of electrons. This beam is then deflected to a particular place on the phosphorescent screen of the CRT where it causes a small spot to glow. The particular location of the spot is determined by the value of the voltage applied to the vertical and horizontal inputs.

All the other circuits in the scope are used to take the real world signal and convert it to a form usable by the CRT. Let's take a look at how a signal travels through the oscilloscope circuitry. We will assume the trigger select switch is in the INTERNAL position (see Fig 48).

The first thing the input signal comes to is the input coupling switch. The switch allows the coupling of low-level ac signals that are superimposed on a large dc signal (this is often the case in audio amplifiers). In the AC position the dc component is blocked from reaching the vertical amplifier chain and saturating it (this would

Fig 47—Full-size dial template.

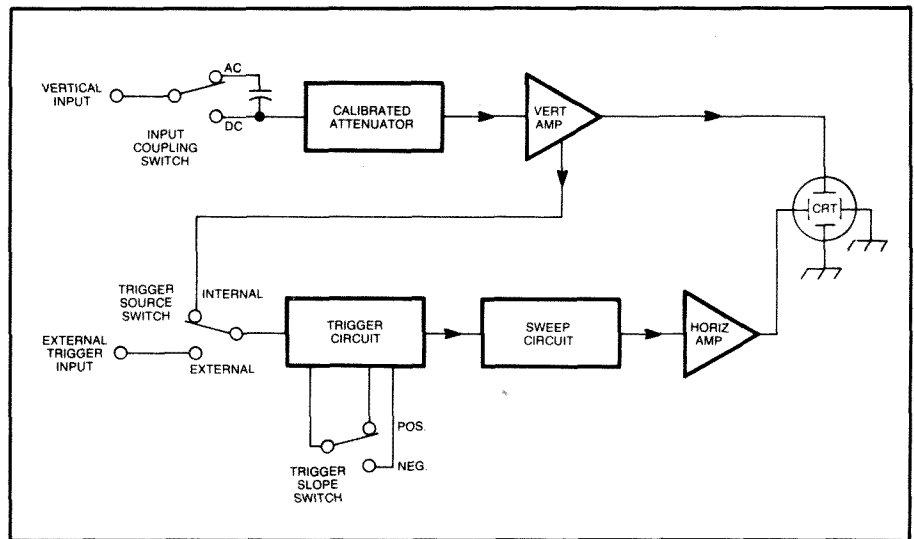

Fig 48—A block diagram of a simple triggered-sweep oscilloscope.

cause distortion that would make the displayed ac signals meaningless). It is important to note that at frequencies below 30 Hz it is not advisable to use ac coupling because the value of the blocking capacitor represents a considerable series impedance to very low-frequency signals. After the coupling switch, the signal next comes to a calibrated attenuator which is used to reduce the signal to a level that can be tolerated by the scope's vertical amplifier. The vertical amplifier amplifies the signal to a level that can drive the CRT and also adds a bias component to properly position the waveform on the screen.

A small sample of the signal from the vertical amplifier is sent to the trigger circuitry. The trigger circuit feeds a start pulse to the sweep generator when the input signal reaches a certain level. The sweep generator gives a precisely timed signal that looks like a triangle (see Fig 49). This triangular signal causes the scope trace to sweep from left to right, with the zero voltage point representing the left side of the screen and the maximum voltage representing the right side of the screen.

Fig 49—The sweep circuit produces a ramp pulse that is used to sweep the CRT electron beam from side to side.

The sweep circuit feeds the horizontal amplifier, which in turn drives the CRT. It is also possible to trigger the sweep system from an external source (such as the system clock in a digital system). This is done by using an external input jack with the trigger select switch in the EXTERNAL position.

Fig 50—Selection of the trigger point is very important. Selecting the trigger point in A produces a stable display, but the trigger shown at B will produce a display that “jitters” from side to side.

Fig 51—Oscilloscopes can be used to measure frequency. Here the displayed wave has a period of 80 microseconds (8 divisions  $\times$  10 microseconds per division) and a frequency of 12.5 kHz ( $1/80 \mu s$ ).

An explanation of the operation of the trigger system may be useful at this point. Basically, the trigger system looks at the reference signal (internal or external) to determine if it is positive- or negative-going and to see if the signal has passed a particular level. Fig 50A shows a typical signal, the dotted line on the figure representing the trigger level. If we assume that the trigger slope switch is set to the POSITIVE position it is obvious that the only points where a trigger will occur are the points

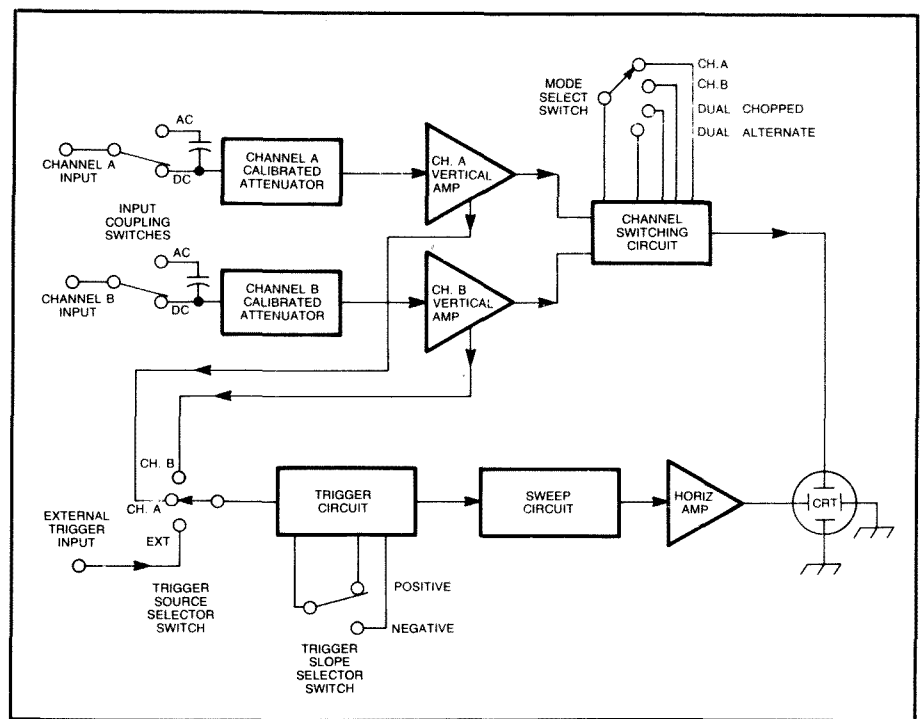

Fig 52—Block diagram of a modern dual-trace oscilloscope.

marked “T.” It is important to note that once a trigger circuit is “fired” it cannot fire again until the sweep has completed one complete traversal of the screen from left to right. It is also important that the trigger level be chosen properly so the display “locks” in place.

Fig 50B shows a situation where the level has not been properly selected. Because there are two points during a single cycle of the waveform that meet the triggering requirements, the trigger circuit will have a tendency to jump from one trigger point to another. This will cause the waveform to appear to jitter from left to right. Simple adjustment of the trigger level control will solve this problem.

Up to now we have not discussed what the travel across the horizontal axis represents. This axis is calibrated in units of time. This is especially helpful because knowing the time of one cycle can give us the frequency of the waveform. In Fig 51, for example, if we know that the sweep speed selector is set at  $10 \mu s/\text{division}$  and we count the number of divisions (vertical bars) between peaks of the waveform (or any similar well-defined points that occur once per cycle) we can determine the period of one cycle. In this case it is  $80 \mu s$ . This means that the frequency of the waveform is 12,500 Hz ( $1/80 \mu s$ ). The accuracy of the measured frequency depends on the accuracy of the scope’s sweep oscillator (usually approximately 5%) and the linearity of the ramp generator. Obviously, this accuracy cannot compete with even the least expensive frequency counter, but the scope can still be used to determine that a circuit is functioning properly.

Unfortunately, if we wanted to compare two signals (like the input and the output of an amplifier) we would have to alternately connect the scope input to each of the two points to be measured. This inconvenience can be solved by using a *dual-trace* oscilloscope. This scope has two vertical input channels which can be displayed either individually or simultaneously.

Fig 52 shows a simplified block diagram of a dual-trace triggered-sweep oscilloscope. The only differences between this scope and our previous example are the additional vertical amplifier and the “channel switching circuit.” This block selects whether we display channel A, channel B or both (simultaneously). The dual display is not a true dual display (there is only one electron gun in the CRT) but the dual traces are synthesized in the scope. True dual-trace dual-beam scopes are rare and very expensive.

There are two methods of synthesizing a dual-trace display from a single-beam scope. These two methods are referred to as “chopped mode” and “alternate mode.” In the chopped mode a small portion of the channel A waveform is written to the CRT, then a corresponding portion of the channel B waveform is written to the CRT. This procedure is continued until both waveforms are completely written on the CRT. The chopped mode is especially useful where an actual measure of the time difference between the two waveforms is required. The chopped mode is usually most useful on slow sweep speeds (times greater than a few microseconds per division).

In the alternate mode, the complete

channel A waveform is written to the CRT followed immediately by the complete channel B waveform. This occurs so quickly that it appears that the waveforms are displayed simultaneously. This mode of operation is used to measure the absolute phase difference between two signals by triggering both sweeps from the same vertical input signal. Unfortunately, this mode of operation is not useful at very slow sweep speeds, but is good at most other sweep speeds.

Most dual-trace oscilloscopes also have a feature called "X-Y" operation. This feature allows one channel to drive the horizontal amplifier of the scope (called the X channel) while the other channel (called Y in this mode of operation) drives the vertical amplifier. Some oscilloscopes also have an external Y input. X-Y operation allows the scope to display Lissajous patterns for frequency and phase comparison, and to use specialized test adapters such as curve tracers, spectrum analyzer front ends, etc. Because of frequency limitations of most scope horizontal amplifiers the X channel is usually limited to a 5- or 10-MHz bandwidth.

The oscilloscope has limits, like every other device. For most purposes the voltage range of the scope can be expanded by the use of appropriate probes (which we will cover later). The most important limiting factor for most oscilloscopes is the *frequency response* (also called the *bandwidth*) of the oscilloscope. At the specified maximum response frequency, the response will be down 3 dB (0.707 voltage). For example, if we put a 100-MHz 1-V sine wave into a 100-MHz bandwidth scope we will read approximately 0.707 V on the scope display. The same scope at frequencies below 30 MHz (down to dc) should be accurate to about 5%.

Directly related to bandwidth is a parameter called *rise time*. This term refers to the fact that if a very sharp and square waveform is put into a scope input the display will appear to take a finite amount of time to rise to a specified fraction of the input voltage level. The rise time is usually defined as the time required for the display to show a transition from the 10% to 90% points of the input waveform, as shown in Fig 53. The mathematical definition of rise time is given by:

$$t_r = \frac{0.35}{BW}$$

where

$t_r$  = rise time ( $\mu$ s)  
BW = bandwidth (MHz)

It is also important to note that all but the most modern (and expensive) scopes are not designed for precise measurement of either time or frequency. At best they will not have better than 5% accuracy in these applications. This does not diminish the usefulness of even a moderately priced oscilloscope, however.

Fig 53—Oscilloscope bandwidth has a limiting effect on the rise time of the signals displayed on the scope.

### Oscilloscope Probes

Connecting the signal to be measured to the input of the oscilloscope requires some form of electrical connection, preferably a shielded connection. Your first thought would probably lead you to a piece of small-diameter coax cable. Unfortunately, as we go higher in frequency the capacitance of the cable would produce a capacitive reactance considerably lower than the one-megohm input impedance of

the oscilloscope. In addition, the scope has a certain built-in capacitance at its input terminals (usually between 5 and 35 pF). These two capacitances cause problems if we are probing a circuit with a relatively high impedance.

The simplest method of connecting the signal to the scope is to use a specially designed probe. The most common scope probe is a "×10" probe (called a "times ten probe"). This probe forms a 10 to 1 voltage divider using the built-in resistance of the probe and the input resistance of the scope. When you use a times ten probe you must multiply the value of the calibrated attenuator by 10. For example, if your scope is on the 1-V/div range and you were using an ×10 probe the actual readings on the scope face would be 10 V/div.

Unfortunately, if we just put a resistor in series with the scope input it seriously degrades the scope's rise-time performance and therefore its bandwidth. This is because the scope's input looks like a parallel RC circuit and the series resistor feeding it causes a significant reduction in available charging current from the source. We can correct this by using a compensating capacitor in parallel with the series resistor. This in fact forms two dividers: one resistive voltage divider and one capacitive voltage divider. With these two dividers connected in parallel with the RC relationships shown in Fig 54, the probe and scope should have a flat response curve through the whole bandwidth of the scope.

To account for manufacturing tolerances in the scope and the probe the com-

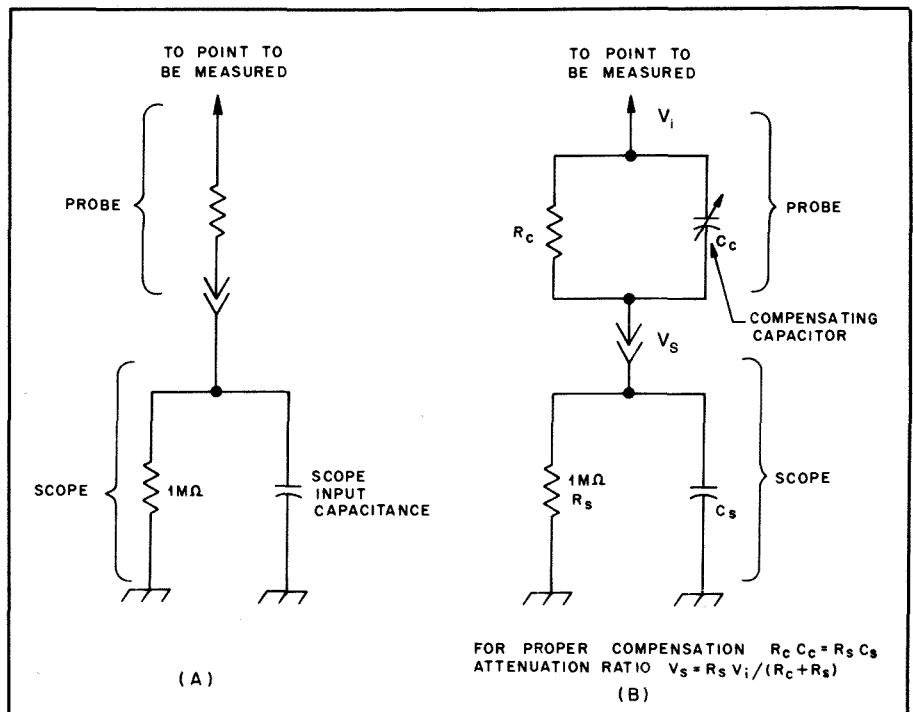

Fig 54—The probe at A is uncompensated; the compensating capacitor in the probe shown at B can be used to "tweak" the probe to compensate for circuit capacitances (see text for details).

Fig 55—Oscilloscope displays showing a squarewave input and undercompensated, overcompensated and properly compensated probes. Refer to the text for a discussion of the figure.

compensating capacitor is made variable and is used to “tweak” the probe and scope for proper response when they are connected together. Most scopes provide a “calibrator” output that produces a known-frequency square wave for the purpose of adjusting the compensating capacitor in a probe. Fig 55 shows possible responses when the probe is connected to the oscilloscope’s calibrator jack. We can see that the leading edge shown in the top and bottom traces of Fig 55 is incorrect. If you get these pictures from the calibrator jack, adjust the compensating capacitor until you get a perfectly square display as is shown in the middle trace of the figure.

If the probe cable is too short, do not attempt to extend the length of the cable by adding a piece of common coaxial cable. There are two reasons for this. First, the compensating capacitor is chosen to compensate for the provided length of cable. It usually will not have enough range to compensate for extra lengths. Additionally, the cable used to make a scope probe is of specialized construction and electrical characteristics. Its requirements are significantly different than normal coax cable.

Another important point in scope probe use is to use the shortest ground lead possible. Long ground leads are inductors at high frequencies. In these circuits they cause ringing and other undesirable effects.

### Digital Oscilloscopes

Up to now we have discussed versions of the classic oscilloscope that has existed for over 30 years. As we have noted, the cost of the oscilloscope has dropped with the widespread use of semiconductor technology. This is not the only change that semiconductors have brought to the oscilloscope market, however. In the past five years the *digital oscilloscope* has appeared in laboratories around the world. This type of oscilloscope has quickly gone from a laboratory oddity to an affordable tool in reach of the active experimenter. The design of a digital oscilloscope relies heavily on microcomputer technology, and the prominence and affordability of digital scopes has roughly paralleled the microcomputer market. We will not spend significant space on this type of scope only because almost any details we give will be

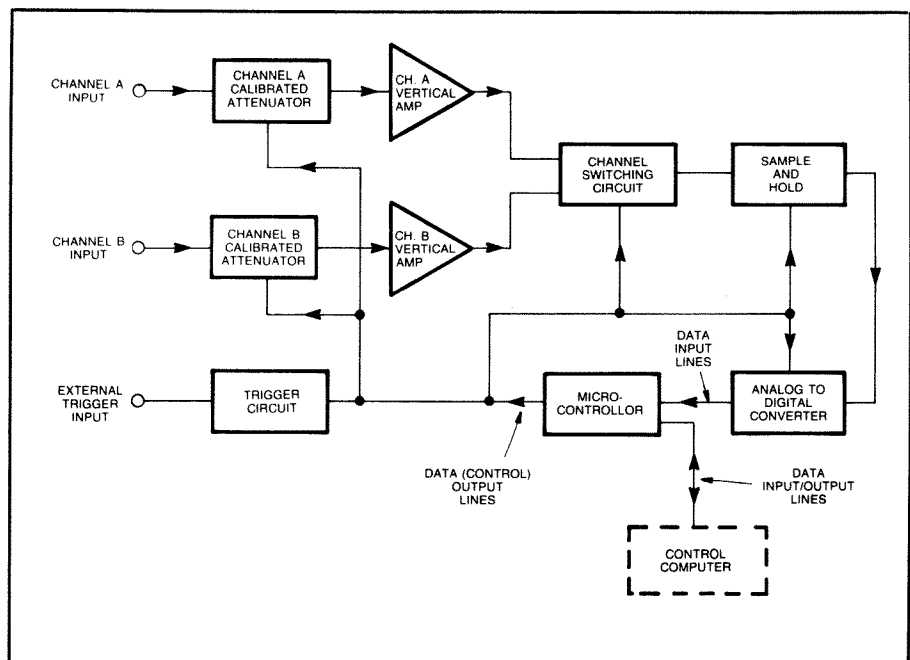

Fig 56—Block diagram of a dual-trace digital oscilloscope.

quickly overtaken by technological advances. A basic primer may be of interest, however.

A block diagram of the basic digital oscilloscope is given in Fig 56. The only thing we have previously not seen are the blocks labeled *sample and hold* (S/H), *analog to digital converter* (ADC) and *microcontroller*. These blocks take the analog signal and convert it to a sequence of digital bits which can be used to represent the waveform. Processing the signals in this way means that the information can then be passed to a computer where it can be stored (on floppy disks) or analyzed using advanced mathematical techniques (such as Fast Fourier Transforms). In fact, most digital oscilloscopes that are in the price range of the

experimenter do not even have a CRT; they use the computer terminal to display their result. Measurement parameters are adjusted via the computer keyboard, rather than with front-panel knobs and switches. Fig 57 shows a picture of a digital oscilloscope of this type. In the parlance of the engineer they are sometimes referred to as *waveform digitizers*, or *scope front ends*.

Referring to the block diagram, we can discuss the operation of the digital oscilloscope. Like most digital devices, the digital scope has a microprocessor “brain.” The microprocessor commands the sample and hold circuit to sample the amplitude of the input signal at regular intervals. The sample and hold circuit then holds this value while the analog to digital converter converts the sampled value to its digital

Fig 57—A digital “oscilloscope front end” for a personal computer. Other digital oscilloscopes take the form of a circuit board that plugs into an expansion slot in the computer (photo courtesy of Heath Co).

(A)

(B)

Fig 58—Two displays of the same waveform. The display at A was produced with an analog storage scope. The display at B was produced with a digital oscilloscope. Notice that the digital display is not continuous, leaving the actual shape of the rising and falling edges open to interpretation.

equivalent. This digital equivalent and information representing the time at which the sample was taken can either be sent to internal RAM for later use or can be sent out to the host microcomputer. The whole process is repeated a number of times until the waveform is duplicated.

Unfortunately, if the sample rate is not high enough, very fast signal perturbations between sampling points do not appear on the display. For example Fig 58A and 58B show the same signal as measured on an analog and digital scope. As you can see, there are large spikes in the analog scope that do not seem to show up on the digital scope. Some of the more expensive digital scopes use special methods to overcome this problem, but these methods are unlikely to come to lower priced units for a few years.

Some digital oscilloscopes are now appearing on the market in a portable form; these scopes employ a liquid-crystal display (LCD) very similar to that used on many lap-top computers. This type of digital scope requires no outboard computer and is usually battery operated. It is important to note that these scopes display the waveform as a series of unconnected dots. In certain very complex waveforms this

may cause some difficulty in interpretation. Also, as a consequence of other circuitry restrictions these hand-held scopes usually have very limited bandwidth (in the 100 to 500 kHz range) which means they are only useful in audio and slow digital work. Undoubtedly as technology advances, the performance of these scopes will improve considerably.

As with all new technology items, specifications are sometimes misleading because of lack of standard definitions for terms. If you are considering buying a digital scope we recommend you either attempt to see the unit you are interested in in operation or consult with a local ham in the electronics business who can offer some experienced advice.

### Storage Oscilloscopes

*Storage scopes* are now showing up on the surplus markets at prices available to many amateurs. Storage scopes are analog instruments with special long-persistence phosphor CRTs that allow them to capture single-shot events. For example, if you wanted to determine the switching time of an antenna sequencer you would trigger the scope from the control signal input to the sequencer and monitor the contacts with the vertical input to determine when the relay had switched. With a regular oscilloscope the trace would be gone from the CRT before you could determine the switching time, but with the storage scope's long-persistence CRT for a reasonable time (15 to 120 seconds) you can observe the switching action before the trace fades from the screen.

A newer version of the storage scope is the *digital storage oscilloscope* (DSO). The DSO uses a high-speed semiconductor memory which is continually read back to the display so that the waveform can be viewed for as long as necessary. The DSO is a relatively straightforward extension of the digital oscilloscopes we have previously discussed.

### Lissajous Figures

When sinusoidal ac voltages are applied to both sets of deflecting plates in the oscilloscope, the resultant pattern depends on the relative amplitudes, frequencies and phases of the two voltages. If the ratio between the two frequencies is constant and can be expressed in integers, a stationary pattern will be produced.

The stationary patterns obtained in this way are called Lissajous figures. Examples of some of the simpler Lissajous figures are given in Fig 59. The frequency ratio is found by counting the number of loops along two adjacent edges. Thus in C there are three loops along a horizontal edge and only one along the vertical, so the ratio of the vertical frequency to the horizontal frequency is 3:1. Similarly, in E there are four loops along the horizontal edge and three along the vertical edge, giving a ratio of 4:3.

Fig 59—Lissajous figures and corresponding frequency ratios for a 90-degree phase relationship between the voltages applied to the two sets of deflecting plates.

Assuming that the known frequency is applied to the horizontal plates, the unknown frequency is

$$f_2 = \frac{n_2}{n_1} f_1$$

where

$f_1$  = known frequency applied to horizontal plates

$f_2$  = unknown frequency applied to vertical plates

$n_1$  = number of loops along a vertical edge

$n_2$  = number of loops along a horizontal edge.

An important application of Lissajous figures is in the calibration of audio-frequency signal generators. For very low frequencies the 60-Hz power-line frequency is held accurately enough to be used as a standard in most localities. The medium audio-frequency range can be covered by comparison with the 440- and 600-Hz modulation on WWV transmissions. It is possible to calibrate over a 10:1 range, both upward and downward from these frequencies and thus cover the audio range useful for voice communication.

An oscilloscope having both horizontal and vertical amplifiers is desirable, since it is convenient to have a means for adjusting the voltages applied to the deflection plates to secure a suitable pattern size.

The result of an adjustment is instantly visible as an increase or decrease in the recovered audio. This method of noise evaluation is by no means new. Most modern automatic noise-figure meters turn the excess-noise source on and off and then, through rather sophisticated methods, evaluate the results. This technique is sometimes called Y-parameter testing.

While the method and circuit described here are not exceptional, they represent a fresh approach to noise evaluation. This approach does not require long-term integrating detectors and tedious "twice-power" measurements that, without absolute calibration, can result in no more than simply optimizing the system.

In some cases the available noise generated by this unit may be too great. The output may be reduced by inserting attenuators between the generator output and the device under test or by adding a 2000-ohm potentiometer at the point marked in Fig 61. The use of an attenuator is preferred because it reduces the apparent output VSWR of the generator by increasing the return loss. If a control is used it must be returned to its minimum insertion-loss position when starting a test or no signal may be heard.

This circuit uses readily available junk-box parts and may be easily duplicated. The lead placement in and around the diode itself should follow good VHF practices with short leads and direct placement.

### Theory of Operation

Q1 and Q2 are used in a cross-coupled multivibrator circuit, operating at approximately 700 Hz. The value of C1 is greater than C2 to cause the duty cycle to favor the conduction of Q2 slightly. When Q2 conducts, the pulse is coupled to Q3 via C3, turning on Q3 and causing current flow through R7, D1 and R8.

The diode generates broadband noise that is passed through R9 to the output. R7, C4 and C5 form a low-pass filter to prevent high-order harmonics of the switching pulses from appearing in the output.

The influence of stray RF signals entering the device under test through the generator may be minimized by shielding the components shown. A simple box may be built by using PC-board scraps. For best match, this source should be connected directly to the input of the device under test; therefore, the unit is equipped with a male connector. This matching becomes a greater consideration as the frequency of interest increases.

### Operation on Other Than AM

Some contemporary receivers and transceivers cannot be operated in the AM mode, and consequently the noise source seems unusable. The detection of noise is the process by which the noise source operates; therefore, it will not work through an FM detector, nor will it work

Fig 62—A simple detector that can be used when aligning SSB and FM receivers (see text for details).

through a product detector since one of the terms of the detection (the noise) is not coherent.

The SCOPE jack on most receivers is loosely coupled to the IF amplifier, preceding the detector. A wide-band scope connected to this point will show the train of pulses and eliminate the need for aural detection. The alignment of the later IF stages of a system should have the least impact on the noise performance, and maximum signal response will always occur at the same setting. Therefore, the simple detector of Fig 62 will generally work for aural AM detection. Connect point A to the last IF amplifier plate or collector. Connect point B to the audio amplifier, at or near the volume control, and ground point C. With this arrangement the normal detector output is turned down with the volume control, and the temporary detector provides AM detection.

The gated noise source has been used for literally hundreds of applications and has proved to be a powerful yet simple addition to the test bench. While no guarantee of duplication may be made, these units develop approximately 18 dB of excess noise in the region of 50-300 MHz. This unit was originally described by Hartsen in January 1977 *QST*.

### NOISE BRIDGE FOR 160 THROUGH 10 METERS

The noise bridge, sometimes referred to as an antenna (RX) noise bridge, is an instrument that will allow the user to measure the impedance of antennas or other electrical circuits. The unit described here, designed for use in the 160- through 10-meter range, provides adequate accuracy for most measurements. Battery operation and small physical size make this unit ideal for remote-location use. Tone modulation is applied to the wide-band noise generator as an aid for obtaining a null indication. A detector, such as the station receiver, is required for operation of the unit.

### The Circuit

The noise bridge consists of two parts—the noise generator and the bridge circuitry. See Fig 64. A 6.8-volt Zener diode serves as the noise source. U1 generates an approximate 50-percent duty cycle, 1000-Hz, square-wave signal, which is applied to the cathode of the Zener diode. The 1000-Hz

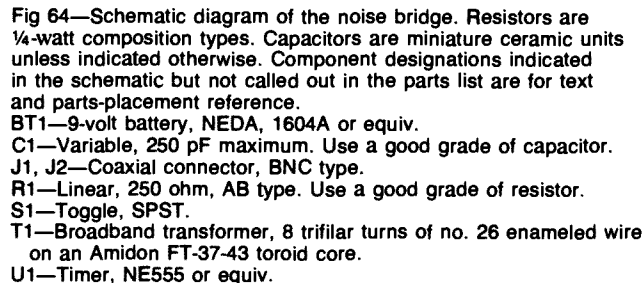

Fig 63—Interior and exterior views of the noise bridge. The unit is finished in red enamel. Press-on lettering is used for the calibration marks. Note that the potentiometer must be isolated from ground.

modulation appears on the noise signal and provides a useful null-detection enhancement effect when used with an AM receiver. The broadband-noise signal is amplified by Q1, Q2 and associated components to a level which produces an approximate S-9 signal in the receiver. Slightly more noise is available at the lower end of the frequency range, as no frequency compensation is applied to the amplifier. Roughly 20 mA of current is drawn from the 9-volt battery, thus ensuring long-battery life—as long as the power is switched off after use!

The bridge portion of the circuit consists of T1, C1, C2 and R1. T1 is a trifilar-wound transformer with one of the windings used to couple noise energy into the bridge circuit. The remaining two windings are arranged so that each one is in an arm of the bridge. C1 and R1 complete one arm and the UNKNOWN circuit along with C2 comprise the remainder of the bridge. The terminal labeled RCVR is for connection to the detector.

### Construction

The noise bridge is contained in a homemade aluminum enclosure that measures 5 × 2-3/8 × 3-3/4 inches. Many of the circuit components are mounted on a circuit board that is fastened to the rear wall of the cabinet. The circuit-board layout is such that the lead lengths to the board from the bridge and coaxial connectors are at a minimum. A parts-placement guide is shown in Fig 65.

of phenolic rod were used to further isolate the control from ground where the shaft passes through the front panel. A high-quality potentiometer is a must if good measurement results are to be obtained.

Mounting the variable capacitor is not a problem since the rotor is grounded. As with the potentiometer, a good grade of capacitor is important. If you must cut cor-

ners to save money, look elsewhere in the circuit. Two BNC-type female coaxial fittings are provided on the rear panel for connection to a detector (receiver) and to the UNKNOWN circuit. There is no reason other types of connectors can't be used. One should avoid the use of plastic insulated phono connectors, however, as these might influence accuracy at the higher frequencies. As can be seen from the photograph, a length of miniature coaxial cable (RG-174) is used between the RCVR connector and the appropriate circuit board foils. Also, C2 has one lead attached to the circuit board and the other connected directly to the UNKNOWN circuit connector.

Calibration of the bridge is straightforward and requires no special instruments. A receiver tuned to any portion of the 15-meter band is connected to the RCVR terminal of the bridge. The power is switched on and a broadband noise with a 1000-Hz note should be heard in the receiver. Calibration of the resistance dial should be performed first. This is accomplished by inserting small composition resistors of appropriate values across the UNKNOWN connector of the bridge. The resistors should have the shortest lead lengths possible in order to mate with the connector. Start with 25 ohms of resistance (this may be made up of series- or parallel-connected units). Adjust the capacitance and resistance dials for a null of the signal as heard in the receiver. Place a calibration mark on the front panel at that location of the resistance dial. Remove the 25-ohm resistor and insert a 50-ohm resistor, a 100-ohm unit and so on until the dial is completely calibrated.

The capacitance dial is calibrated in a similar manner. Initially, this dial is set so that the plates of C1 are exactly half meshed. If a capacitor having no stops is used, orient the knob so as to unmesh the plates when the knob is rotated into the positive-capacitance region of the dial. A 50-ohm resistor is connected to the UNKNOWN terminal and the resistance control is adjusted for a null. Next, the reactance dial is adjusted for a null and its position is noted. If this setting is significantly different than the half-meshed position, the value of C2 will need to be changed. Unit-to-unit value variations of 120-pF capacitors may be sufficient to provide a suitable unit. Alternatively, other values can be connected in series or parallel and tried in place of the 120-pF capacitor. The idea is to have the capacitance dial null as close as possible to the half-meshed position of C1.

Once the final value of C2 has been determined and the appropriate component installed in the circuit, the bridge should be adjusted for a null. The zero-reactance point can be marked on the face of the unit.

Fig 66—Graph for determining actual inductance from the calibration marks on the negative portion of the dial. These curves are accurate only for bridges having 120 pF at C2.

The next step is to place a 20-pF capacitor in series with the 50-ohm load resistor. Use a good grade of capacitor such as a silver-mica type, and keep the leads as short as possible. Null with the capacitance dial and make a calibration mark at that point. Remove the 20-pF capacitor and insert a 40-pF unit in series with the 50-ohm resistor. Again null the bridge and make a calibration mark for 40 pF. Continue in a similar manner until that half of the dial is calibrated.

To calibrate the negative half of the scale, the same capacitors may be used. This time they must be placed temporarily in parallel with C2. Connect the 50-ohm resistor to the UNKNOWN terminal and the 20-pF capacitor in parallel with C2. Null the bridge and place a calibration mark on the panel. Remove the 20-pF unit and temporarily install the 40-pF capacitor. Again null the bridge and make a calibration mark at that point. It should be pointed out that the exact resistance and capacitance values used for calibration can be determined by the builder. If resistance values of 20, 40, 60, 80, 100 ohms and so on are more in line with the builder's needs, the scale may be calibrated in these terms. The same is true for the capacitance dial. The accuracy of the bridge is determined by the components that are used in the calibration process.

Many amateurs use a noise bridge simply to find the resonant (nonreactive) impedance of an antenna system. For this service it is necessary only to calibrate the zero-reactance point of the capacitance dial. This simplification relaxes the stringent quality requirement for the bridge capacitors, C1 and C2.

### Operation

The resistance dial is calibrated directly in ohms, but the capacitance dial is calibrated in picofarads of capacitance. The + C half of the dial indicates that the load is capacitive, and the - C portion is for inductive loads. To find the reactance of the load when the capacitance reading is positive, the dial setting must be applied to the standard capacitive reactance formula

$$X = \frac{1}{2\pi fC}$$

The result will be a capacitive reactance.

Inductance values corresponding to negative capacitance dial readings may be taken from the graph of Fig 66. The reactance is then found from the formula

$$X = 2\pi fL$$

When using the bridge, remember that the instrument measures the impedance of loads as connected at the UNKNOWN terminal. This means that the actual load to be measured must be directly at the connector rather than being attached to the bridge by a length of coaxial cable. Even a short length of cable will transform the load impedance to some other value. Unless the electrical length of line is known and taken into account, it is necessary to place the bridge at the load. An exception to this would be if the antenna were to be matched to the characteristic impedance of the cable. In this case the bridge controls may be preset for 50-ohms resistance and 0-pF capacitance. With the bridge placed at any point along the coaxial line, the load

(antenna) may be adjusted until a null is obtained. If the length of line is known to be an even multiple of a half-wavelength at the frequency of interest, the readings obtained from the bridge will be accurate.

### Interpreting the Readings

A few words on how to interpret the measurements are in order. For example, assume the impedance of a 40-meter inverted-V antenna fed with a half-wavelength of cable was measured. The antenna had been cut for roughly the center of the band (7.150 MHz), and the bridge was nulled with the aid of a receiver tuned to that frequency. The results were 45 ohms of resistance and 70 picofarads of capacitance. The 45-ohm resistance reading is as close to 50 ohms as would be expected for this type of antenna. The capacitive reactance calculates to be 318 ohms from the equation

$$X = \frac{1}{2\pi(7.15 \times 10^6)(70 \times 10^{-12})} = 318 \Omega$$

When an antenna is adjusted for resonance, the capacitive or inductance reactance will be zero. The antenna in question is a long way from that mark. Since the antenna looks capacitive it is too short; wire should be added to each side of the antenna. An approximation of how much wire to add can be made by tuning the receiver higher in frequency until a point is reached where the bridge nulls with the capacitance dial at zero. The percentage difference between this new frequency and the desired frequency indicates the approximate percentage that the antenna should be lengthened. The same system will work if the antenna has been cut too long. In this case the capacitance dial would have nulled in the - C region, indicating an inductive reactance. This procedure will work for most antennas.

### SIGNAL GENERATORS FOR RECEIVER TESTING

The oscillator shown in Figs 67 and 68 was designed for testing high-performance receivers. Parts cost for the oscillator has been kept to a minimum by careful design. While the stability is slightly less than that of a well-designed crystal oscillator, the stability of the unit should be adequate for measurements of most amateur receivers. In addition, the ability to shift frequency is important when dealing with receivers that have spurious responses. More importantly, LC oscillators with high-Q components often have superior phase noise performance compared to crystal oscillators, because of power limitations in the crystal oscillators (crystals are easily damaged by excessive power).

The circuit is a Hartley oscillator

followed by a class-A buffer amplifier. To keep the frequency of the oscillator somewhat independent of the supply voltage, a 5-V regulator is used. The amplifier is cleaned up by a seven-element Chebyshev low-pass filter which is terminated by a

6-dB attenuator. The attenuator insures that the filter works properly, even with a receiver that has an input impedance other than 50 ohms. A receiver designed to work with a 50-ohm system may not have a 50-ohm input impedance. The +4 dBm of

output is adequate for most receiver measurements. It may even be too much for some receivers; the potential exists for damage to narrow crystal filters following amplifiers. It is assumed that the user will use a step attenuator to lower the output level to an appropriate value.

### Construction

This unit was built in a box made of double-sided circuit board. The box used in the prototype has inside dimensions of  $1 \times 2.2 \times 5$  inches (HWD). The copper foil of the circuit board makes an excellent shield, while the fiberglass helps temperature stability. Capacitor C2 should be soldered directly across L1 to insure high Q. As with any RF circuit, the component leads should be kept short. While silver mica capacitors have slightly better Q, NP0 capacitors may offer better stability. Mounting the three inductors orthogonally (axis of the inductors 90 degrees from each other) reduced the 2nd order harmonic by 2 dB compared to an initial prototype.

### Alignment and Testing

The output of the regulator should be +5 V. The output of the oscillator should

Fig 67—This LC oscillator for receiver measurements offers good performance at relatively low cost.

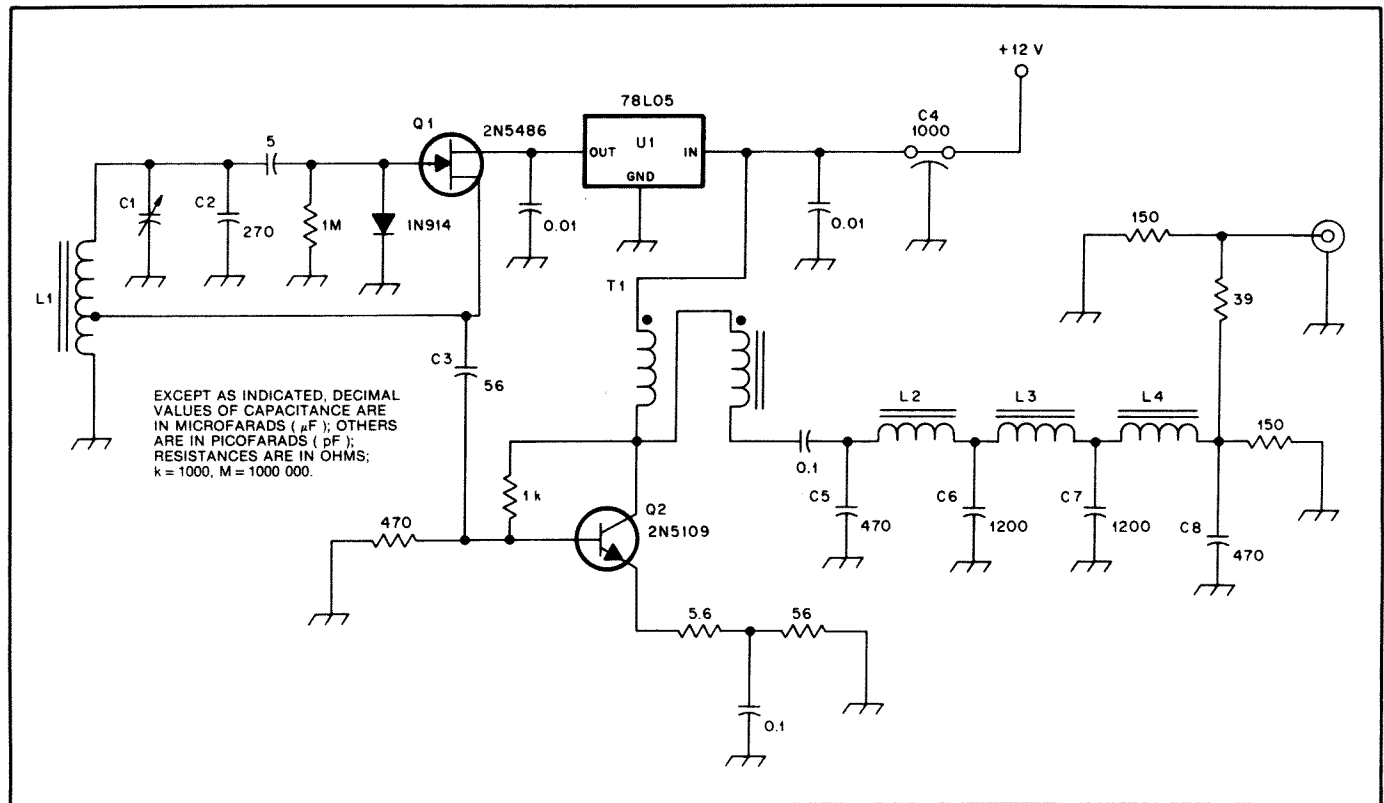

Fig 68—Schematic diagram of the 3.7-MHz oscillator. All resistors are  $\frac{1}{4}$  W, 5% units. Except as indicated, decimal values of capacitance are in microfarads ( $\mu$ F); others are in picofarads (pF); resistances are in ohms; K = 1000, M = 1,000,000.

C1—1.4 to 9.2 pF air trimmer (value and type not critical)

be +4 dBm (2.5 milliwatts) into a 50-ohm load. Increasing the value of C3 will increase the power output to a maximum of about 10 milliwatts. The frequency should be around 3.7 MHz. Adding additional capacitance across inductor L1 (in parallel with C2) will lower the frequency if desired, while the trimmer capacitor (C1) specified will allow adjustment to a specific frequency. The drift of one of the prototypes was 5 Hz over 25 minutes after a few minutes of warm up. If the warm-up drift is large, changing C2 may improve the situation somewhat. For most receivers, a drift of 100 Hz during the measurement period has a negligible effect on measurements.

## HYBRID COMBINERS FOR SIGNAL GENERATORS

Many receiver performance measurements require two signal generators to be attached simultaneously to a receiver. A combiner that isolates the two signal generators is necessary to keep one generator from being frequency or phase modulated by the other. Commercially made hybrid combiners are available from Mini-Circuits, PO Box 350166, Brooklyn NY 11235-0003. Hybrid combiners are not difficult to construct, however, as the following project shows.

The combiners described here provide 40 to 50 dB of isolation between ports while attenuating the desired signal paths (each input to output) by 6 dB. A second feature of these combiners is that of maintaining the 50-ohm impedance of the system—very important if accurate measurements are to be made.

The combiners are constructed in small boxes made from double-sided circuit-board material. Each piece is soldered to the adjacent one along the entire length of the seam. This makes an essentially RF-tight enclosure. BNC coaxial fittings are used on the units shown. However, any type of coaxial connector can be used. Leads must be kept as short as possible and precision resistors (or matched units from

the junk box) should be used. The circuit diagram for the combiners is shown in Fig 70.

Fig 69—Exterior view of the two hybrid combiners. The one on the left is designed to cover the 1 to 50 MHz range; the one on the right 50 to 500 MHz.

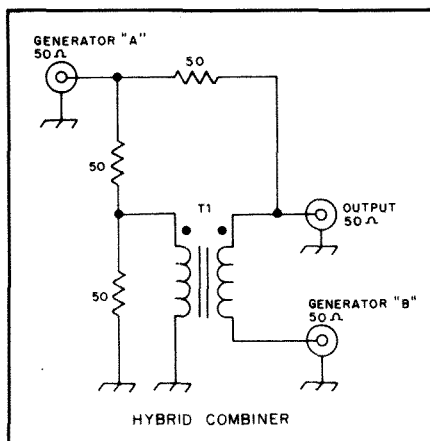

Fig 70—Schematic diagram of the hybrid combiners. For the 1- to 50-MHz model, T1 is 10 turns of no. 30 enameled wire bifilar wound on an FT-23-72 ferrite core. For the 50 to 500 MHz model, T1 consists of 10 turns of no. 30 enameled wire bifilar wound on an FT-23-63 ferrite core. Keep all leads as short as possible when constructing these units.

## LOW-POWER STEP ATTENUATORS

A step attenuator is a useful and important tool for receiver testing. Step attenuators may often be found at flea

markets for reasonable prices; in addition, the construction of an attenuator is well within the capabilities of most builders. Described here is a simple low-power step attenuator suitable for receiver front-end protection, and as a calibrated attenuator for receiver performance evaluation. This attenuator uses double-pole, double-throw slide switches to select different amounts of attenuation. Coaxial fittings are used at each end of the attenuator.

### Description

Fig 71 is the schematic diagram of the attenuator. Eight pi-network resistive sections are employed; the attenuation is variable in 1-dB steps. A total attenuation value of 81 dB is available with all the sections switched in. The maximum attenuation of any single section is limited to 20 dB because leak-through would probably degrade the effect of higher attenuation sections and result in inaccuracy.

This is a low-power attenuator; it is not designed for use at power levels exceeding ¼ watt. If for some reason the attenuator will be connected to a transceiver, a means of bypassing the unit during transmit periods must be devised.

### Parts

All the switches are DPDT standard size slide types. Stackpole S-5022CD03-0 units are used here. Other switch types may work as well, but have not been tested. The use of subminiature switches should be avoided.

Carbon-composition or film, ¼-watt, 5%-tolerance resistors are used. Ideally, the resistors should be selected using a reliable ohmmeter; this will ensure accuracy.

Double-sided PC board is used for the enclosure. Dimensions for the model described here are given in Fig 72. The attenuator has identification lettering etched into the top surface (or front panel) of the unit. This adds a nice touch, and is a permanent means of labeling. Of course, rub-on transfers or Dymo tape labels could be used as well.

Female BNC single-hole, chassis-mount connectors are used at each end of the

Fig 71—Schematic diagram of the attenuator. Resistors are ¼-W, 5%-tolerance, carbon-composition or film types. Resistances are given in ohms.

Fig 72—Mechanical dimensions of the attenuator enclosure.

enclosure. These connectors are small and easy to mount, have excellent RF qualities, and provide a means of easily connecting and disconnecting the attenuator by a simple twist of the wrist.

### Construction

After all the box parts are cut to size and the necessary holes are made, scribe light lines to locate the inner partitions. Carefully tack-solder all partitions in position. Dress any PC-board parts that do not fit squarely. Once everything is in proper position, run a solder bead all the way around the joints. Caution: Do not use an excessive amount of solder, as the switches must later be fit flat inside the sections. The top, sides, ends and partitions can be completed. Dress the outside of the box to suit your taste. For instance, you might wish to bevel the box edges. Buff the copper with steel wool, add lettering, and finish off the work

with a coat of clear lacquer or polyurethane varnish.

Using a little lacquer thinner or acetone (and a lot of caution), soak the switches to remove the grease that was added during the manufacture. When dry, spray the inside of the switches lightly with a TV-tuner cleaner/lubricant. Using a sharp drill bit (about 3/16 inch will do), countersink the mounting holes on the actuator side of the switch mounting plate. This ensures that the switches will fit flush against the top plate. At one end of each switch, bend the two lugs over and solder them together. Cut off the upper halves of the remaining switch lugs. (A look at Fig 73 will help clarify these steps.)

Solder the horizontal members of the pi sections between the appropriate switch lugs. Try to keep the lead lengths as short as possible, and do not overheat the resistors. Now solder the switches in place

Fig 73—Close-up of the switch detail.

to the top section of the enclosure by flowing solder through the mounting holes and onto the circuit-board material. Be certain that you place the switches in their proper positions; correlate the resistor values with the degree of attenuation. Otherwise, you may wind up with the 1-dB step at the wrong end of the box.

Once the switches are installed, thread a piece of no. 18 bare-copper wire through the center lugs of all the switches, passing it through the holes in the partitions. Solder the wire at each switch terminal. Cut the wire between the poles of each individual switch, leaving the wire connecting one switch pole to that of the neighboring one on the other side of the partition, as shown in Fig 74.

At each of the two end switch terminals, leave a wire length of approximately 1/8 inch. Install the BNC connectors, and solder the wire pieces to the connector center conductors.

Now install the resistors that comprise the grounded legs of each pi section. Use short lead lengths. Remember that physical

Fig 74—An inside view of the completed attenuator. Use of short, direct leads enhances the performance of the unit. Brass nuts soldered at each of the four corners allow machine screws to be used to secure the bottom cover. File one corner of each nut to permit a flat, two-sided fit within the enclosure.

symmetry is conducive to good performance. Do not use excessive amounts of heat when soldering.

Solder a no. 4-40 brass nut at each inside corner of the enclosure. Recess the nuts approximately 1/16 inch from the bottom edge of the box to allow sufficient room for the bottom panel to fit flush. Secure the bottom panel with four no. 4-40, 1/4-inch machine screws and you're done!

This circuit was described by Shriner and Pagel in September 1982 *QST*. Resistance values for pi- and T-network resistive attenuators are given in Tables 2 and 3. Values are for use in 50-ohm unbalanced systems. These values can be scaled for use in other systems by dividing the resistance values by 50 and then multiplying by the system resistance. The resistances shown in Fig 71 are the nearest standard values to those resistances appearing in Tables 2 and 3, taking 5% tolerances into account. Although some of the values are a few ohms off, they are quite acceptable for amateur work.

## MEASURING RECEIVER PERFORMANCE

Comparing the performance of one receiver to another is difficult at best. The features of one receiver may outweigh a second, even though its performance under some conditions is not as good as it should be. Although the final decision on which receiver to own will more than likely be based on personal preference, there are ways to compare receiver performance characteristics. The most important parameters are noise floor, intermodulation distortion, blocking (gain compression) and cross modulation.

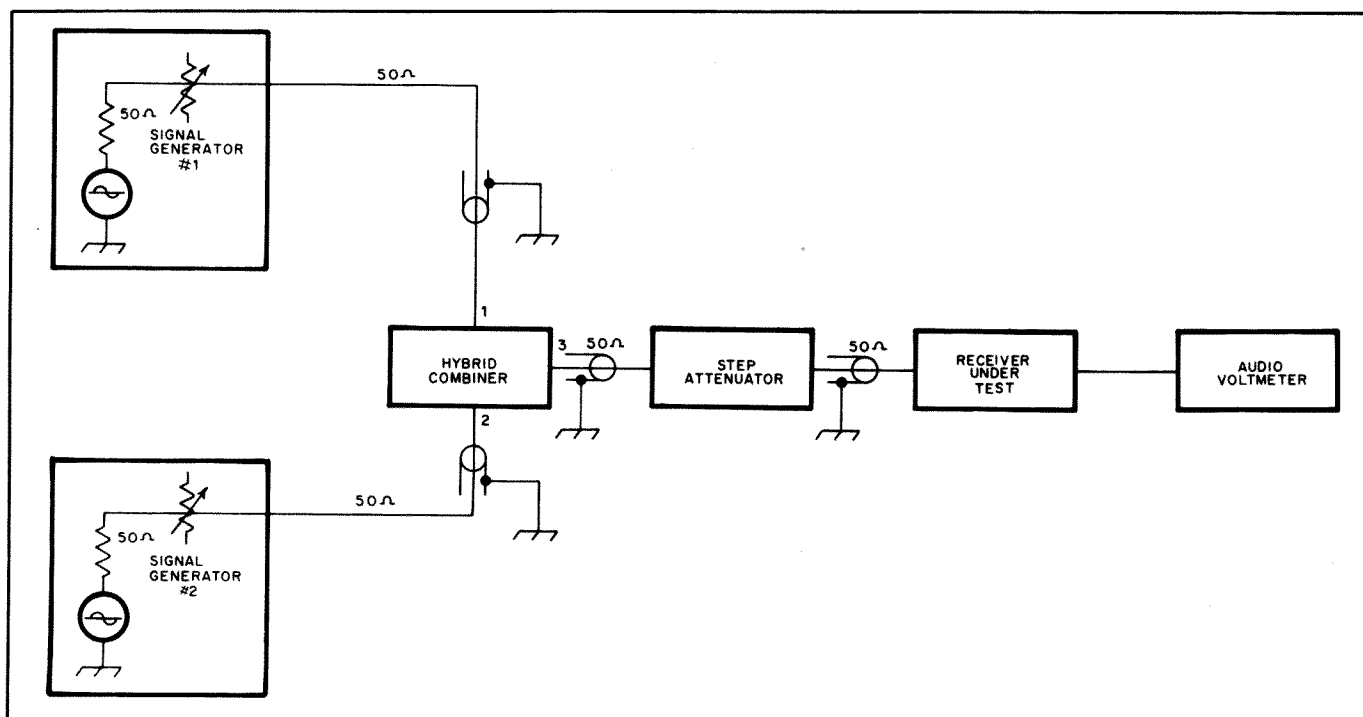

Fig 75—General test setup used for evaluating receiver performance. Two signal generators (calibrated), a hybrid combiner, a step attenuator and an audio voltmeter are required for the measurements.

The general test setup is shown in Fig 75. Two calibrated signal generators are required, along with a hybrid combiner, a step attenuator and an ac voltmeter. A hybrid combiner is essentially a unit with three ports. This device is used to combine the signals from a pair of generators. It has the characteristic that signals applied at ports 1 or 2 appear at port 3, and are attenuated by 6 dB. However, a signal from port 1 is attenuated 30 or 40 dB when sampled at port 2. Similarly, signals applied at port 2 are isolated from port 1 some 30 to 40 dB. The isolating properties of the box prevent one signal generator from being frequency or phase modulated by the other. A second feature of a hybrid combiner is that a 50-ohm impedance level is maintained throughout the system. A commercial example of a directional bridge of this kind is an HP-8721A.

The signal generators used in the test setup must be calibrated accurately in dBm or microvolts. The generators should have extremely low leakage. That is, when the output of the generator is disconnected, no signal should be detected at the operating frequency with a sensitive receiver. Ideally, at least one of the signal generators should be capable of amplitude modulation. A suitable lab-quality piece would be the HP-8640B.

While most signal generators are calibrated in terms of microvolts, the real concern is not with the voltage from the generator but with the power available. The fundamental unit of power is the watt. However, the unit which is used for most low-level RF work is the milliwatt, and power is often specified in decibels with respect to 1 milliwatt (dBm). Hence, 0 dBm would be 1 milliwatt. The dBm level, in a 50-ohm load, can be calculated with the aid of the following equation

$$\text{dBm} = 10 \log_{10} [ 20 (V_{\text{RMS}})^2 ]$$

where dBm is the power with respect to 1 milliwatt and V is the RMS voltage available at the output of the signal generator.

The convenience of a logarithmic power unit like the dBm becomes apparent when signals are amplified or attenuated. For example, a  $-107\text{-dBm}$  signal that is applied to an amplifier with a gain of 20 dB will result in an output of  $-107\text{ dBm} + 20\text{ dB}$ , or  $-87\text{ dBm}$ . Similarly, a  $-107\text{-dBm}$  signal applied to an attenuator with a loss of 10 dB will result in an output of  $-107\text{ dBm} - 10\text{ dB}$ , or  $-117\text{ dBm}$ .

#### Noise-Floor Measurement

A generator that is tuned to the same frequency as the receiver is used for noise-floor measurements. Output from the generator is increased until the ac voltmeter at the audio-output jack of the receiver shows a 3-dB increase. This measurement indicates the minimum discernible signal (MDS) that can be detected with the receiver. This level is defined as that which

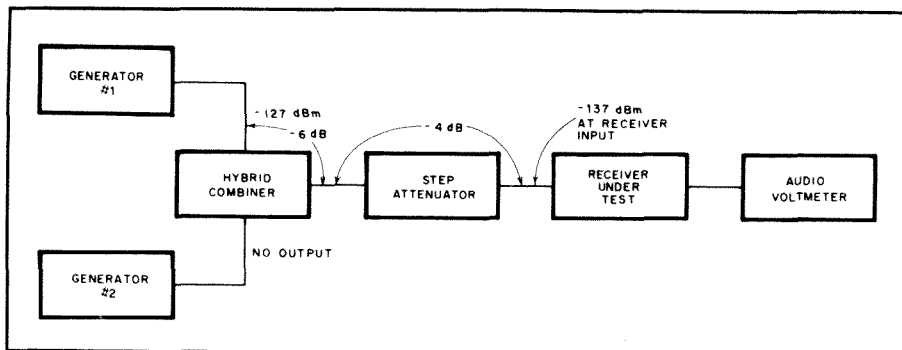

Fig 76—General test setup for measuring receiver noise floor. Signal levels for a hypothetical measurement are indicated. See text for a detailed discussion.

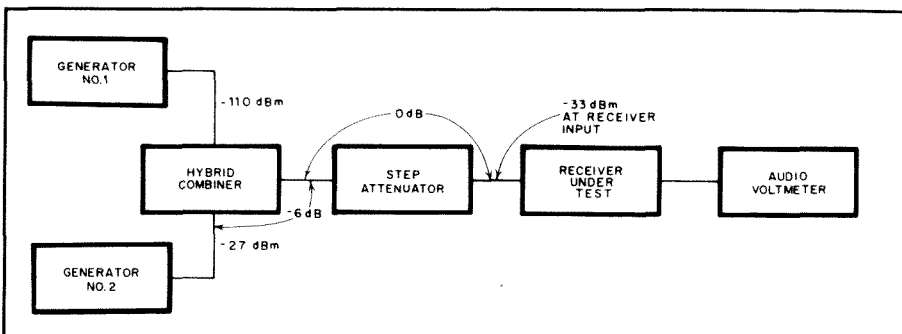

Fig 77—Test setup for measuring receiver blocking performance. Hypothetical measurements are included on the drawing.

will produce the same audio-output power as the internally generated receiver noise. Hence, the term “noise floor.” As a hypothetical example, say the output of the signal generator is  $-127\text{ dBm}$ , the loss through the combiner is fixed at 6 dB and the step attenuator is set to 4 dB. The equivalent noise floor can then be calculated as follows:

$$\begin{aligned} \text{Noise floor} &= -127\text{ dBm} - 6\text{ dB} - 4\text{ dB} \\ &= -137\text{ dBm} \end{aligned}$$

where the noise floor is the power available at the receiver antenna terminal,  $-6\text{ dB}$  is the loss through the coupler and  $-4\text{ dB}$  is the loss through the attenuator. Refer to Fig 76.

#### Blocking

Blocking concerns gain compression. Both signal generators are used. One is set for a weak signal of roughly  $-110\text{ dBm}$  and the receiver is tuned to this frequency. The other generator is set to a frequency of 20 kHz away and is increased in amplitude until the receiver output drops by 1 dB, as measured with the ac voltmeter. A blocking measurement is indicative of the signal level that can be tolerated at the receiver antenna terminal before desensitization will occur.

As an example, say that the output of the generator is  $-27\text{ dBm}$ , the loss through the combiner is fixed at 6 dB and there is 0 dB attenuation through the attenuator (effec-

tively switched out of the line). See Fig 77. The signal level at the receiver terminal that will cause gain compression is calculated as follows:

$$\begin{aligned} \text{Blocking level} &= -27\text{ dBm} - 6\text{ dB} \\ &= -33\text{ dBm} \end{aligned}$$

This can be expressed as dynamic range when this level is referenced to the receiver noise floor that was calculated earlier. This term can be called “receiver blocking dynamic range.” Calculate it as follows:

$$\begin{aligned} \text{Blocking dynamic range} &= \text{noise floor} - \text{blocking level} \\ &= -137\text{ dBm} - (-33\text{ dBm}) \\ &= -104\text{ dB} \end{aligned}$$

This value is usually taken in terms of absolute value and would be referred to as 104 dB.

#### Two-Tone IMD Test

One of the most significant parameters that can be specified for a receiver is a measure of the range of signals that can be tolerated while producing essentially no undesired spurious responses. The evaluation is made with a two-tone intermodulation-distortion (IMD) test. It is generally a conservative evaluation for other effects, such as blocking, which will occur only for signals well outside the IMD dynamic range of the receiver.

Two signals of equal level spaced 20 kHz

apart are injected into the input of the receiver. Call these frequencies  $f_1$  and  $f_2$ . The so-called third-order intermodulation-distortion products will appear at frequencies of  $(2f_1 - f_2)$  and  $(2f_2 - f_1)$ . Assume that the two input frequencies are 14.040 and 14.060 MHz. The third-order products will be at 14.020 and 14.080 MHz.

The step attenuator will be useful in this experiment. Adjust the two generators for an output of  $-10$  dBm each at frequencies spaced 20 kHz. Tune the receiver to either of the third-order IMD products. Adjust the step attenuator until the IMD product produces an output 3 dB above the noise level as read on the ac voltmeter.

For an example, say the output of the generator is  $-10$  dBm, the loss through the combiner is 6 dB and the amount of attenuation used is 40 dB. See Fig 78. The signal level at the receiver antenna terminal that just begins to cause IMD problems is calculated as:

$$\begin{aligned}\text{IMD level} &= -10 \text{ dBm} - 6 \text{ dB} - 40 \text{ dB} \\ &= -56 \text{ dBm}\end{aligned}$$

This can be expressed as a dynamic range when this level is referenced to the noise floor. This term is referred to as "IMD dynamic range" and can be calculated

$$\begin{aligned}\text{IMD dynamic range} &= \text{noise floor} - \text{IM level} \\ &= -137 \text{ dBm} - (-56 \text{ dBm}) \\ &= -81 \text{ dB}\end{aligned}$$

Therefore, the IMD dynamic range of this receiver would be 81 dB.

### Evaluating the Data

Thus far, a fair amount of data has been gathered with no mention of what the numbers really mean. It is somewhat easier to understand exactly what is happening by arranging the data in a form something like that in Fig 79. The base line is just a power line with a very small level of power at the left and a higher level (0 dBm) at the right.

The noise floor of the hypothetical receiver is drawn in at  $-137$  dBm, the IMD level (the level at which signals will begin to create spurious responses) at  $-56$  dBm and the blocking level (the level at which signals will begin to desense the receiver) at  $-33$  dBm. As can be seen, the IMD dynamic range is some 23 dB smaller than the blocking dynamic range. This means IMD products will be heard across the band long before the receiver will begin to desense — some 23 dB sooner.

The figures for the hypothetical receiver represent those which would be expected from a typical communications receiver on the market today. It is interesting to note that it is possible for the home constructor to build a receiver that will outperform commercially available units (even the high-priced ones).

### THE SPECTRUM ANALYZER

The spectrum analyzer is like an

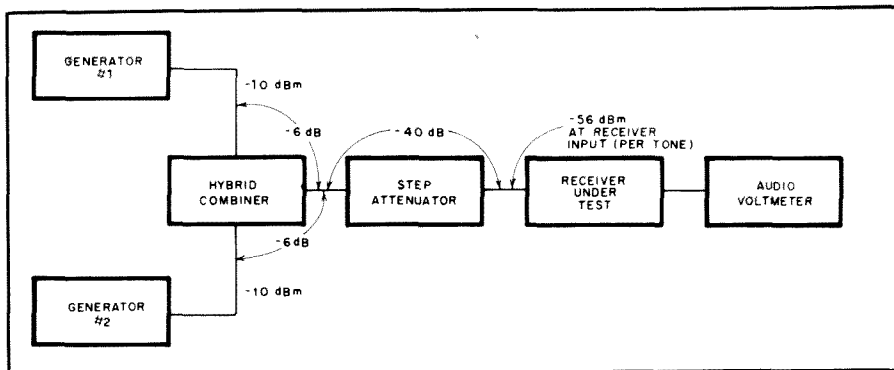

Fig 78—Receiver IMD performance test setup. Signal levels for a hypothetical measurement are given. A detailed discussion of this measurement is given in the text.

Fig 79—This graph displays the performance of a hypothetical (though typical) receiver under test. The noise floor is  $-137$  dBm, blocking level is  $-33$  dBm and the IMD level is  $-56$  dBm. This corresponds to a receiver blocking dynamic range of 104 dB and an IMD dynamic range of 81 dB.

oscilloscope in that both present an electrical signal through graphical representation. The oscilloscope is used to observe electrical signals in the time domain (amplitude as a function of time). However, not all signals can be represented properly in only the time domain. Amplifiers, mixers, oscillators, detectors, modulators and filters are best characterized in terms of their frequency response. This information is obtained by viewing electrical signals in the frequency domain (amplitude as a function of frequency). One instrument that can display the frequency domain is the spectrum analyzer.

### Time and Frequency Domain

To better understand the concepts of time and frequency domain, see Fig 80. The three-dimensional coordinates show time (as the line sloping toward the bottom right), frequency (as the line rising toward the top right) and amplitude (as the vertical axis). The two discrete frequencies shown are harmonically related, so we'll refer to them as  $f_1$  and  $2f_1$ .

In the representation of time domain at Fig 80B, all frequency components of a signal are summed together. In fact, if the two discrete frequencies shown were applied to the input of an oscilloscope, we would see the solid line (which corresponds to  $f_1 + 2f_1$ ) on the display.

In the frequency domain, complex signals (signals composed of more than one frequency) are separated into their individual frequency components. Additionally, a measurement is made as to the power level at each discrete frequency. The display depicted at Fig 80C is typical of that obtained with a spectrum analyzer.

Fig 80—Different ways in which a complex signal may be characterized. At A is a three-dimensional display of amplitude, time and frequency. At B, this information is shown only in the time domain as would be seen on an oscilloscope. At C the same information is shown in the frequency domain as it would be viewed on a spectrum analyzer.

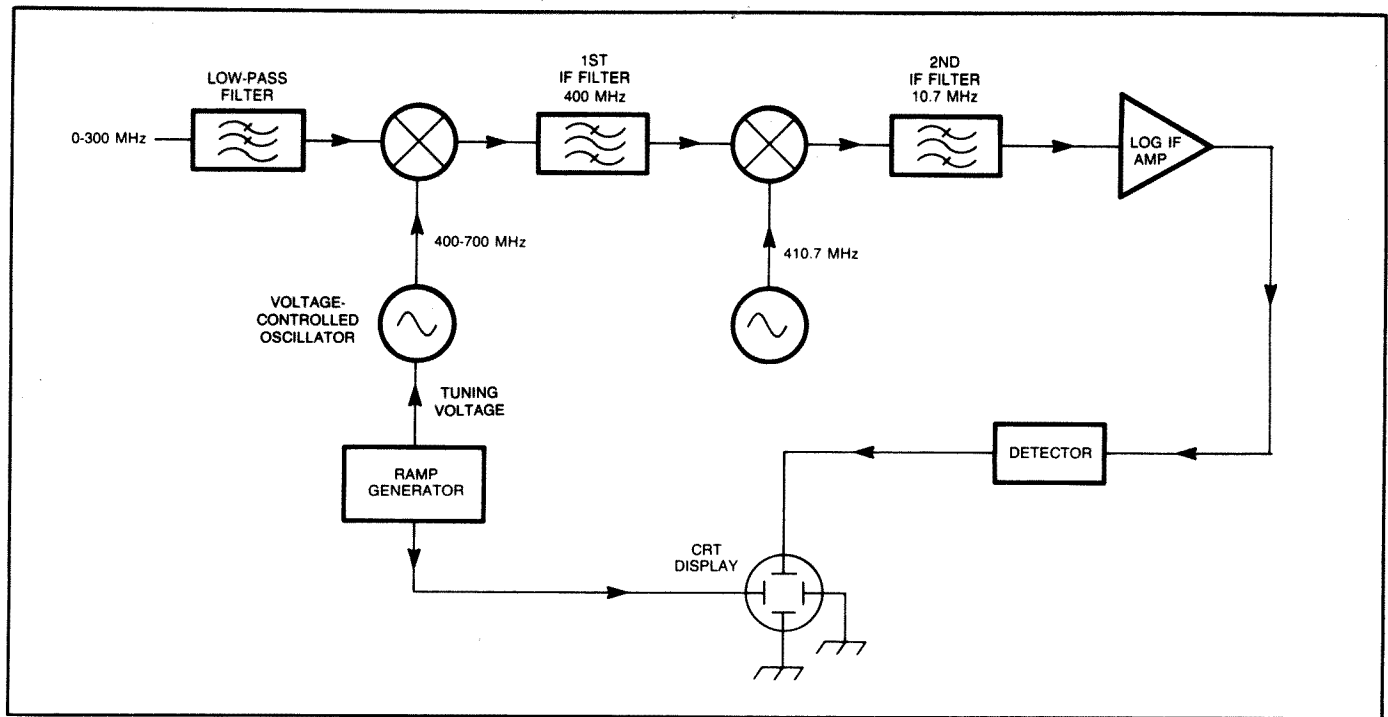

Fig 81—A block diagram of a superheterodyne spectrum analyzer.

The frequency domain can contain information not found in the time domain and therefore the spectrum analyzer offers advantages over the oscilloscope for certain measurements. As might be expected, there are some measurements that require data gathering to be done in the time domain. In these cases, the oscilloscope is an invaluable instrument.

There are several different types of spectrum analyzers, but by far the most common is nothing more than an electronically-tuned superheterodyne receiver. The receiver is tuned using a ramp voltage; this ramp voltage performs two functions: First, the ramp voltage sweeps the frequency of the analyzer local oscillator. Second, the ramp is used to deflect the horizontal axis of a CRT display, as shown in Fig 81. The vertical axis of the CRT display is provided deflection from the signal strength of the received signal. In this way, the CRT display has frequency on the horizontal axis and signal strength on the vertical axis.

Most spectrum analyzers use the up-converting technique so that a fixed-tuned input filter is capable of removing the image. Only the first local oscillator need be tuned to tune the receiver. In the up-conversion design, a wideband input is converted to an IF higher than the highest input frequency. As with most up-converting communications receivers, it is not easy to achieve the desired ultimate selectivity at the first IF, because of the rather high frequency. For this reason, dual or higher orders of conversion are used to generate an IF low enough that the desired selectivity can be achieved practically. In the example of Fig 81 dual conversion is

used; the first IF is at 400 MHz with a second IF at 10.7 MHz.

In the example spectrum analyzer, the first local oscillator is swept from 400 MHz to 700 MHz; this converts the input (from nearly 0 MHz to 300 MHz) to the first IF of 400 MHz. The usual rule of thumb for varactor-tuned oscillators is that the maximum practical tuning ratio (the ratio of the highest frequency to the lowest frequency) is an octave or a two-to-one ratio. As it can be seen from the example spectrum analyzer, the tuning ratio of the first local oscillator is 1.75 to one, which meets this specification.

The image frequency spans 800 MHz to 1100 MHz and is easily eliminated using a low-pass filter with a cut-off frequency around 300 MHz. The 400-MHz first IF is converted to 10.7 MHz where the ultimate selectivity of the analyzer is obtained. The image of the second conversion, (421.4 MHz), is eliminated by the first IF filter. The attenuation of the image should be rather great, on the order of 60 to 80 dB. This requires a first IF filter with a high Q; this is achieved by using helical resonators, SAW resonators or cavity-type filters. Another method of eliminating the image problem is to use triple conversion; converting first to an intermediate IF such as 50 MHz and then to 10.7 MHz. As with any receiver, an additional frequency conversion requires added circuitry and produces further potential spurious responses.

Most of the signal amplification takes place at the lowest IF; in the case of the example analyzer this is 10.7 MHz. This is where the communications receiver and the spectrum analyzer differ. A communi-

cations receiver demodulates the incoming signal so that the modulation can be heard or further demodulated for RTTY or packet or other mode of operation. In the spectrum analyzer, only the signal strength is needed.

In order for the spectrum analyzer to be most useful, it should be convenient to display signals of widely different levels. As an example, signals differing by 60 dB, which is a thousand to one difference in voltage or a million to one in power, would be difficult to display. This would mean that if power were displayed, one signal would be one million times larger than the other (in the case of voltage one signal would be a thousand times larger). In either case it would be difficult to display both signals on a CRT. The solution to this problem is to use a logarithmic display and to display the relative signal levels in decibels. Using this technique, a one-thousand-to-one ratio of voltage reduces to a sixty-decibel difference.

The conversion of the signal to a logarithm is usually performed in the IF amplifier or detector, resulting in an output voltage proportional to the logarithm of the input RF level. This output voltage is then used to drive the CRT display.

### Spectrum Analyzer Performance Specifications

The performance parameters of a spectrum analyzer are specified in terms similar to those used for radio receivers, in spite of the fact that there are many differences between a receiver and a spectrum analyzer.

The *sensitivity* of a receiver is often specified as the minimum detectable signal, which means the smallest signal that can

be heard. In the case of the spectrum analyzer, it is not the smallest signal that can be heard, but the smallest signal that can be seen. The *dynamic range* of the spectrum analyzer determines the largest and smallest signals that can be viewed on the analyzer. As with a receiver, there are several factors that can affect dynamic range, such as intermodulation distortion, 2nd and 3rd order distortion and blocking. *IMD dynamic range* is the maximum difference in signal level between the minimum detectable signal and the level of two signals of equal strength that generate an intermodulation product equal to the minimum detectable signal.

This is a good point to explain another of the significant differences between a communications receiver and a spectrum analyzer. Although the communications receiver is an excellent example to introduce the spectrum analyzer, there are several differences such as the previously explained lack of a demodulator. Unlike the communications receiver, the spectrum analyzer is not a sensitive radio receiver. To preserve a wide dynamic range, the spectrum analyzer often uses passive mixers for the first and second mixers. Therefore, referring to Fig 81, the noise figure of the analyzer is no better than the losses of the input low pass filter plus the first mixer, the first IF filter, the second mixer and the loss of the second IF filter. This often results in a combined noise figure of more than 20 dB. With that kind of noise figure the spectrum analyzer is obviously not a communications receiver for extracting very weak signals from the noise but a measuring instrument for the analysis of frequency spectrum.

The *selectivity* of the analyzer is called the *resolution bandwidth*. This term refers to the minimum frequency separation of two signals of equal level that can be resolved so that there is a 3-dB dip between the two. The IF filters used in a spectrum analyzer differ from a communications receiver in that the filters in a spectrum analyzer have very gentle skirts and rounded passbands, rather than the flat passband and very steep skirts used on an IF filter in a high-quality communications receiver. This rounded passband is necessary because the signals pass into the filter passband as the spectrum analyzer scans the desired frequency range. If the signals suddenly pop into the passband (as they would if the filter had steep skirts), the filter tends to ring; a filter with gentle skirts is less likely to ring. This ringing, called *scan loss*, distorts the display and requires that the analyzer not be swept in frequency at an excessive rate. All this means that the scan rate must be checked periodically to be certain that the signal amplitude is not affected by excessive rate.

### Spectrum Analyzer Applications

When and where is a spectrum analyzer used? Spectrum analyzers are used in situations where the signals to be analyzed are

very complex and an oscilloscope display would be an undecipherable jumble. The spectrum analyzer is also used when the frequency of the signals to be analyzed is very high. Although high-performance oscilloscopes are capable of operation into the UHF region, moderately-priced spectrum analyzers can be used well into the GHz region.

The spectrum analyzer can also be used to view very low-level signals. For an oscilloscope to display a VHF waveform, the bandwidth of the oscilloscope must extend from zero to the frequency of the waveform. If harmonic distortion and other higher-frequency distortions are to be seen the bandwidth of the oscilloscope must exceed the fundamental frequency of the waveform. This broad bandwidth can also admit a lot of noise power. The spectrum analyzer, on the other hand, analyzes the waveform using a narrow bandwidth; thus

it is capable of reducing the noise power admitted.

Probably the most common application of the spectrum analyzer is the measurement of the harmonic content and other spurious signals in the output of a radio transmitter. Fig 82 shows two ways to connect the transmitter and spectrum analyzer. The method shown at A should not be used for wide-band measurements since most line-sampling devices do not exhibit a constant-amplitude output over a broad frequency range. Using a line sampler is fine for narrow-band measurements, however. The method shown at B is used in the ARRL Lab.

The attenuator must be capable of dissipating the transmitter power, and it must have sufficient attenuation to protect the spectrum analyzer input. Many spectrum analyzer mixers can be damaged by only a few milliwatts, so most analyzers

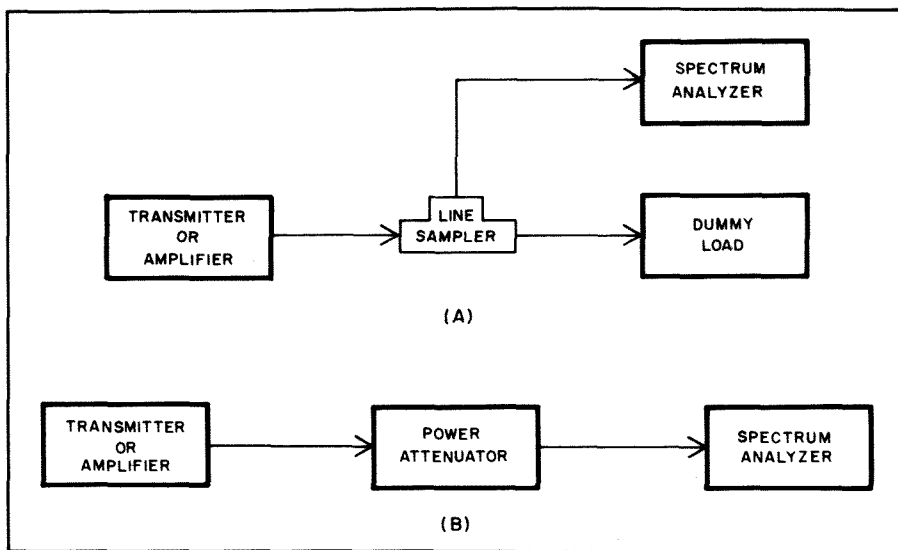

Fig 82—Two commonly used setups for observing the output of a transmitter or amplifier on a spectrum analyzer. The system at A uses a line sampler to pick off a small amount of the transmitter or amplifier power. At B, the majority of the transmitter power is dissipated in the power attenuator.

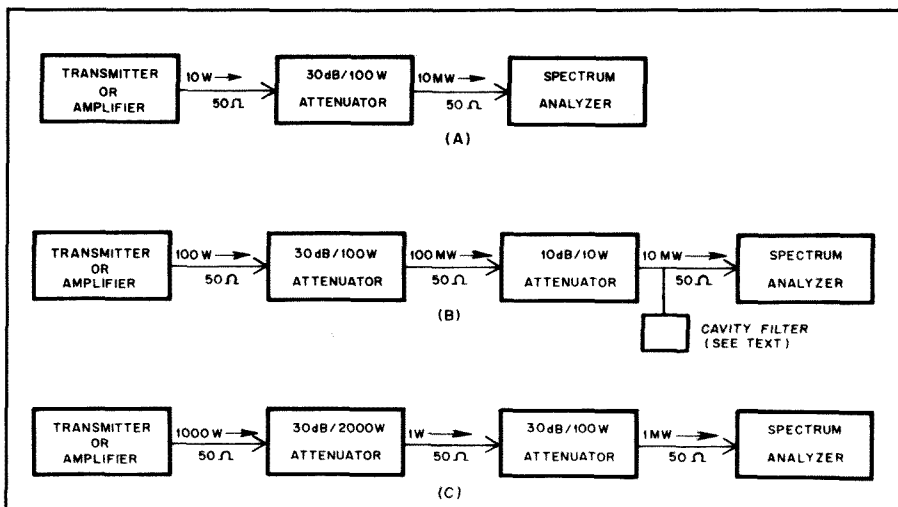

Fig 83—ARRL laboratory test setup for transmitters or amplifiers with several different power levels.

have an adjustable input attenuator that will provide a reasonable amount of attenuation to protect the sensitive input mixer from damage. The power limitation of the attenuator itself is usually on the order of a watt or so, however. This means that 20 dB of additional attenuation is required for a 100 watt transmitter, 30 dB for a 1000 watt transmitter, and so on, to limit the input to the spectrum analyzer to one watt. There are specialized attenuators that are made for transmitter testing; these attenuators provide the necessary power dissipation and attenuation in the 20 to 30 dB range.

The test setup used in the ARRL laboratory for measuring an HF transmitter or amplifier is shown in Fig 83. As can be seen, different power levels dictate different amounts of attenuation between the transmitter or amplifier and the spectrum analyzer.

When using a spectrum analyzer it is very important that the maximum amount of attenuation be applied before a measurement is made. In addition, it is a good practice to view the entire spectrum of a signal before the attenuator is adjusted. The signal being viewed could appear to be at a safe level, but another spectral component, which is not visible, could be above the damage limit. It is also very important to limit the input power to the analyzer when pulse power is being measured. The *average* power may be small enough so that the input attenuator is not damaged, but the *peak* pulse power, which may not be readily visible on the analyzer display, can destroy a mixer, literally in microseconds.

Fig 84 shows the broadband spectrum of a transmitter, showing the harmonics in the output. The horizontal (frequency) scale is 5 MHz per division; the main output of the transmitter at 7 MHz can be seen about 1.5 major divisions from the left of the trace. A very large apparent signal is seen at the extreme left of the trace. This occurs at what would be zero frequency and it is caused by the first local oscillator frequency being exactly the first IF. All up-converting superheterodyne spectrum analyzers have this IF feedthrough; in addition, this signal is occasionally accompanied by smaller spurious signals generated within the analyzer. To determine what part of the displayed signal is a spurious response caused by IF feedthrough and what is an actual input signal, simply remove the input signal and observe the trace.

It is not necessary or desirable that the transmitter be modulated for this broadband test. Investigating the sidebands from a modulated transmitter requires a narrow band spectrum analysis and produces displays similar to that shown in Fig 85. The test setup used to produce this display is shown in Fig 86. In this example a two-tone test signal is used to modulate the transmitter. Fig 85 shows the two test tones plus some of the intermodulation produced by the single-sideband transmitter.

(A)

(B)

Fig 84—Spectrum analyzer display of two different transmitters on the 40-meter band. Each horizontal division represents 5 MHz and each vertical division is 10 dB. The photograph at A shows a clean transmitted signal; the transmitter at B shows more spurious signal content. Both transmitters are legal, however, according to current FCC spectral purity requirements.

Fig 85—Spectrum analyzer photograph showing the result of an SSB transmitter two-tone test. Each horizontal division represents 1 kHz and each vertical division is 10 dB. The third-order products are 30 dB below the PEP (top line), the fifth-order products are down 37 dB and seventh-order products are down 44 dB. This represents acceptable (but not ideal) performance.

When using a spectrum analyzer it is necessary to ensure that the analyzer does not generate additional spurious signals that are then attributed to the system under test. Some of the spurious signals that can be generated by a spectrum analyzer are harmonics and intermodulation distortion. If it is desired to measure the harmonic levels of a transmitter at a level below the

spurious level of the analyzer itself, a notch filter can be inserted between the attenuator and the spectrum analyzer as shown in Fig 87. This reduces the level of the fundamental signal and prevents that signal from generating harmonics within the analyzer, while still allowing the harmonics from the transmitter to pass through to the analyzer without attenuation. Caution should be used when using this technique; detuning the notch filter or inadvertently changing the transmitter frequency will allow potentially high levels of power to enter the analyzer. In addition, care must be exercised with the choice of filters; some filters (such as cavity filters) will respond not only to the fundamental but will notch out odd harmonics as well.

It is good practice to check for the generation of spurious signals within the spectrum analyzer. When a spurious signal is generated by a spectrum analyzer, adding attenuation at the analyzer input will cause the internally generated spurious signals to decrease by an amount greater than the added attenuation. If attenuation added ahead of the analyzer causes all of the visible signals to decrease by the same amount, this indicates a spurious-free display.

The input impedance for most RF spectrum analyzers is 50 ohms; not all circuits

Fig 86—The test setup used in the ARRL laboratory for measuring the IMD performance of transmitters and amplifiers.

Fig 87—A notch filter can be used to reduce the level of a transmitter's fundamental signal so that the fundamental does not generate harmonics within the analyzer.

Fig 88—A voltage probe designed for use with a spectrum analyzer.

have convenient 50-ohm connections that can be accessed for testing purposes, however. Using a probe such as the one shown in Fig 88 allows the analyzer to be used as a troubleshooting tool. The probe can be used to track down signals within a transmitter or receiver, much like an oscilloscope is used. The probe shown offers a 100-to-one voltage reduction and provides a loading to the circuit of 5000 ohms.

A different type of probe is shown in Fig 89. This inductive pickup coil (sometimes called a "sniffer") is very handy for troubleshooting. The coil is used to couple signals from the radiated magnetic field of a circuit into the analyzer. A short length of miniature coax is wound into a pick-up loop and soldered to a larger piece of coax. The use of the coax shields the loop from coupling energy from the electric field component. The dimensions of the loop are not critical, but the smaller the dimensions of the loop, the more accurate the loop will be in locating the source of radiation of RF energy. The shield of the coax provides a complete electrostatic shield without introducing a shorted turn.

The sniffer allows the spectrum analyzer to sense RF energy without contacting the circuit being analyzed. If the loop is brought near an oscillator coil, the oscillator can be tuned without directly contacting (and thus disturbing) the circuit. The oscillator can then be checked for reliable starting and the generation of spurious sidebands. With the coil brought near the

tuned circuits of amplifiers or frequency multipliers, those stages can be tuned using a similar technique.

Even though the sniffer does not contact the circuit being evaluated, it does extract some energy from the circuit. For this reason, the loop should be placed as far from the tuned circuit as is practical. If the loop is placed too far from the circuit, the signal will be too weak or the pick-up loop will pick up energy from other parts of the circuit and not give an accurate indication of the circuit under test.

One very handy application of the sniffer is to locate sources of RF leakage. By probing the shields and cabinets of RF generating equipment (such as transmitters) egress and ingress points of RF energy can be identified by indications on the analyzer display.

One very powerful characteristic of the spectrum analyzer is the instrument's capability to measure very low-level signals. This characteristic is very advantageous when very high levels of attenuation are measured. Fig 90 shows the set-up for tuning the notch and bandpass of a VHF duplexer. The spectrum analyzer, being capable of viewing signals well into the low microvolt region, is capable of measuring the insertion loss of the notch cavity more than 100 dB below the signal generator output. Making a measurement of this sort requires care in the interconnection of the equipment and a well-designed spectrum analyzer and signal generator. RF energy

Fig 89—An inductive pickup loop, called a "sniffer" probe. This probe does not load the circuit under test. See text for details.

leaking from the signal generator from the cabinet, the line cord or even the coax itself, can leak into the spectrum analyzer through similar paths and corrupt the measurement. This leakage can make the measurement look either better or worse than the actual attenuation depending on the phase relationship of the leaked signal.

### Extensions of Spectral Analysis

What if a signal generator is connected to a spectrum analyzer so that the signal generator output frequency is exactly the same as the receiving frequency of the spectrum analyzer? It would certainly appear to be a real convenience not to have to continually reset the signal generator to the desired frequency. It is, however more than a convenience. A signal generator connected in this way is called a *tracking generator* because the output frequency tracks the spectrum analyzer input frequency. The tracking generator makes it possible to make sweep-frequency measurements of the attenuation characteristics of circuits, even when the attenuation involved is large as the bandpass of narrow filters such as the cavity described in the previous example.

Fig 91 shows the connection of a tracking generator to a circuit under test. In order for the tracking generator to create an output frequency exactly equal to the input frequency of the spectrum analyzer, the internal local oscillator frequencies of the spectrum analyzer must be known; this is the reason for the interconnections between the tracking generator and the spectrum analyzer. The test set-up of Fig 91 will measure the gain or loss of the circuit under test. Only the magnitude of the gain or loss is available; in some cases, the phase angle between the input and output would also be an important and necessary parameter.

The spectrum analyzer is not sensitive to the phase angle of the tracking generator output. In the process of generating the tracking generator output, there were no guarantees that the phase of the tracking generator would be either known or constant. This is especially true of VHF spectrum analyzers/tracking generators where a few inches of coaxial cable represents a

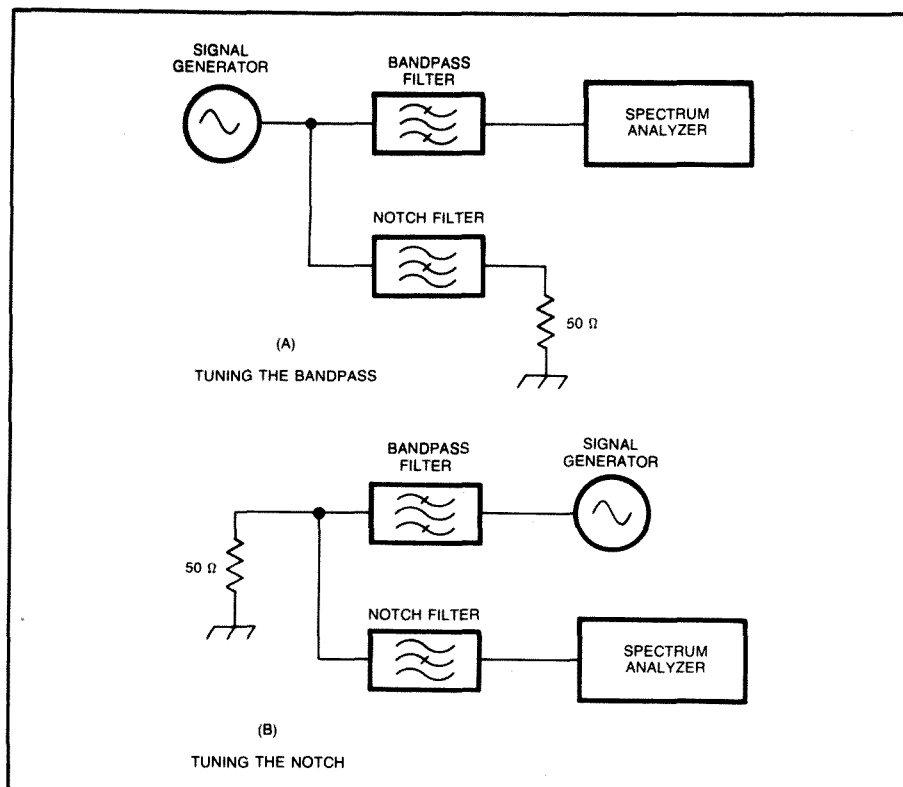

Fig 90—A spectrum analyzer and signal generator can be used to tune the bandpass and notch filters of a duplexer. Leakage around the duplexer must be kept to a minimum.

number of degrees of phase shift.

One effective way of measuring the phase angle between the input and output of a device under test is to sample the phase of the signal applied to the device under test and apply the sample to a phase detector. The phase of the output of the device under test is also sampled and applied to the phase detector. Fig 92 shows a block diagram of this technique. An instrument that can measure both the magnitude and phase

of a signal is called a *vector network analyzer*, or simply a network analyzer.

The magnitude and phase can be displayed either separately or together. When the magnitude and phase are displayed together the two can be presented as two separate traces similar to the two traces on a dual-trace oscilloscope. A much more useful method of display is to present the magnitude and phase as a polar plot where the locus of the points of a vector having

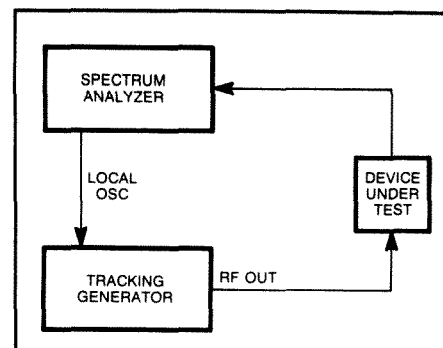

Fig 91—Filter response over a range of frequencies can be plotted by tracking a signal generator with the local oscillator of the spectrum analyzer.

Fig 92—A network analyzer can measure both the phase and magnitude of the filter input and output signals. See text for details.

the length of the magnitude and the angle of the phase are displayed. Very sophisticated network analyzers can display all of the S parameters of a circuit in either a polar format or a Smith chart format.

#### Spectrum Analyzer Bibliography

Helfrick, A D, "An Inexpensive Spectrum Analyzer for The Radio Amateur," *QST*, Nov 1985.  
Helfrick, A D, "A Pocket-Sized Spectrum Analyzer," *RF Design*, Jan 1988.

# Troubleshooting and Repair

**T**raditionally, the radio amateur has maintained a working knowledge of station equipment. This knowledge, and the resourcefulness to make repairs with whatever supplies are available, keeps amateur installations operating when all other communications fail. The radio amateur's ability to troubleshoot and repair equipment is not only a tradition; it is fundamental to the existence of the service.

Every amateur must make a decision when faced with equipment failure. Not everyone is an electronics wizard; your set may end up at the repair shop. The theory you learned for the FCC examinations and the information in this handbook can help you make an intelligent choice. If the problem is something simple (and most are), why not avoid the effort of shipping the radio to the manufacturer? Although the saving of time and money is gratifying, the experience and confidence gained may prove far more valuable. Especially when a problem appears during an emergency.

Troubleshooting and repair of electronic gear need not be a mystical subject. It is more like detective work. A knowledge of complex math is not required. However, one must have, or develop, the ability to read a schematic diagram and to visualize signal flow through the circuit. A working knowledge of resistors, capacitors, inductors and semiconductor devices, and how they affect the dc resistance of a network, is also necessary. The fundamental concepts are covered elsewhere in this book.

We are all a bit nervous when we enter new territory. Do not be intimidated by the intricate circuits of a modern radio. Even the most complex transceiver is made up of relatively simple circuits. As you gain experience, you will develop a first-hand understanding of circuit functions. This insight, and the confidence gained from experience, distinguish the skillful troubleshooter.

### SAFETY FIRST

*Always! Death is permanent.* Before we

---

**Table 1**  
**Safety Rules**

- 1) Keep one hand in your pocket when working on "live" circuits or checking to see that capacitors are discharged.
  - 2) Include a conveniently located ground-fault-interrupter/circuit breaker in the workbench wiring.
  - 3) Use grounded plugs and receptacles on all equipment that is not double insulated.
  - 4) Use double-insulated equipment when working:
    - a) outdoors.
    - b) on a concrete or dirt floor.
    - c) near standing water.
  - 5) Use an isolation transformer when working on ac/dc devices.
  - 6) Switch off the power, ground the positive lead from the supply and discharge capacitors when making circuit changes.
  - 7) Do not subject electrolytic capacitors to:
    - a) excessive voltage.
    - b) ac.
    - c) reverse voltage.
  - 8) Test leads should be well insulated.
  - 9) Do not work alone!
  - 10) Wear safety glasses for protection against sparks and metal fragments.
  - 11) Always use a safety belt when working above ground level.
  - 12) Wear shoes with nonslip soles that will support your feet when climbing.
  - 13) Wear a hard hat when someone is working above you.
  - 14) Be careful with tools that may cause short circuits.
  - 15) Replace fuses only with those having proper ratings.
- 

begin considering the equipment and techniques of troubleshooting, we must discuss the preservation of the worker and his tools.

Electricity can be lethal. Only 50 mA flowing through the body is painful; 100 to 500 mA is usually fatal. Under certain conditions, as little as 24 V can kill. Keep one hand in your pocket while working on "live" circuits to prevent the possibility of resting your free hand on a ground. This reduces the risk of electricity passing

through your chest (the most fatal current path). A list of safety rules can be found in Table 1.

### TEST EQUIPMENT

Test equipment is required for efficient troubleshooting. We cannot see electrons flow. Electrons do affect various devices in our equipment, however, with results that we can see.

Many fear that repairing their own ham gear means purchasing a bench full of expensive test instruments. This is not so! In fact, you probably already own the most important instruments. Some others may be purchased inexpensively, rented, borrowed or built at home. A shortage of test gear may limit the kind of repairs you attempt, but do not let it stop you from making repairs that *are* within your capabilities.

Most hams elect to buy test gear. Before buying, consider whether your use of the item merits the expense. Instruments that do not give sufficient return for an individual, may for a club. Expensive test instruments look more reasonable when the cost is split among the members of a club (and a pool of test gear may also serve to pull a sleepy club out of the doldrums).

I mentioned that you already own some of the most important instruments. We each have some of these natural test instruments.

- **Eyes** — Use them to search for evidence of heat or arcing. Often these conditions are indicated by discoloration or charring of components and circuit boards.
- **Ears** — Gross distortion can be detected by ear. The "snaps" and "pops" of arcing or the sizzling of a burning component may help you track down circuit faults.
- **Nose** — Arcing in a circuit produces ozone (what you sometimes smell in the air during a thunderstorm). Smoke from hot components can usually be smelled before it is seen. Some components emit a "hot" smell when overheated. This

<sup>††</sup>Write for manual prices (specify model).

smell remains long after power is removed. Nerves in the nose are extremely sensitive; heat that generates no smell can be felt when brought within 1 or 2 inches of the nose.

- **Fingers** — Use your fingers to measure low heat levels in components. Solid-state devices are temperature sensitive; if you can hold your finger on them while they are operating (be careful!), they are cool enough. If an operating device is too hot to hold, check for excessive current flow; additional heat sinks may be required.
- **Brain** — More troubleshooting problems have been solved with a VOM and a brain than with the most expensive spectrum analyzer. Use your brain to assemble information and analyze data collected by other instruments. (The magnifying glass did not make Sherlock Holmes famous; it was his mind!)

**Information**

There is a sea of information available (a bibliography is included at the end of this chapter). Sometimes it is difficult to find information on a specific item, but remember that Amateur Radio offers a great resource to each of us. Check into a few roundtable QSOs and ask for help. There are over 400,000 hams in the U.S.; chances are someone else has had the same trouble you are experiencing. Look in

Amateur Radio publications; ownership clubs for particular radios may advertise.

Before beginning work, obtain a manual for the radio. An owner's manual or schematic is mandatory; a service manual is better. Some sources of manuals are listed in Table 2.

ARRL members have other resources. ARRL Hq. may be able to provide copies of manuals that are in the ARRL files, and equipment-modification references for back issues of *QST*.<sup>1</sup> Place a "HamAds" listing in *QST* when searching for a rare manual.

The ARRL Technical Coordinator (TC) program may also be able to help. TCs and Assistant Technical Coordinators (ATCs) are volunteers who are willing to help hams with technical questions. For the name of a local ATC, contact your Section Manager (listed on page 8 of any issue of *QST*).

**ELECTRONIC TEST EQUIPMENT**

Simple test gear is frequently included in the equipment under repair. Nearly all receivers include a speaker. An S meter is usually connected ahead of the audio chain. If the S meter shows signals, the RF chain is probably functioning. The antenna jack of a receiver can serve as a crude signal in-

jector. (Noise should be heard from the speaker when a test lead is rubbed against the center conductor of the antenna jack.) Some receivers include a calibrator. The calibrator signal, which is rich in harmonics, is injected in the RF chain close to the antenna jack and may be used for signal tracing and alignment. Every transmitter has an oscillator that may be used as a signal generator.

Spare components enable you to test by substitution. A lot of troubleshooting may be done without what is normally called test equipment.

Here is a summary of test instruments and their applications. Some items serve several purposes and may substitute for others on the list. The list does not cover all equipment available, only the most common and useful instruments.

- **Multimeters** — This group includes vacuum-tube voltmeters (VTVMs), volt-ohm-milliammeters (VOMs), field-effect-transistor VOMs (FETVOMs), digital multimeters (DMMs). Meter operation and use is explained in Chapter 25.

Look for a meter with an input impedance of 20 k $\Omega$ /V or better. Reasonably priced models are available with 30 k $\Omega$ /V (\$35) and 50 k $\Omega$ /V (\$40).

The high-Z input characteristic of FETVOMs, VTVMs and other electronic voltmeters makes them the preferred instruments for voltage measurements. DMMs are usually high-Z meters, but they may be sensitive to RF. Most technicians keep an analog-display VOM handy for use near RF equipment.

Multimeters are used to read bias voltage, circuit resistance, presence and level of signal (with an appropriate probe). They can test resistors, capacitors (within certain limitations), diodes and transistors.

- **Test Leads** — Keep an assortment of leads that terminate in medium and small alligator clips. It is best to make your own leads because ready-made leads use small wire that is not soldered to the clips.

Open wire leads (Fig. 1A) can pick up RFI that disturbs measurements. RFI is reduced somewhat if the leads are twisted together (Fig. 1B). A coaxial cable lead (Fig. 1C) *increases* RFI problems *if* the shield is *not* grounded. The cable shield must be grounded to reduce RFI.

Low capacitance, or  $\times 10$ , probes (Fig. 1D) are used to reduce the effect of instrument-input and shield capacitance on the circuit under test. A network in the probe serves as a 10:1 divider and compensates for frequency distortion in the cable and test instrument. The trimmer capacitor on  $\times 10$  and  $\times 100$  oscilloscope probes should be adjusted for the best-looking square wave from the internal calibrator. See Fig. 1H.

Demodulator probes (see Fig. 1E and Chapter 25) convert ac voltages to dc for measurement. They are also used to allow scope triggering from a modulation envelope.

<sup>1</sup>Write to ARRL Headquarters for information on costs and availability of specific manuals, copies and back issues.

Fig. 1 — An array of test probes for use with various test instruments.

A capacitively coupled probe (Fig. 1F) can be made from a connector and a length of coax cable. Remove about  $\frac{3}{4}$  inch of the cable jacket at one end. Trim the shield to  $\frac{1}{2}$  inch from the end and tin it. Use some RTV (room-temperature-vulcanizing) adhesive to seal the end against moisture. Install the connector at the other end of the cable.

Capacitive coupling increases with proximity and potential at the test point. Be very careful with this probe around high voltage. (The dielectric strength of air is about 80 V per 0.001 inch.)

A probe for inductive coupling (Fig. 1G) can be made in similar fashion. Connect a two- or three-turn loop across the center conductor and shield before sealing the

end. The inductive pick up is useful for coupling to high-current points.

• SWR Meter — Every shack should have one! It can be the first indicator of antenna trouble. The SWR meter can also be used between an exciter and power amplifier to spot an impedance mismatch.

Simple meters indicate relative SWR and are fine for Transmatch adjustment and

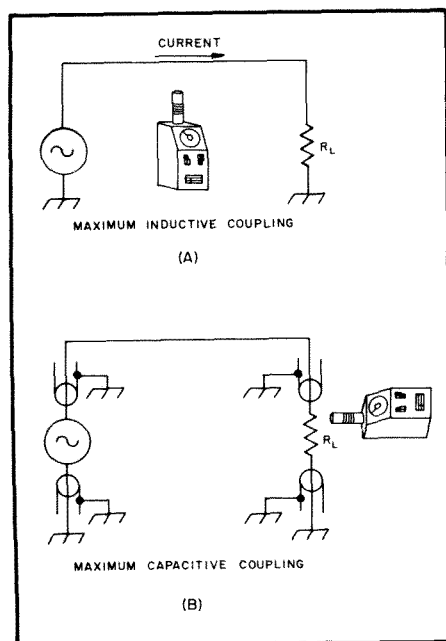

Fig. 2 — Optimum inductive and capacitive dip-meter coupling.

line monitoring. However, if you want to make accurate measurements of antenna impedance or calculate SWR at the antenna feed point, a calibrated wattmeter with a directional coupler is required (one is shown in Chapter 25).

- **Dummy Load** — This is a necessity! Do not put a signal on the air while repairing equipment. Courtesy demands that we spare other amateurs from the QRM of tests until we are reasonably sure of the repair. More important, before a transmitter is fixed, we have no idea what spurious emissions it may generate. A dummy load also works to the technician's benefit by providing a known, matched load for use during adjustments.

When buying a dummy load, avoid used, oil-cooled dummy loads unless you can be sure that the oil does not contain PCBs. This biologically hazardous compound was common in transformer oil until a few years ago.

- **Dip Meter** — This device is often called a transistor dip meter or a grid-dip oscillator (from vacuum-tube days). Principles of dip-meter operation are covered in Chapter 25.

Most dip meters can also serve as an absorption frequency meter (in this mode, measurements are read at the current peak, rather than the dip). Further, some meters have a connection for headphones. The operator can usually hear signals that do not register on the meter. Because the dip meter is an oscillator, it can be used as a signal generator in certain cases where high accuracy or stability are not required.

A dip meter may be coupled to a circuit either inductively or capacitively. Inductive coupling results from the magnetic field generated by current flow. Therefore, inductive coupling should be used when a

Fig. 3 — An oscilloscope display showing the relationship of the time-base setting and graticule lines.

conductor with relatively high current flow is convenient. Maximum inductive coupling results when the axis of the pick-up coil is placed perpendicular to a nearby current path (see Fig. 2A).

Capacitive coupling is required when current paths are magnetically confined or shielded. (Toroidal inductors and coaxial cables are common examples of magnetic self shielding.) Capacitive coupling depends on the electric field produced by voltage. Use capacitive coupling when a point of relatively high voltage is convenient. Capacitive coupling is maximum when the end of the pick-up coil is near a point of high voltage (see Fig. 2B). In either case, the circuit under test is affected by the presence of the dip meter. Always use the minimum coupling that yields a noticeable indication.

Use the following procedure to make reliable measurements. First, bring the dip meter gradually closer to the circuit while slowly varying the dip-meter frequency. When a current dip occurs, hold the meter steady and tune for minimum current. Once the dip is found, move the meter away from the circuit and confirm that the dip comes from the circuit under test (the current reading should increase with distance from the circuit until the dip is gone). Finally, move the meter back toward the circuit until the dip is just noticed. Retune the meter for minimum current and read the dip-meter frequency with a calibrated receiver or frequency meter.

The current dip of a good measurement is smooth and symmetrical. A non-symmetrical dip indicates that the dip-meter oscillator frequency is being significantly influenced by the test circuit. Such conditions do not yield usable readings.

When purchasing a dip meter, look for one that is mechanically and electrically stable. The coils should be in good condition. A headphone connection is helpful. Battery-operated models are easier to use for antenna measurements.

- **Oscilloscope** — A picture is worth a

Fig. 4 — Information available from a typical oscilloscope display of a waveform.

thousand words, and the moving trace of a 'scope can give us more information about a signal than any other piece of test gear. A discussion of oscilloscope basics appears in Chapter 25.

The simplest way to display a waveform is to connect the vertical amplifier of the 'scope to a point in the circuit through a simple test lead. (When viewing RF, use a low-capacitance probe that has been "matched" to (compensated for) the 'scope amplifier.) See Fig. 1F. First, check to make sure that the circuit under test is isolated from the ac line by a transformer. Set the vertical-amplifier sensitivity so the circuit voltage will cover about half of the CRT screen. Connect the 'scope leads. Set the sweep-rate (sometimes called the TIME-BASE control so that one or more cycles are shown (see Fig. 3). Adjust the SYNC and SYNC-LEVEL controls for a stable display. Line sync only "locks" signals that are some multiple of 60 Hz.

An examination of the waveform gives peak-to-peak voltage (if calibrated), approximate period (frequency is the reciprocal of the period) and a rough idea of signal purity (see Fig. 4). If the 'scope has dual trace (can display two signals at once) capability, a second waveform may be displayed and compared to the first. When the two signals are taken from the input and output of a stage, stage linearity and phase shift can be checked (see Fig. 5).

Other display techniques are covered in previous chapters and later in this chapter. For more information, see the bibliography at the end of this chapter.

A primary performance characteristic of a 'scope is amplifier bandwidth. This specification tells us the frequency at which amplifier response has dropped 3 dB. The instrument will display higher frequencies, but cannot be used for accurate measurement of them. Expect an accuracy of no better than 3% when a 'scope is used well below its rated bandwidth. Most 'scope applications in Amateur Radio, however, do not require accurate measurements. Thus,

Fig. 5 — A dual-trace scope display of amplifier input and output waveforms.

'scopes are useful to hams well beyond the specifications. Do not believe that transmitter emissions are clean based only on a 'scope display. A bandwidth of 250 to 500 MHz is required to display all significant harmonics from an HF transmitter.

When buying a 'scope, get the greatest bandwidth you can afford. Old and wide is better than new and narrow, with respect to bandwidth. Old Hewlett Packard or Tektronix scopes of great bandwidth are occasionally sold at hamfests. Keep to well-known manufacturers when buying a used scope, or any test equipment for that matter.

• **Signal Generators** — Although signal generators are used for sophisticated circuit tests, their role in troubleshooting is limited to use in signal injection and alignment techniques. An AF/RF signal-injector schematic is shown in Fig. 6. For those instances where more accuracy is needed, the crystal-controlled signal source of Fig. 7 can be used. The AF/RF circuit provides usable harmonics up to 30 MHz, while the crystal-controlled oscillator will function with crystals from 1 to 15 MHz. These two projects are not meant to compete with standard signal generators, but they are adequate for signal injection.<sup>2</sup> A better generator is required for receiver alignment or for receiver quality testing.

When shopping for a signal generator, look for one with a pure sine-wave signal. A good signal generator is double or triple shielded against leakage. Fixed-frequency audio should be available for modulation of the RF and for injection into audio stages. The frequency control of a good generator does not slip or exhibit backlash. Signal level should be controlled by a switch, labeled in dBm, not a potentiometer. The output jack should be a coaxial connector (usually a BNC), not the kind used for microphone connections. Some older, high-quality units are common. Look for World War II surplus units of the

URM series, Hewlett Packard/Boonton model 202, Measurements Inc. model 80 and 65, military units TS-497 and BC-221 and Hewlett Packard model 606. (The Technical Department at ARRL Headquarters has a bibliography of articles about the BC-221 that includes a solid-state conversion and calibration technique.) Home-built signal generators may be quite good, but make sure to check construction techniques, level control and shielding quality. Some 1000-Hz square-wave generators produce harmonics that are useful up to 10 MHz.

- **Signal Tracers** — Signals can be traced with a voltmeter and an RF probe, a dip meter or an oscilloscope, but there are some devices made especially for signal tracing. Most convert the traced signal to audio (often using a voltmeter RF probe) and apply the amplified audio to a speaker. The tracer must function as a receiver and detector for each frequency range in the test circuit. A high-impedance tracer input is necessary to prevent circuit loading.

An old radio can be converted into a signal injector/tracer for use with common IFs (Fig. 8). Modify the radio so a test probe can be connected to each functional block. If the stages preceding the test probe are disabled, the set is a signal tracer; if the preceding stages are operating, the set is a signal injector. (Use a step attenuator to adjust injected-signal level.) Avoid ac/dc radios for this use.

A general-coverage receiver can be used to trace signals in radios with uncommon IFs. Most receivers, however, have a low-impedance input that severely loads the test circuit. To minimize loading, use a capacitive probe. When the probe is held near the circuit, signals will be picked up and carried to the receiver. It may also pick up stray RF; make sure you are listening to the correct signal by switching the circuit under test on and off while listening.

Dedicated signal tracers are limited test instruments. All things considered, a dip meter, with an absorptive mode and a headphone connection, is a much better value.

- **Tube Tester** — Two types of tube

testers are common. The first is the emission tester. As the name implies, this tester checks the tube by measuring the amount of electron emission from the cathode (cathode current,  $I_c$ ). Each grid is shorted to the plate through a switch and the current is observed while the tube operates as a diode. By opening the switches from each grid to the plate (one at a time) we can check for opens and shorts. If the plate current does not drop slightly as a switch is opened, the element connected to that switch is either open or shorted to another element. We cannot tell an open from a short with this test. The emission tester does not indicate the ability of a tube to amplify.

The other common tube tester checks transconductance. Some transconductance testers read plate current with a fixed bias network. Others use an ac signal to drive the tube while measuring plate current. Both of these tests are meant to indicate the transconductance (amplification) of a tube.

Leakage is another tube fault that testers often check. Contamination inside the tube envelope may result in current leakage between elements. The paths can have high resistance (250 kΩ), and may result from gas or deposits of electron-emitting material that have been transferred from the cathode. Leakage can be checked with an ohmmeter using the  $\times 1M$  range, depending on the actual spacing of tube elements. Tube testers use a moderate voltage to check for leakage. Beware: This voltage may *cause* shorts in tubes with very close element spacings (6AK5, GL-2C51 and GL-5670).

Use the same caution in the purchase of a tube tester that you would with any other used equipment. Know the testing method, make sure the manual is included and see that it checks the tubes you want to check.

- **Transistor Tester** — Transistor testers are similar to transconductance tube testers. Collector current is measured while the device is biased into conduction or while an ac signal is applied at the control terminal.

Most transistor failures appear as either an open or shorted junction. Opens and shorts can be found easily with an ohm-

meter; a special tester is not required. Transistor gain characteristics vary widely, however, even between units with the same device number.

Testers are useful to determine the characteristics of a particular transistor. A tester that uses no ac signal can read the transistor dc alpha and beta, while testers that apply an ac signal show the ac alpha or beta. The tester can help you decide if a particular transistor has sufficient gain for use as a replacement. It may also help when matched transistors are required.

Transistor testers are inexpensive, so purchase of a used instrument is unnecessary. The functions of a dc tester can be performed with a power supply and a meter (details are shown later in this chapter under "Components"). Construction of a suitable ac tester for bipolar transistors, JFETs and MOSFETs is covered in Chapter 25.

- **Frequency Meter** — Various instruments for frequency measurement, their construction and operation are covered in Chapter 25.

Almost any digital frequency counter is good enough for troubleshooting and repair work. No special temperature compensation is necessary unless you require accuracy greater than 1 part per million. Used equipment should be in good working order with no signs of damage or abuse.

- **Power supplies** — A well-equipped test bench should include a means of varying the ac-line voltage, a variable-voltage regulated dc supply and an isolation transformer. If you want to work on vacuum-tube gear, the maximum voltage available from the dc supply should be high enough to serve as a bias supply for common tubes.

Ac-line voltage varies slightly with load. An autotransformer with a movable tap lets you boost or reduce the line voltage slightly. This is helpful when testing equipment supply-voltage tolerance.

A variable-voltage dc supply may be used to power various small items under repair and as a variable bias supply for testing active devices. Construction details for a laboratory power supply appear in Chapter 27.

As mentioned earlier, ac/dc radios must be isolated from the ac line during testing and repair. Keep an isolation transformer handy if you want to work on table-model broadcast radios or television sets. Some transceivers of the 1960s also used the ac/dc power supply.

• **Accessories** — There are a few small items that may be used in troubleshooting. You may want to keep them handy.

A cold source is useful when searching for intermittent connections. Most parts suppliers carry some kind of cooling agent in a spray can. Poor connections frequently become open circuits when cooled.

A heat source helps locate components that fail only when hot. A small incandescent lamp can be mounted in a large piece of sleeve insulation to produce localized

Fig. 9 — A source of local heat made from insulating sleeve and a small dial lamp.

heat for test purposes (see Fig. 9).

A stethoscope (with the pickup removed — Fig. 10) or a long piece of sleeve insulation can be used to listen for arcing or sizzling in a circuit.

Fig. 10 — A stethoscope, with the pickup removed, used to listen for arcing in crowded circuits.

## Troubleshooting Procedures

Connector faults are more common than component troubles. Consider poor connections as prime suspects in our troubleshooting detective work. Begin every job with an inspection of the connections. Is the antenna connected? How about the speaker, fuses and TR switch? Are transistors and ICs firmly seated in their sockets? Are all interconnection cables sound and securely connected? After checking the obvious, begin an in-depth investigation.

To begin that investigation, define the problem accurately. Ask yourself these questions:

- 1) What functions of the equipment do not work as they should; what does not work at all?
- 2) What kind of performance can you realistically expect?
- 3) Is there anything in the operational history of the equipment that could have caused the trouble?
- 4) Has the trouble occurred in the past? (Keep a record of troubles, maintenance and repair in the owner's manual or log book.)

Write the answers to the questions. The information will help with your work, and help service personnel if their advice or professional service is required.

### SEARCHING AT THE BLOCK LEVEL

The block diagram is a road map. It shows the signal paths for each circuit function. These paths may run together, they may cross occasionally, or not at all. Those blocks that are not in the paths of faulty functions can be eliminated as suspects. Sometimes the symptoms point to a single block, and no further search is necessary.

In cases where more than one block is suspect, several approaches may be used. Each requires that a block, or stage, be tested. Signal injection, signal tracing or a

combination of both techniques may be used for this purpose.

### THE INSTINCTIVE APPROACH

First, consider an instinctive approach. The check for connector problems mentioned at the beginning of this section is an

example of this procedure. Experience has shown connector faults to be so common that they should be checked even before a systematic approach begins.

When instinct springs from a base of experience, search by instinct may be the fastest procedure. If instinct is correct,

Table 3

#### Symptoms and Their Causes for All Electronic Equipment

Symptom	Cause
<b>Power Supply Problems</b>	
No output voltage	Open circuit (usually a fuse or transformer winding).
Hum or ripple	Faulty regulator, capacitor or rectifier, low-frequency oscillation.
<b>Amplifiers</b>	
Low gain	Transistor, coupling capacitors, emitter-bypass capacitor, AGC component, alignment.
<b>Noise Transistors, Coupling capacitors, resistors</b>	
Oscillations	Dirt on variable capacitor or chassis, shorted op-amp input.
Untuned (oscillations do not change with frequency)	Audio stages.
Tuned	RF, IF and mixer stages.
Squeal	Open AGC-bypass capacitor.
Static-like crashes	Arcing trimmer capacitors, poor connections.
Static in FM receiver	Faulty limiter stage, open capacitor in ratio detector, weak RF stage, weak incoming signal.
Intermittent noise	All components and connections, band-switch contacts, potentiometers (especially in dc circuits), trimmer capacitors, poor antenna connections.
Distortion (constant)	Oscillation, overload, faulty AGC, leaky transistor, open lead in tab-mount transistor, dirty potentiometer, leaky coupling capacitor, open bypass capacitors, imbalance in tuned FM detector, IF oscillations, RF feedback (cables).
Distortion (strong signals only)	Open AGC line, open AGC diode.
Frequency change	Physical or electrical variations, dirty or faulty variable capacitor, broken switch, loose compartment parts, poor voltage regulation, oscillator tuning (trouble when switching bands).
<b>No Signals</b>	
All bands	Dead VFO or heterodyne oscillator.
One band only	Defective crystal, oscillator out of tune, band switch.
No function control	Faulty switch, poor connection, defective switching diode or circuit.
<b>Improper Dial Tracking</b>	
Constant error across dial	Dial drive.
Error grows worse along dial	Circuit adjustment.

**Table 4****Transmitter Problems**

Symptom	Cause
Key clicks	Keying filter, distortion in stages after keying.
<b>Modulation problems</b>	
Loss of modulation	Broken cable (microphone, PTT, power), open circuit in audio chain, defective modulator.
Distortion on transmit	Defective microphone, RF feedback from: lead dress, modulator imbalance, bypass capacitor, improper bias, excessive drive.
Arcing	Dampness, dirt, improper lead dress.
Low output	Incorrect control settings, improper carrier shift (CW signal outside of passband), audio oscillator failure, transistor or tube failure, SWR protection circuit.
<b>Antenna Problems</b>	
Poor SWR	Damaged antenna element, matching network, feed line, balun failure (see below), resonant conductor near antenna, poor connection at antenna.
Balun failure	Excessive SWR, weather or cold-flow damage in coil choke, broken wire.
RFI	Arcing or poor connections anywhere in antenna system or nearby conductors.

**Table 5****Transceiver Problems**

Symptom	Cause
Inoperative S meter	Faulty relay
PA noise in receiver	
Excessive current on receive	
Arcing in the PA tank	
Reduced signal strength on transmit and receive	IF failure
Poor VOX operation	VOX amplifiers and diodes
Poor VOX timing	Adjustment, component failure in VOX timing circuits or amplifiers
VOX consistently tripped by receiver audio	AntiVOX circuits or adjustment

repair time and effort may be reduced substantially. As experience and confidence grow, the merits of the instinctive approach grow with them. However, the inexperienced technician who chooses this approach is at the mercy of chance.

As an example, suppose an AM receiver suddenly begins producing weak and distorted audio. An inexperienced person frequently suspects poor alignment as a common problem. Even though the manufacturer's instructions and the proper equipment are not available, our friend begins twiddling the transformer cores. Before long, the set is hopelessly misaligned. Now our misguided ham must send the radio to a shop for an alignment that was not needed before repairs were attempted.

Alignment does not shift suddenly. A normal signal-tracing procedure would have shown that the signal was good up to the detector, but badly distorted after that stage. The defective detector diode that caused the problem would have been easily found and quickly replaced.

Tables 3 through 6 list common symptoms, and their probable causes. Background information about the items in the tables and symptoms that cannot be itemized appear in the text. These servicing hints have been collected from many sources and may save some time if similar

troubles are encountered. The tables list only problems that occur often in troubleshooting and repair. If a problem matches one listed, proceed to testing at the component level. If a particular symptom is not found in the tables, continue at the block level with a systematic approach.

**The Power Supply**

Many equipment failures are caused by trouble in the power supply. Fortunately, most power-supply problems are easy to find and repair (see Fig. 11). First, use a voltmeter to measure output. Loss of output voltage is usually caused by an open circuit. (A short circuit draws excessive current that opens the fuse, thus becoming an open circuit.) If the fuse has opened, turn off the power, replace the fuse and measure the load-circuit dc resistance. The measured resistance should be consistent with the power-supply ratings:

$$R \geq \frac{E}{I}$$

where

R = load-circuit resistance

E = supply voltage

I = maximum supply current

If R is too low, check the load circuit with an ohmmeter to locate the trouble. (Nominal circuit resistances are included in most equipment manuals.) If the load-circuit resistance is normal, look for a shorted filter capacitor or defective regulator IC. Electrolytic capacitors fail with long (two years) disuse; the electrolytic layer may be re-formed as explained later in this chapter.

IC regulators are often victims of oscillations in their high-gain amplifiers. Such oscillations are normally prevented by capacitors that connect the IC input and output pins to the adjustment or ground pin. Check or replace these capacitors whenever a regulator has failed.

Ac ripple, or hum, is caused by feedback, poor regulation or defective filter components. Look for a defective

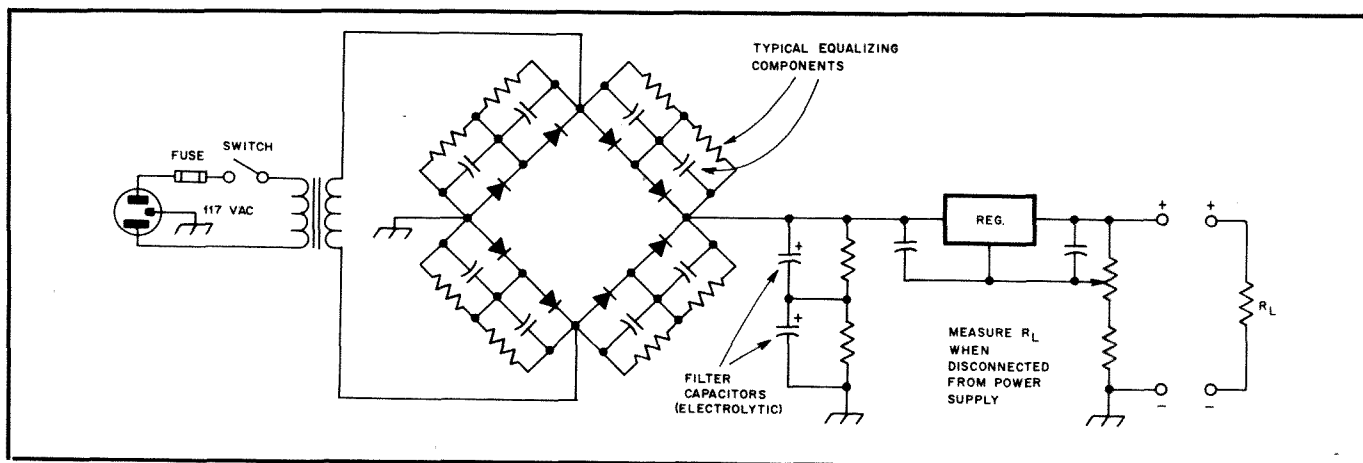

Fig. 11 — A schematic of a typical power supply showing the components mentioned in the text.

**Table 6**  
**Receiver Problems**

Symptom	Cause
Low sensitivity	Semiconductor contamination weak tube, alignment
Signals and calibrator heard weakly (low S-meter readings) (strong S-meter readings)	RF chain
No signals or calibrator heard, only hissing	AF chain, detector RF oscillators
<b>Distortion</b>	
On strong signals only	AGC fault
AGC fault	Active device cut off or saturated
Difficult tuning	AGC fault
Inability to receive	Detector fault
AM weak and distorted	Poor detector, power or ground connection
CW/SSB unintelligible	BFO off frequency or dead
FM distorted	Open detector diode

regulator, a shorted choke or open capacitor in the filter. In new construction projects make sure RF is not getting into the power supply.

Once the faulty component is found, inspect the surrounding circuit and consider what may have caused the problem. Referred symptoms (where a faulty component is the result of another failure, rather than the cause) are often encountered. For example, a shorted filter capacitor will increase current flow and burn out a rectifier diode. The defective diode is easy to find but the capacitor may show no visible damage. When a component has been subjected to excess current or voltage, as a result of another failure, check it.

### Amplifiers

Amplifiers are the most common circuits in electronics. The output of an ideal amplifier would match the input signal in every respect except magnitude: No distortion or noise would be added. Real amplifiers *always* add noise and distortion.

### Gain

Gain is the measure of amplification and it is usually expressed in decibels (dB) over a specified frequency range, known as the bandwidth or passband of the amplifier. When an amplifier is used to provide a stable load for the preceding stage, or as an impedance transformer, there may be little or no power gain. Amplifier failure usually results in a loss of gain or excessive distortion at the amplifier output. In either case, check external connections first. Is there power to the stage? Has the fuse opened? Check the speaker and leads in audio output stages, the microphone and push-to-talk (PTT)

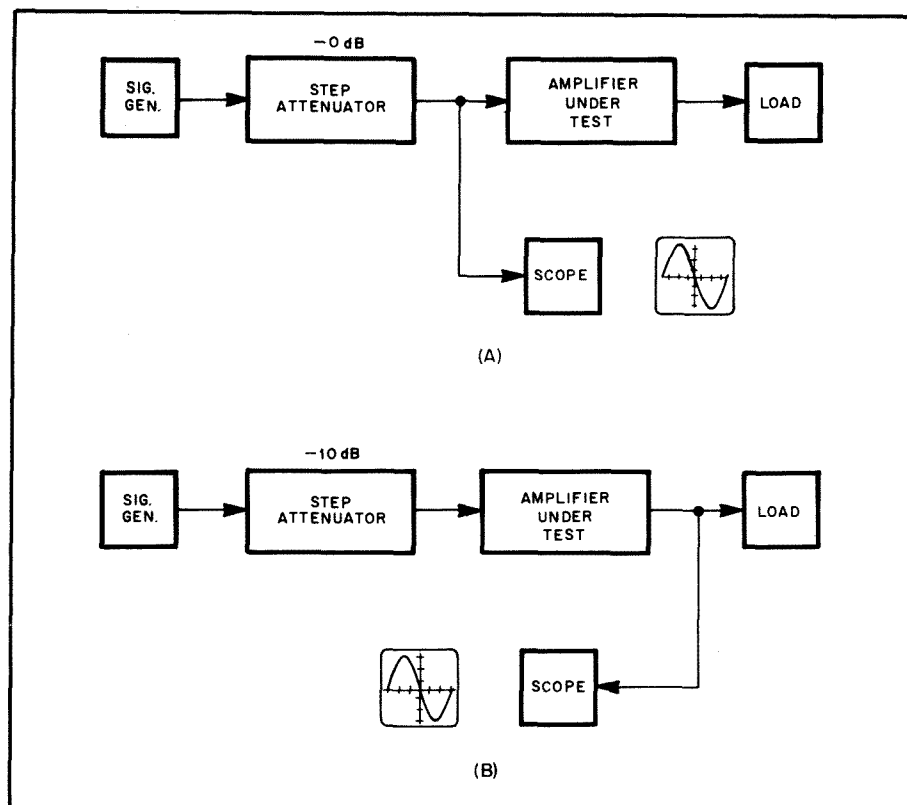

Fig. 12 — Equipment set up for amplifier gain testing. Connect the equipment as shown in A and adjust the 'scope display so that the waveform peaks are at graticule lines. Move the 'scope probe to the amplifier output and increase attenuation until the envelope size matches that of the input signal. Stage gain, independent of 'scope calibration, is shown on the step attenuator.

line in transmitter audio sections.

Excess voltage, excess current or thermal runaway lead to sudden failure of semiconductors. The failure may appear as either a short, or open, circuit of one or more PN junctions.

Thermal runaway is characteristic of bipolar transistors. If degenerative feedback (the emitter resistor reduces base-emitter voltage as conduction increases) is insufficient, thermal runaway will allow excessive current flow and device failure. Check transistors by substitution, if possible.

Faulty coupling components can reduce amplifier output. Look for component failures that would increase series, or decrease shunt, impedance in the coupling network. Coupling faults can be located by signal tracing or parts substitution. Other passive-component defects reduce amplifier output by shifting bias or causing active-device failure. These failures are evident when the dc operating voltages are measured.

A fault in the AGC loop may force a transistor into cutoff or saturation. Open the AGC line to the device and substitute a variable voltage for the AGC signal. If amplifier action varies with voltage, suspect the AGC components; otherwise, suspect the amplifier.

Gain bandwidth measurements can be

made with a stable signal source, step attenuator and oscilloscope. See Fig. 12.

### Noise

A slight hiss is normal in all electronic circuits. This noise is produced whenever current flows through a conductor that is warmer than absolute zero. Noise is compounded and amplified by succeeding stages. Repair is necessary only when noise threatens to obscure normally clear signals.

Semiconductors can produce hiss in two ways. First, faulty devices frequently produce excessive hiss under normal conditions. Second, any semiconductor junction produces white noise (hiss) when reverse biased. Both conditions worsen with increased temperature, so localized heat may help you find the source. Hiss can also be traced with an oscilloscope. Hissing from a resistor may increase when the component is tapped with a pencil or other insulator.

Typical sources of impulse noise are resistors, capacitors, semiconductors, vacuum tubes and connections. Poor connections and arcing are the most common causes of impulse noise.

Use signal-tracing techniques and substitution to locate noise sources. Physical shock and temperature increase noise from faulty components. A stethoscope lets you hear arcing in crowded

Fig. 13 — An in-circuit test for noise in active devices/coupling components. R1 should duplicate the collector-ground impedance of the active device.

circuits. Check connections at cables, sockets and switches. Look for dirty variable-capacitor wipers and potentiometers. Procedures for cleaning parts are given later in this chapter.

Rotary switches may be tested by bridging the contacts with a clip lead. Loose contacts may sometimes be repaired by gluing them to the switch deck. Operate variable components through their range while observing the noise level at the circuit output.

Potentiometers are particularly noise prone when used in dc circuits. Clean them with spray cleaner and rotate the shaft several times.

Mica trimmer capacitors often sound like lightning when arcing occurs. Test them by installing a series 0.01- $\mu$ F capacitor. If the noise disappears, replace the trimmer.

Noise in transformers and loads can be spotted by substituting a suitable current-limiting resistor for the active device (Fig. 13). If the noise stops, the active component is at fault.

### Oscillations

An amplifier oscillates whenever there is sufficient positive feedback. Oscillation may occur at any frequency from a slow audio buzz (often called "motorboating") up to the frequency where active-device gain is zero. Unwanted oscillations are usually the result of changes in the active device (increased junction or interelectrode capacitance), failure of an oscillation-suppressing component (open decoupling or bypass capacitors, neutralizing components) or new feedback paths (improper lead dress, dirt on the chassis or components). A shift in bias or drive levels may aggravate oscillation problems.

Oscillations that occur in audio stages do not change as the radio is tuned because the operating frequency, and therefore the component impedances, do not change. However, RF and IF oscillations vary in amplitude as operating frequency is changed.

Oscillation stops when the output circuit of the offending stage is changed enough to upset the feedback amplitude or phase. An additional bypass capacitor may pro-

(A)

(B)

(C)

Fig. 14 — Examples of distorted wave forms. The result of clipping is shown in A and non-linear amplification at B. A pure sine wave is shown in C for comparison. An example of harmonic distortion is shown in Fig. 4, earlier in this chapter.

duce such a change. The defective stage can be found more reliably with a signal tracer or oscilloscope.

### Distortion

Distortion is the product of nonlinear operation. The resultant waveform contains not only the input signal, but new signals, at other frequencies as well. All of the frequencies combine to produce the distorted waveform. Distortion in a transmitter gives rise to splatter, harmonics and RFI.

Fig. 14 shows some typical cases of distortion. Clipping (also called flat-topping — Fig. 14A) is the consequence of excessive drive. The corners on the waveform show that harmonics are present. (A square wave contains the fundamental and all odd harmonics.) These odd harmonics would be evident as splatter above and below the operating frequency, possibly outside the amateur band. Key clicks are similar to clipping.

Harmonic distortion produces radiation at frequencies far removed from the fundamental. Harmonic distortion is a

major cause of RFI; it is the product of improper neutralization or ineffective harmonic suppression.

Incorrect bias brings about unequal amplification of the positive and negative wave sections. Consequences similar to those of clipping or harmonic distortion may be present.

In most cases, the amateur's ability to detect and measure distortion is limited by available test equipment. (Instruments used for distortion measurement are the distortion meter, noise meter, spectrum analyzer and phase meter.) However, some rough measurements of distortion can be made with a function generator and an oscilloscope.

### Distortion Measurement

First, set the generator for a square wave and view it on the 'scope. Use a low-capacitance probe. The wave should show square corners and a flat top. Next, inject a square wave at the amplifier input and again view the input wave on the 'scope. Any new distortion is a result of the test circuit loading the generator output. (If the wave shape is severely distorted, the test is not valid.) Now, move the test probe to the test circuit output and read the waveform. Refer to Fig. 15 to estimate circuit distortion and its cause.

The above applies only to audio amplifiers without frequency tailoring. In RF gear, the transmitter may have a very narrow audio passband, so inserting a square wave into the mic input may result in an output that is difficult to interpret. The frequency of the square wave will have a significant effect.

All components listed as sources of impulse noise may also produce distortion. Check variable capacitors and resistors, switches, connectors and sockets for dirt or corrosion. Distortion that only affects strong signals usually indicates an AGC defect.

Leaky transistors produce distorted signals. A vacuum tube with an interelectrode short also causes distortion. These semiconductor and vacuum-tube conditions may mimic AGC trouble.

IF oscillations may produce distortion. They cause constant, full AGC action. (This is evident on a 'scope display or in bias measurements.) The S meter shows strong signals even with the antenna disconnected. AGC and conduction levels in RF sections are nearly constant as the operating frequency is varied.

Improper bias often results from an overheated or open resistor. Heat causes resistor values to permanently increase. Leaky, or shorted capacitors and RF feedback can also produce distortion by disturbing bias levels. Distortion is also caused by circuit imbalance in Class AB or B amplifiers.

### Oscillators

While the loss of oscillator output

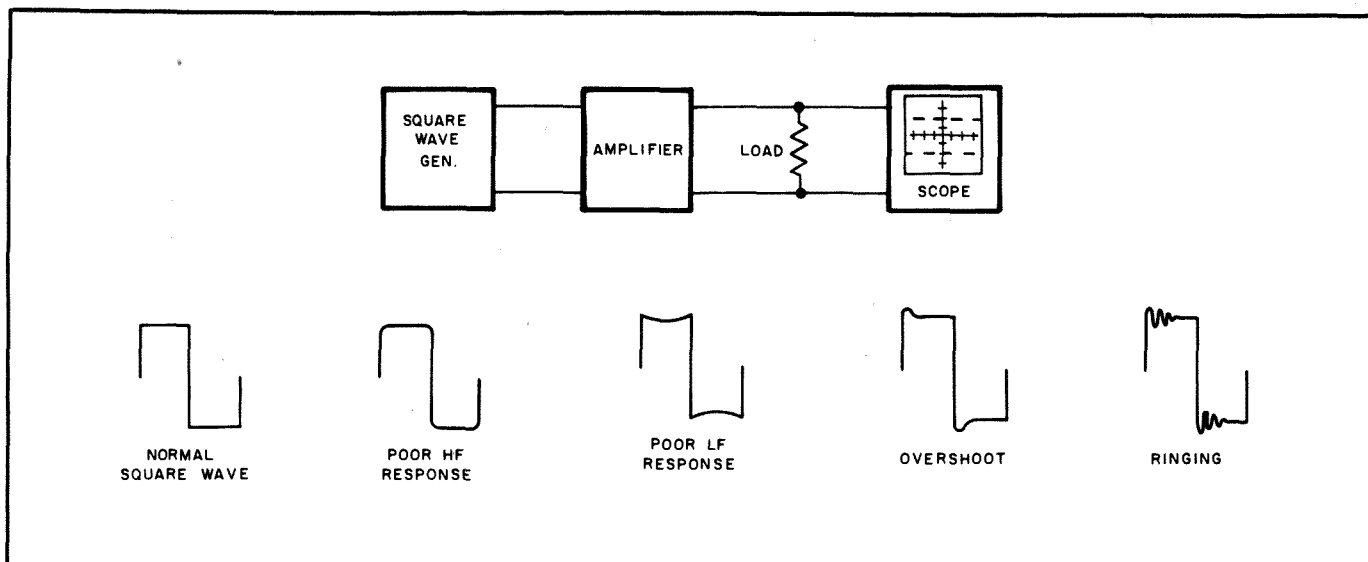

Fig. 15 — Square wave distortion and probable causes.

usually has drastic effects on equipment operation, the effects do not point directly to oscillator failure. Whenever there is weakening or complete loss of signal, check oscillator operation and frequency. There are several methods:

- Use a receiver with a coaxial probe to listen for the oscillator signal.
- A dip meter can be used to check oscillators. In the absorptive mode, tune the dip meter to within  $\pm 15$  kHz of the oscillator, couple it to the circuit, and listen for a beat note in the dip-meter headphones.

A dip meter in the active mode can be set to the oscillator frequency and coupled to the oscillator output. If the oscillator is dead, the dip-meter signal will restore circuit operation. Tune the dip meter slowly, or you may pass stations so quickly that they sound like "birdies."

- Oscillator waveform shows on a scope. However, operating frequency cannot be determined accurately. Use a low-capacitance (10X) probe for oscillator observations.

- Tube oscillators usually have no grid bias at startup, but negative bias when oscillating. Use a high-impedance voltmeter to measure grid bias. The bias also changes with frequency.

- Emitter current varies with frequency in transistor oscillators. Use a sensitive, high-impedance voltmeter across the emitter resistor to observe the current level.

- Control voltage changes with oscillation (for both tubes and transistors) in a crystal oscillator. Measure the control (either grid, or base) voltage while shunting the crystal with a  $0.001\text{-}\mu\text{F}$  capacitor; if the stage is oscillating, the level will vary when the capacitor is added. Do not short the crystal!

#### Stability

Judge stability by the standards in practice when the circuit was made. Drift of

several kilohertz per hour was quite normal years ago. Your needs may demand more stability, and modifications may be in order, but drift that is consistent with the equipment design is not a defect. This applies to new equipment as well as old. It is normal for some digital displays to flash back and forth between two values for the least-significant digit.

Drift is caused by variations in the oscillator. Poor voltage regulation and heat are the most common culprits. Check regulation with a voltmeter (use one that is not affected by RF). Regulators are usually part of the oscillator circuit. Check them by substitution. Check bypass capacitors by bridging them with good capacitors.

Solid-state replacements for tubes may improve oscillator stability by reducing heat and, therefore, temperature change in the circuit.<sup>3</sup> Long warm-up times can be avoided by keeping the oscillator compartment warm constantly. A small lamp, such as that used in a night light, mounted in the oscillator compartment keeps components near normal operating temperature. Wire the lamp so that it is on when the receiver is off, and off when the receiver is on.

Chirp is a form of rapid drift that is usually caused by excessive oscillator loading or poor power-supply regulation. When troubleshooting chirp, look for defects in buffer stages that affect the oscillator load. (For example, a shorted coupling capacitor increases loading drastically.) Also check lead dress, tubes and switches for new feedback paths (feedback defeats buffer action).

Frequency instability may also result from defects in feedback components. Too much feedback may produce spurious

signals, while too little makes oscillator startup unreliable.

Sudden frequency changes are frequently the result of physical variations. Loose components or connections are probable causes. Check for arcing or dirt on printed-circuit boards, trimmers and variable capacitors, loose switch contacts, bad solder joints or loose connectors.

Many older rigs used rivets to hold terminal strips, tube mounting rings and transistor sockets against ground. Rivets made a fine connection to chassis ground when the rigs were new. But, as time goes on, corrosion and mechanical weakening cause intermittent or high-impedance ground connections. To locate this type of problem, use a short piece of flexible, insulated wire (such as the braid from a piece of RG-174) with a piece of insulated tubing over it. Attach an alligator clip to each end. Connect one alligator clip to the suspect terminal and the other clip to the nearest chassis ground point. If the problem disappears, drill out the offending rivet and replace it with a machine screw, lockwasher and nut of the appropriate size.

A similar problem occurs when the screws around the edge of a PC board are used to connect the board to the chassis ground. If you run into this problem, remove the mounting screws and lightly sand the edge of the circuit board with fine sandpaper. Also clean the portions of the chassis that make contact with the board and its mounting screws. Remount the board to the chassis with machine screws, lockwashers and nuts.

#### Dial Tracking

Dial tracking errors may be associated with oscillator operation. Misadjustments in the frequency-determining components make dial accuracy worse at the ends of the dial. Tracking errors that are constant everywhere in the passband arise from slip-page in the dial drive. This is usually cured

<sup>3</sup>Background design tips are in the reference for Sartori at the end of this chapter.

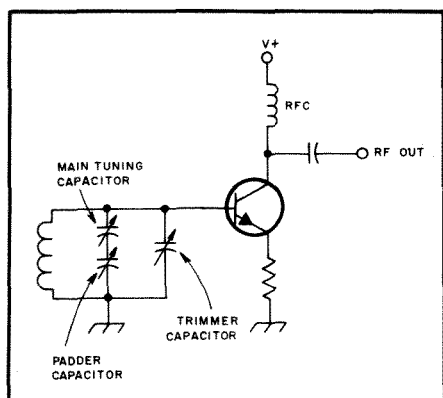

Fig. 16 — A schematic of a simple oscillator showing the locations of trimmer and padder capacitors.

by a simple mechanical or calibration adjustment.

Tracking at the high-frequency end of the dial is controlled by trimmer capacitors. A trimmer is a variable capacitor connected in parallel with the main tuning capacitor (see Fig. 16). The trimmer represents a higher percentage of the total capacitance at the high end of the tuning range. It has little effect on tuning characteristics at the low-frequency end of the dial.

Low-end tracking is adjusted by a padder capacitor. A padder is a variable capacitor that is connected in series with the main tuning capacitor. Padder capacitance has a greater effect at the low-frequency end of the dial. The padder capacitor is often eliminated to save money. In that case, the low-frequency tracking is adjusted by the main tuning coil.

### Controls

Semiconductors have made it practical to place a transistor or diode at each point where switching is required and run only dc leads to that point. This eliminates many problems caused by long leads.

Mechanical switches are relatively rugged. They can withstand substantial voltage and current surges. The environment does not drastically affect them, and there is usually visible damage when they fail.

Semiconductor switching offers inexpensive, high-speed operation. When subjected to excess voltage or current, most transistors and diodes silently expire. Occasionally, one sends up a smoke signal to mark its passing.

Temperature alters semiconductor characteristics. A normally adequate control signal may not be effective when transistor beta is lowered by a cold environment. Heat may cause a control voltage regulator to produce an improper control signal.

The control signal is actually a bias for the semiconductor switch. Forward-biased diodes and transistors act as closed switches while reverse biased components simulate

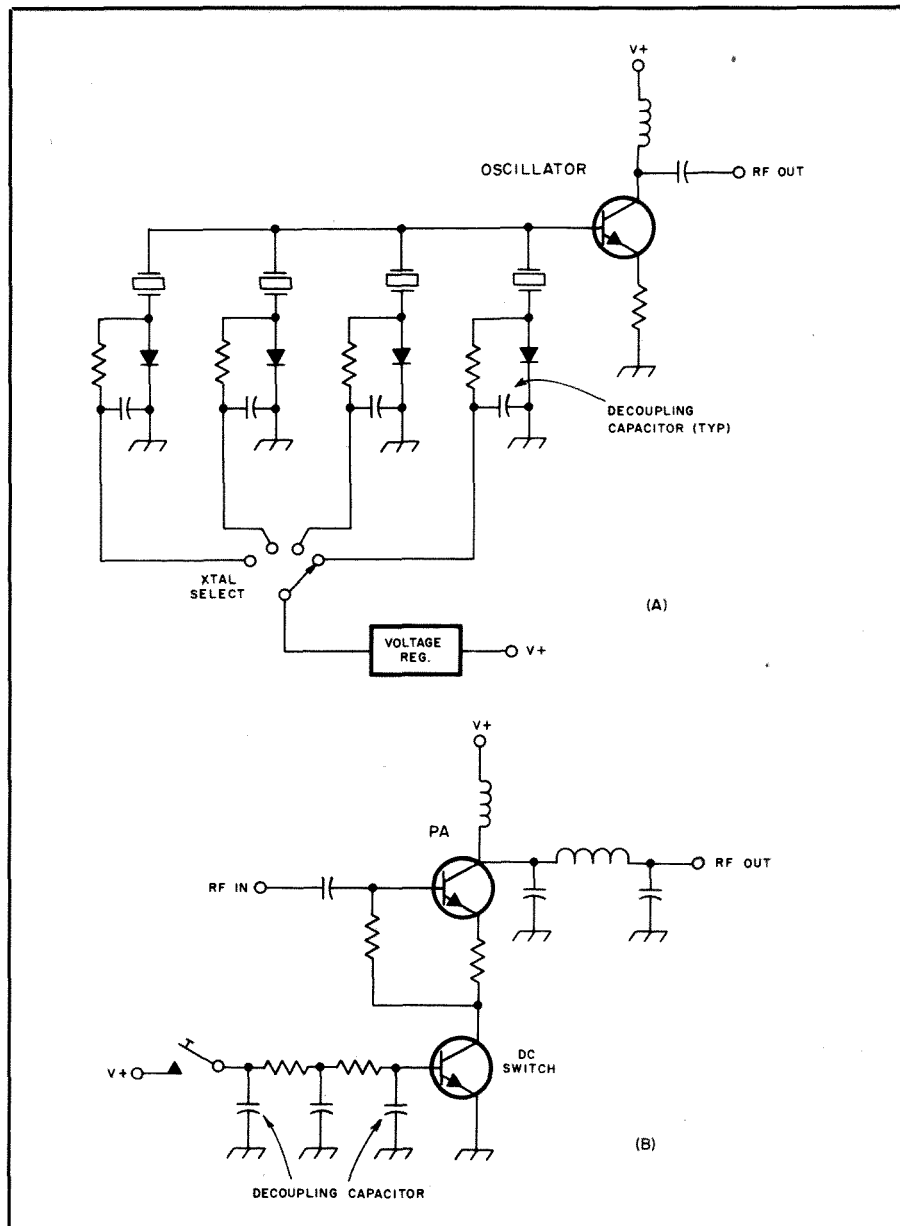

Fig. 17 — Diode switching selects oscillator crystals at A. A transistor switch is used to key a power amplifier at B.

open switches. If the control (bias) signal is not strong enough to completely saturate the semiconductor, conduction may not continue through a full ac cycle. Severe distortion results.

When dc control leads provide unwanted feedback paths, switching transistors may become modulators or mixers. Additionally, any reverse-biased semiconductor junction is a potential source of white noise.

Semiconductor switching usually reduces the cost and complexity of switching components. Switching speed is increased, contact corrosion and breakage are eliminated. In exchange, troubleshooting is complicated by additional support components such as voltage regulators and decoupling capacitors (see Fig. 17). The technician must consider many more components and symptoms when working with diode- and

transistor-switched circuits.

Another kind of control circuit is becoming common in amateur equipment. Nearly every new transceiver is controlled by a miniature computer. Microprocessor control is beyond the scope of this chapter. For successful repair of microprocessor-controlled circuits, the technician should have the knowledge and test equipment necessary for computer repair. Familiarity with machine-language programming may also be desirable.

### Transmitters

Many transmitter faults have already been covered. However, there are few techniques used to ensure stable operation of RF amplifiers in transmitters that are not covered elsewhere.

A parasitic choke frequently consists of

a 51- to 100- $\Omega$  non-inductive resistor with a coil wound around the body and connected to the leads. It is used to prevent VHF and UHF oscillations in a vacuum-tube amplifier. The coil has a low impedance at the operating frequency, but effectively blocks VHF and UHF oscillations. The choke is placed in the plate lead, close to the plate connection. Parasitic chokes often fail from excessive current flow. In these cases, the resistor is charred. Occasionally, physical shock or corrosion will produce an open circuit in the coil; test for continuity with an ohmmeter. Low-frequency oscillations are usually not a problem with vacuum-tube amplifiers.

Transistor amplifiers are protected against parasitic oscillations by low-value resistors or ferrite beads in the base or collector leads. Resistors are used only at low power levels (about 0.5 W), and both methods work best when applied to the base lead. Negative feedback is used to prevent oscillations at lower frequencies. An open component in the feedback loop may cause low-frequency oscillation, especially in broadband amplifiers.

### Keying

The simplest form of modulation is on/off keying. Although it may seem that there cannot be much trouble with such an elementary form of modulation, two very important transmitter faults are the result of keying problems.

Key clicks are produced by fast rise and decay times of the keying waveform. Most transmitters include an RF filter across the key connections to shape the waveform and prevent clicks. In order to prevent clicks, all amplifiers following the last keyed stage must maintain linear operation. When clicks are experienced, check the keying filter components first, then the succeeding stages. An improperly biased power amplifier, or a Class C amplifier that is not keyed, may produce key clicks even though the keying waveform is correct. Clicks caused by a linear amplifier are a sign of low-frequency parasitic oscillations.

The other modulation problem associated with on/off keying is called backwave. Backwave is a condition in which the signal is heard (usually at a reduced level) even when the key is up. This occurs when the oscillator signal feeds through a keyed amplifier; neutralization of the keyed amplifier may be necessary.

### Arcing

Although the sound and smell of arcs may conjure up nostalgic memories of the days when radios were made of wood, and operators of steel, it is a sign of trouble in modern gear. Arc sites are usually easy to find because an arc that generates visible light or noticeable sound also pits and discolors conductors.

Arcing is often caused by dampness, dirt or lead dress. If the dampness is temporary, dry the area and resume operation. Dirt

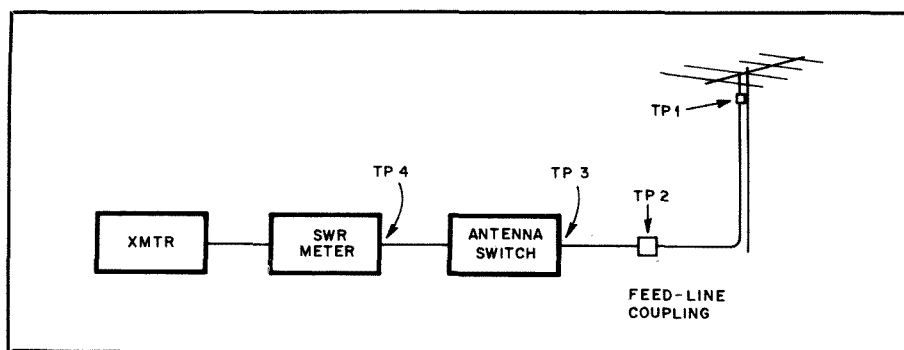

Fig. 18 — Test points used when tracing an antenna system circuit.

may be cleaned from the chassis with a residue-free cleaner. Arrange leads so high-voltage conductors are isolated. Keep them away from sharp corners and screw points.

Operating practice occasionally causes some arcing in control components. Arcing occurs in capacitors when the working voltage is exceeded. Air-dielectric variable capacitors can sustain occasional arcs without damage, but arcing indicates operation beyond circuit limits. Transmitters working beyond their ability may suffer from arcing.

### Low Output Power

Some transmitters automatically reduce power in the TUNE mode. Check the owner's manual to see if the condition is normal. Check the control settings. Transmitters that use broad-bandwidth amplifiers require so little effort from the operator that control settings are seldom noticed. The CARRIER (or DRIVE) control may have been bumped. Remember to adjust tuned amplifiers after a significant change in operating frequency (usually 50 to 100 kHz).

Low power output in a transmitter may also spring from a misadjusted carrier oscillator or defective SWR protection circuit. If the carrier oscillator is set to a frequency well outside the transmitter passband, there may be no measurable output. Output power will increase steadily as the frequency is moved into the passband.

Complete loss of signal occurs when the carrier oscillator stops, although loss of the tone oscillator signal (in transmitters that use an audio tone to generate CW) may have the same effect. The tone oscillator may also be used to produce a CW sidetone. Loss of sidetone together with a loss of RF output indicates a defective tone oscillator.

Transistors may fail if the SWR protection circuit malfunctions. An open circuit in the "reflected" side of the sensing circuit leaves the transistors unprotected, a short "shuts them down."

### Antennas

Begin antenna troubleshooting with a visual inspection of the antenna and surrounding area. Look for resonant conduc-

tors within a few wavelengths of the antenna. (Conductors that are perpendicular to the antenna are not significant.) If there are no obvious problems, test the antenna system.

To test the antenna system, transfer the antenna end of the feed line from the antenna to a dummy load (see Fig. 18). If the SWR appears normal, the problem must lie with the antenna itself. Make a closer inspection; look for corroded connections or an element that has slipped or broken. Check the components in any matching network at the feedpoint. Water in traps, and insects in variable capacitors or coils are common culprits.

If the SWR is still poor, move the dummy load to the next feed-line coupling that is closer to the transmitter and check the SWR again. Repeat this procedure until the SWR returns to normal. The faulty system component is the last one disconnected. Don't forget that SWR meters may have defects also. When in doubt, confirm readings with a second meter.

### Balun Failures

Symptoms of balun failure include burned insulation and arcing between turns. Replace the damaged balun and avoid high-SWR operation.

A coaxial choke (usually 10 turns, 6-inch diameter for RG-58/U, larger cables require larger diameters) serves the same purpose as a balun. Falling branches, weather and so on may damage coaxial-choke baluns. Another threat to the coaxial choke is a phenomenon known as cold flow. The action is very similar to a piece of wire slicing through cheese. The center conductor slowly moves, cutting through the core dielectric as a result of the stress in the bent cable. This problem is most common in foam-dielectric cables, and is aggravated by warm weather.

### RFI

RFI can be produced in any part of the antenna system. The cause is usually poor connections. Almost any metal-to-metal joint can form a diode junction. When RF is induced across the junction, rectification and strong harmonics result. Luckily, only conductors that are of a significant elec-

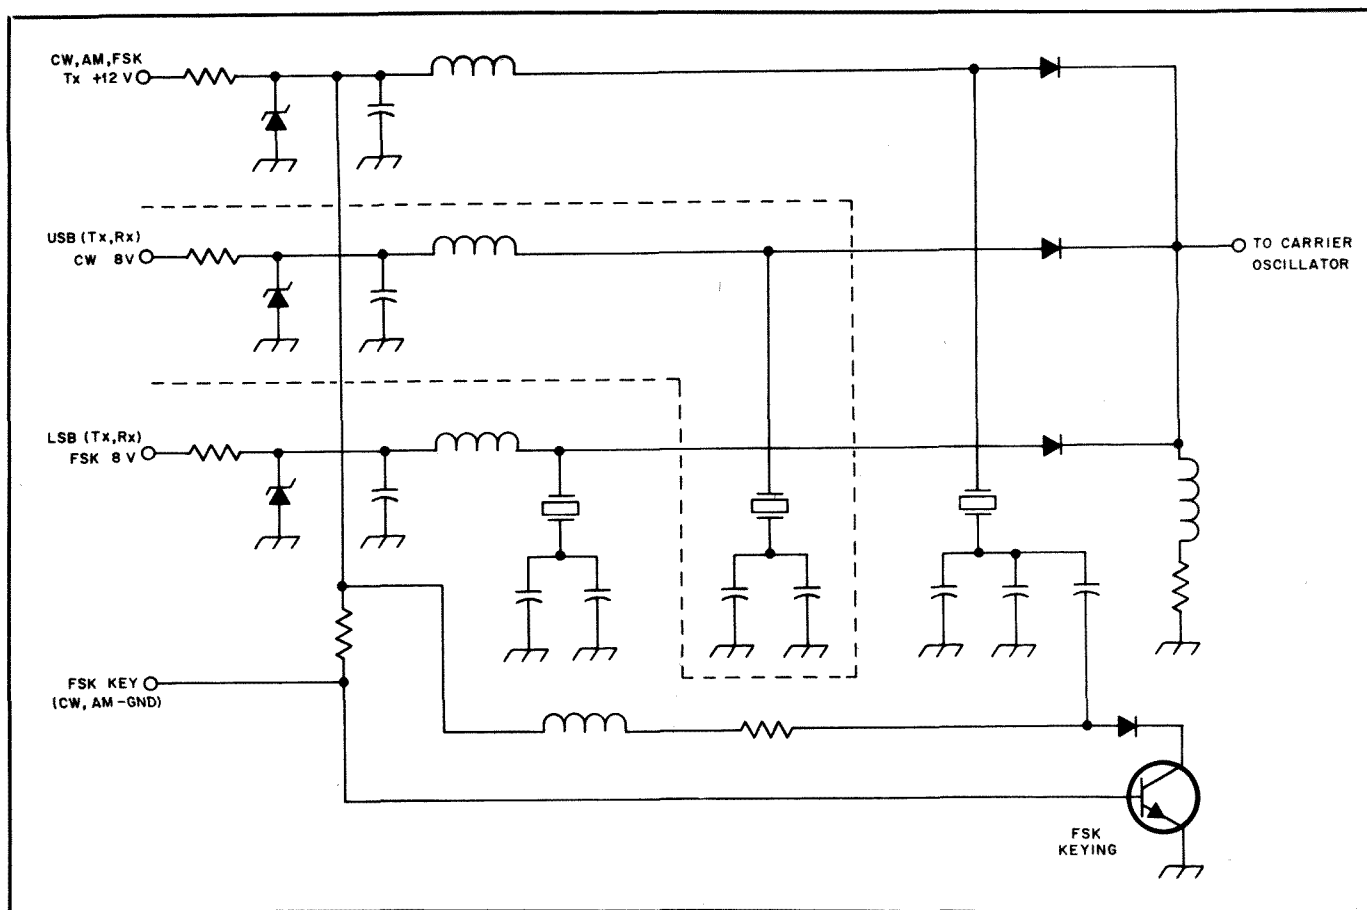

Fig. 19 — Partial schematic of a transceiver oscillator. The symptoms described in the text are caused by one or more components inside the dashed lines or a faulty USB/CW control signal.

trical length develop enough power to radiate the harmonics produced. The most likely troublemakers are tower sections, TV line amplifiers, antenna and feed-line connections, video recorders, guy wires and metal gutters. Less obvious sources can be located with direction-finding techniques. As you get closer to the RFI source, it is possible to hear the noise on higher harmonics. Switch to a higher band to prevent overload as you draw near the source. Once the source is located, correct the problem by electrically bonding the parts together. More information about RFI problems and cures appears in Chapter 40.

### Transceivers

Elaborate switching schemes are used in transceivers for signal control. Many transceiver malfunctions can be attributed to relay or switching problems. Suspect the switching controls when:

- The S meter is inoperative.
- There is arcing in the tank circuit.
- Plate current is high during reception.
- There is PA noise in the receiver.
- Received signals are erratic or weak.

Since transceiver circuits are shared, stage defects frequently affect both the transmit and receive modes, although the symptoms may change with mode.

Oscillator problems usually affect both transmit and receive modes, but different oscillators, or frequencies, may be used for different emissions. Check the block diagram.

For example, one particular transceiver uses a single carrier oscillator with three different crystals (see Fig. 19). One crystal sets the carrier frequency for CW, AM and FSK transmit. Another sets USB transmit and USB/CW receive, and a third sets LSB transmit and LSB/FSK receive. This radio showed a strange symptom. After several hours of CW operation, the receiver produced only a light hiss on USB and CW. Reception was good in other modes, and the power meter showed full output during CW transmission. An examination of the block diagram and schematic showed that only one of the crystals (and seven support components) was capable of causing the problem.

Another potential trouble area is VOX control. If there is difficulty in switching to transmit, check the VOX-SENSITIVITY and ANTI-VOX control settings. Next, see if the PTT and manual (MOX) transmitter controls work. If the PTT and MOX controls function, examine the VOX-control diodes and amplifiers. Test the switches, control lines and control voltage if the transmitter does not respond to other TR controls.

VOX SENSITIVITY and ANTI-VOX settings

should also be checked when the transmitter switches on in response to received audio. Suspect the anti-VOX circuitry next. Unacceptable VOX timing results from a poor VOX-delay adjustment, or a bad resistor or capacitor in the timing circuit or VOX amplifiers.

### Alignment

The mixing scheme of the modern SSB transceiver is complicated. The signal passes through many mixers, oscillators and filters. Satisfactory SSB communication requires accurate adjustment of each stage. Do not attempt any alignment without a copy of the manufacturer's instructions and the necessary test equipment.

### Receivers

The important characteristics of a receiver are selectivity, sensitivity, stability and fidelity. Receiver malfunctions ordinarily affect one or more of these areas.

### Selectivity

Tuned transformers may develop a shorted turn, capacitors can fail and alignment is required occasionally. Such defects are accompanied by a loss of sensitivity. Filters may fall victim to physical damage from external forces. Cavities and resonators are subject to similar hazards.

Except in cases of catastrophic failure

(where either the filter passes all signals, or none), it is difficult to spot a loss of selectivity. Bandwidth and insertion-loss measurements are necessary to judge filter performance.

### Sensitivity

A gradual loss of sensitivity results from gradual failure of an active device or faulty alignment. Sudden, partial sensitivity reductions are the effect of low RF-amplifier output, or a shift in the frequency of an oscillator or a filter passband. Complete and sudden loss of sensitivity is caused by an open circuit anywhere in the signal path or by a "dead" oscillator.

### Stability

The stability of a receiver depends on its oscillators. See the section on oscillators earlier in this chapter.

### Distortion

Causes of distortion are covered earlier in this chapter. Distortion may be the effect of poor connections or faulty components in the signal path. AGC circuits produce many receiver defects that appear as distortion or insensitivity.

### AGC

Distortion that affects only strong signals is the normal symptom of AGC failure. All stages operate at maximum gain when the AGC influence is removed. An S meter can help diagnose AGC failure because it is operated by the AGC loop.

An open AGC bypass capacitor forces feedback through the loop and usually a squeal (oscillation). Changes in the loop time constant affect tuning. If stations consistently blast, or are too weak, the time constant is too fast. An excessively slow

time constant makes tuning difficult, and stations fade after tuning. When loop problems are extreme, AGC-controlled stages may be forced into cut off or saturation.

Some AGC circuit designs provide a shunt Zener diode to clamp loop voltage and prevent cut off or saturation. The protection diode is called an AGC gate.

### Detector Problems

Detector trouble usually appears as distortion of the received signal. AM, SSB and CW signals may be weak and unintelligible, FM signals distorted. Suspect an open circuit in the detector near the detector diodes. If tests of the detector parts indicate no trouble, look for a poor connection in the power-supply or ground leads. A BFO that is "dead" or off frequency prevents SSB and CW reception.

### Alignment

Unfortunately, IF transformers are as enticing to the neophyte technician as a carburetor is to a shade-tree mechanic. In truth, radio alignment (and for that matter, carburetor repair) is seldom required. Circuit alignment may be justified under the following conditions:

- The set is very old and has not been adjusted in many years.
- The circuit has been subject to abusive treatment or environment.
- There is obvious misalignment from a previous repair.
- Tuned-circuit components or crystals have been replaced.
- There is a malfunction, but *all* other circuit conditions are normal. (Faulty transformers can be located because they will not tune.)

Even if one of the above conditions is

met, do not attempt alignment unless you have the proper equipment.

Receiver alignment should progress from the detector to the antenna terminals. When working on an FM receiver, align the detector first, then the IF and limiter stages, and finally the RF and local oscillator stages. For an AM receiver, align the IF stages first, then the RF and oscillator stages.

Both AM and FM receivers can be aligned in much the same manner:

- 1) Set the receiver RF GAIN to maximum, BFO control to zero (or center) and tune to the high end of the receiver passband.
  - 2) Disable the AGC.
  - 3) Set the signal source to the center of the IF passband, with no modulation and minimum signal level.
  - 4) Connect the signal source to the input of the IF section.
  - 5) Connect a voltmeter to the IF output as shown in Fig. 20.
  - 6) Adjust the signal-source level for a slight indication on the voltmeter.
  - 7) Peak each transformer in order, from the meter to the signal source.
- The adjustments interact; repeat steps 6 and 7 until adjustment brings no noticeable improvement.
- 8) Remove the signal source from the IF-section input, reduce the level to minimum, set the frequency to that shown on the receiver dial and connect the source to the antenna terminals.
  - 9) Adjust the signal level to give a slight reading on the voltmeter.
  - 10) Adjust the trimmer capacitor of the RF amplifier for a peak reading of the test signal. (Verify that you are reading the correct signal by switching the source on and off.)
  - 11) Reset the signal source and the

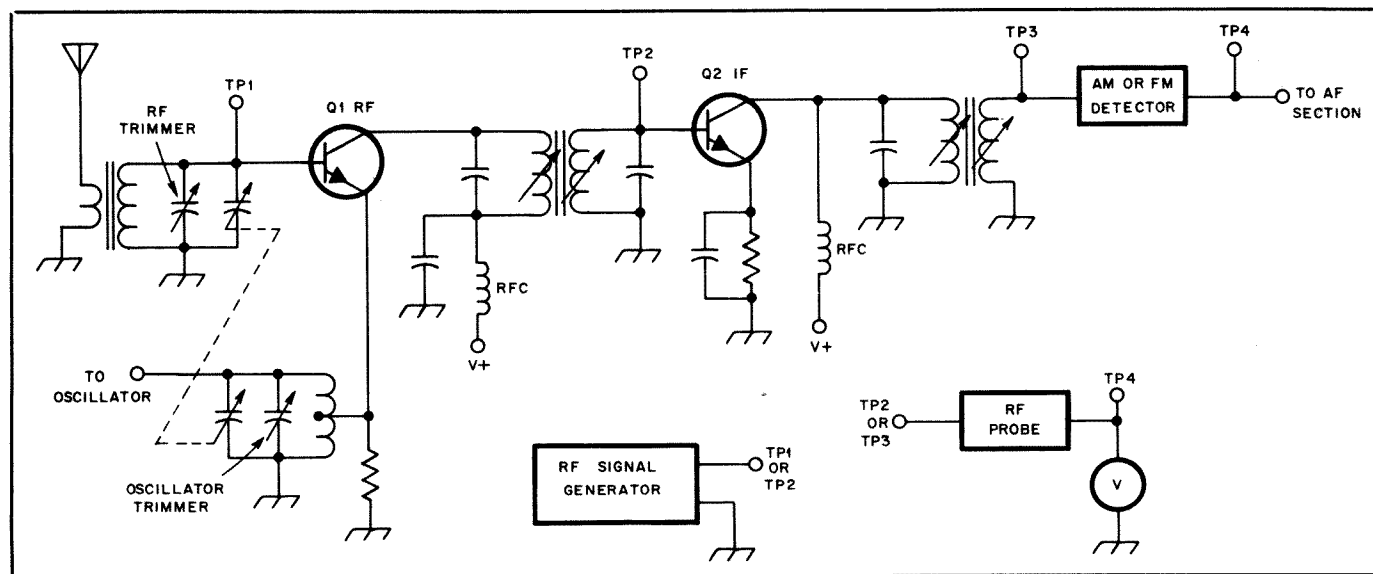

Fig. 20 — Typical receiver alignment test points. To align the entire radio, connect a dc voltmeter at TP4. Inject an IF signal at TP2, and adjust the IF transformers. Move the signal generator to TP1 and inject RF for alignment of the RF and oscillator stages. To align a single stage, place the generator at the input and an RF voltmeter at the output: TP1/TP2 for RF, TP2/TP3 for IF.

receiver tuning for the low end of the passband.

12) Adjust the local-oscillator padder for peak reading.

13) Repeat steps 8 through 11 until the settings do not change.

### Digital Equipment

Few ham shacks across the country show no signs of the digital revolution. The inscrutable number crunchers have brought automated precision to everything from desk clocks to computer-controlled EME antenna arrays. Although every aspect of their operation may be resolved to a simple 1 or 0, the symptoms of their failure are far more complicated. As with other equipment:

- Observe the operating characteristics.
- Study the block diagram and the schematic.
- Test.
- Replace defective parts.

Problems in digital circuits have two elementary causes. First, the circuit may give false counts because of electrical noise at the input. Second, the gates may lock in one state.

False counts from noise are especially likely in a ham shack. (A 15- to 20- $\mu$ sec voltage spike can trigger a TTL flip-flop.) Amateur Radio equipment often switches heavy loads; the attendant transients can follow the ac line or radiate directly to nearby digital equipment. Ringing in filters or leads or oscillation in the digital circuit can also produce false counts.

The effects of extra counts are determined by the design of the digital equipment: A station clock may run fast, but a microprocessor-controlled transceiver may "decide" that it is only a receiver. It might even be difficult to determine that there is a problem without a logic analyzer or multitrace 'scope and a thorough understanding of circuit operation.

Begin by removing the faulty equipment from RF fields. If the symptoms cease with the removal from RF, it will be necessary to shield the equipment against such fields. When it is possible to move the device, distance may be a permanent answer. In other cases, bypass or filter the power, input and output lines of the digital circuit.

Microprocessors use clock speeds of 1 to 10 MHz; it may be impossible to filter RF from the lines when the RF is near the clock frequency. In these cases, the best approach is to shield the digital circuit and all lines running to it.

RFI to nearby equipment may also be a sign that the station is radiating spurious signals. Inspect the station ground and all connections when such problems appear. Also check for radiation from chassis or ac lines with an absorptive wavemeter or a field-strength meter with a capacitive probe.

Strong RF fields may also cause lock up. Deal with this problem in the same

Fig. 21 — Simple digital circuits can be tested with a few components. In this case, an AND gate is tested. Open and close S1 and S2 while comparing the VOLTS reading with a truth table for the device.

manner as with RF-induced noise. Lockup may also be the result of a short, or open, circuit.

Check for the correct voltages at the pins of each chip. (Make the measurements at the pins of the IC, not the socket pins.) Next, smell and feel each IC for heat. Excessive heat is often evidence of a shorted IC.

Repair any power faults, replace overheated components and check for restored operation. If there is still a malfunction, test the circuit board and sockets for open or shorted connections.

Record the placement and orientation of any active devices installed in sockets, then remove them from the circuit board to prevent damage during testing. (Follow the handling precautions for MOS devices.) Consider the maximum voltage specifications of any devices that cannot be removed before testing. Some devices can be damaged by 0.6 V on certain pins. After these precautions, proceed to test the board with an ohmmeter.

Last, lockup can be the effect of a failed logic gate or IC. In clocked circuits, listen for the clock signal with a coax probe and a suitable receiver. If the signal is found at the clock chip, trace it to each of the other ICs, to be sure that the clock system is intact.

If a suitable scope (15-MHz bandwidth, with storage capability and a  $\times 10$  probe) is available, check pulse timing and duration against circuit specifications. Pay special attention at analog-to-digital converters.

Logic gates, flip-flops and counters may be tested (see Fig. 21) by triggering them, manually, with a power supply (4 to 5 V is a safe level). Diodes may be checked with an ohmmeter. Testing of more complicated ICs requires the use of a logic analyzer, multitrace scope or a dedicated IC tester.

Check repaired circuits for restored operation. Test frequency counters against another counter or a calibrated signal generator.

### SYSTEMATIC APPROACHES

The instinctive approach works well for those with years of troubleshooting experience. Those of us who are new to this

game need some guidance. A systematic approach is a disciplined procedure that allows us to tackle problems in unfamiliar equipment with a reasonable hope of success.

There are two common systematic approaches to troubleshooting at the block level. The first is signal tracing; the second is signal injection. The two techniques are very similar. Differences in test equipment and the circuit under test determine which method is best in a given situation.

### Signal Tracing

This approach is best for testing transmitters, solid-state and high-impedance circuits. Signal tracing is the best way to check transmitter blocks because the necessary signals are present by design. Most signal generators cannot supply the wide range of signal levels required to test a transmitter.

Signal tracing requires that a steady signal be present in the circuit passband. (An off-the-air signal may be used when testing a receiver. When the receiver is completely disabled, the signal tracer may be connected at the output of the first RF stage as an indicator of incoming signals.) A signal generator or other *stable* signal source may be used. Use a signal of  $-80$  dBm ( $22 \mu$ V) for most amateur receivers. Higher signal levels (7 dBm, 0.5 V) may damage sensitive components.

### Signal Tracing Equipment

A voltmeter, with an RF probe, is the most common instrument used for signal tracing. Low-level signals cannot be measured accurately with this instrument. Signals that do not exceed the junction drop of the diode, in the probe, will not register at all, but the presence, or absence, of larger signals can be observed.

A dedicated signal tracer can also be used. It is a simple instrument that may not have adjustable sensitivity. Signal information is usually presented as audio. An experienced technician may be able to judge the level and distortion of the signal by ear; only gross changes will be noticeable.

Absorptive wavemeters may be used for signal tracing if they are sufficiently sensitive and have a suitable probe. Use a wavemeter with headphones to trace weak signals. The frequency selectivity of a wavemeter is an advantage in signal tracing. Tracing a crowded circuit, however, may be impossible unless the instrument has provision for a capacitive probe.

An oscilloscope is the most versatile signal tracer. It offers high input impedance, variable sensitivity, and a constant display of the traced waveform. A demodulator probe permits observation of the modulation envelope in RF circuits. Dual-trace scopes can display the waveforms present at the input and output of a circuit simultaneously. Gross distortions

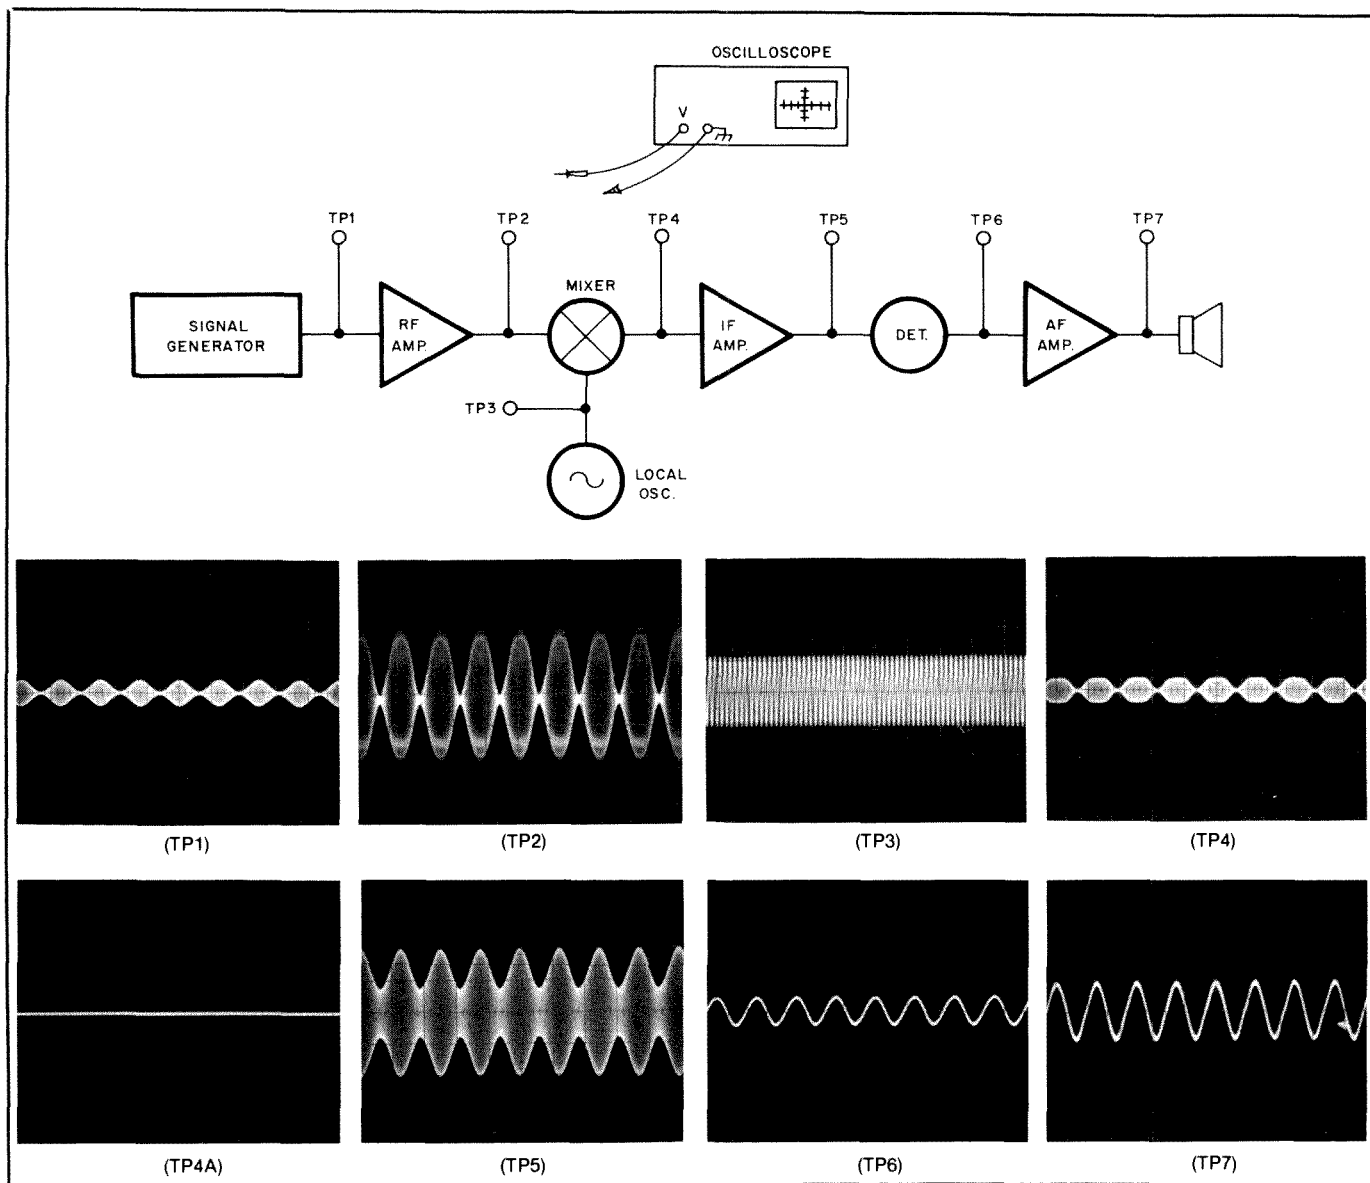

Fig. 22 — Signal tracing in a simple receiver. Photos TP1 through TP6 show typical patterns for a 'scope connected to the corresponding test points. TP1 through TP4 show 0.5 V per vertical division; TP5 through TP7 show 2.0 V per division. TP4A is TP4 with signal source removed. All patterns were made with a 10X probe and a 2-mS-per division sweep rate.

tion and phase relationship are visible on a dual-trace display.

#### Signal-Tracing Procedure

First, make sure that the circuit under test and test instruments are isolated from the ac line by transformers. Set the signal source to an appropriate level and frequency. Switch on power to the test circuit and connect the signal-source output to the test-circuit input. Place the tracer probe at the circuit input and check for presence of the test signal; observe the characteristics of the signal if you are using a 'scope (see Fig. 22). Compare the detected signal to the source signal during tracing. Move the tracer probe to the output of the next stage and observe the signal. Signal level should increase in amplifier stages and may decrease slightly in other stages. The signal will not be present at the

output of a "dead" stage.

Low-impedance test points may not provide sufficient signal to drive a high-impedance signal tracer; tracer sensitivity is important. Also, the circuit/probe impedance relationship may make the output level appear low in stages where there is a radical impedance change from input to output (see Fig. 23). It is important to note that the circuit in Fig. 23 is a current amplifier, and that within reason the voltages at TP1 and TP2 are equal and in phase. Remember that there are two signals (the test signal and the local oscillator signal) present in a mixer stage. Switch the signal source on and off repeatedly to make sure that the tracer reading varies (it need not disappear) with source switching.

#### Signal Injection

Like signal tracing, signal injection is

particularly suited to some situations. Signal injection is a good choice for receiver troubleshooting because a detector is already provided as part of the design. Also, the required signal-injection levels vary less widely in a receiver than in a transmitter. Signal injection is also better for vacuum-tube circuits. Low-impedance circuits may not produce enough signal to drive available signal tracers; signal injection may then be the best technique.

#### Signal-Injection Equipment

If you are testing equipment that does not include a suitable detector as part of the circuit, some form of signal detector is required. Any of the instruments used for signal tracing are adequate. Remember to consider the signal level at the test point when choosing an instrument.

The signal source used for injection must

Fig. 23 — The effect of circuit impedance on a 'scope display. Although the circuit functions as an amplifier, the change in impedance from TP1 to TP2 results in the traces shown.

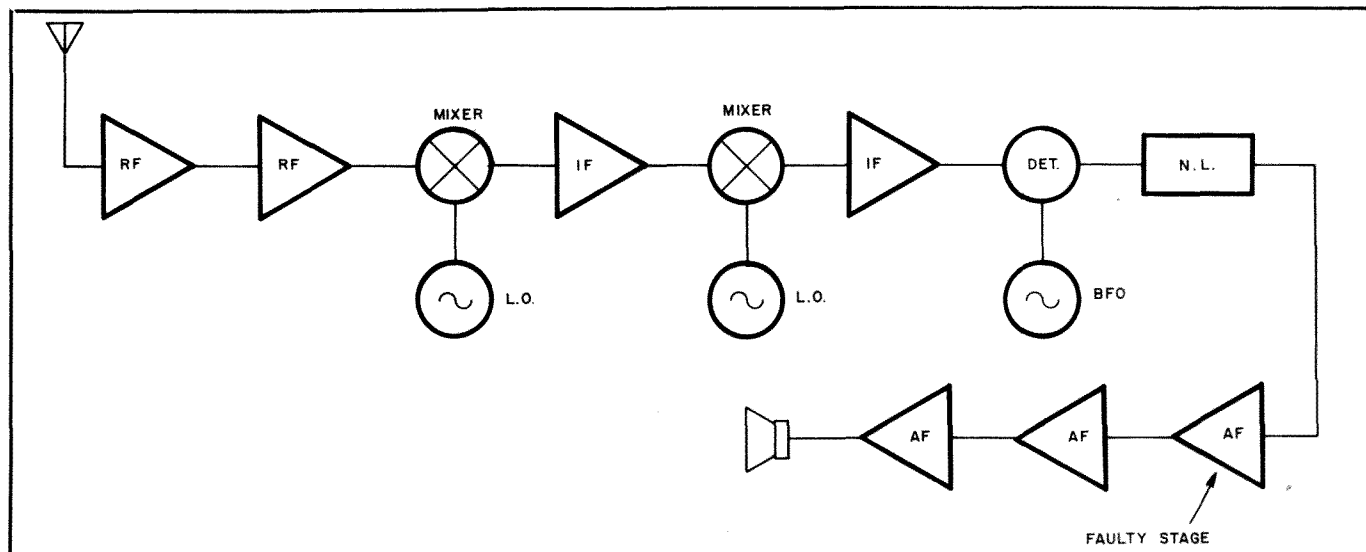

Fig. 24 — The 18-tube receiver diagnosed by the "divide and conquer" technique.

meet many demands. It must be able to supply appropriate frequencies and levels for each stage to be tested. For example, a typical superhet receiver requires AF, IF and RF signals that vary from 6 volts at AF, to  $0.2 \mu\text{V}$  at RF. Each conversion stage used in a receiver requires another IF from the signal source.

#### Signal-Injection Procedure

If an external detector is required, set it to the proper level and connect it to the test circuit. Set the signal source for AF and inject a signal directly into the signal detector to test operation of the injector and detector.

Move the signal source to the input of the preceding stage and observe the signal. Continue moving the signal source to the inputs of successive stages. (Use a  $50\text{-}\Omega$  resistor, in series with the signal-source lead to inject a signal at the input of an inverting amplifier.) The detected signal disappears when the source is at the input of a defective stage. Prevent stage overload by reducing the level of the injected signal as testing progresses through the circuit. Remember to use suitable frequencies for each tested stage.

Make a rough check of stage gain by

using the same injected-signal strength at the input and output of an amplifier stage. As with signal tracing, this test may yield misleading results if there is a radical difference in impedance from stage input to output. Understand circuit operation before testing!

Mixer stages present a special problem because they have two inputs, rather than one. A lack of signal at the test detector may result from either a faulty mixer or a faulty local oscillator (LO). Check oscillator operation with a 'scope, absorption wavemeter or by listening on another receiver. If none of these instruments are handy, inject the frequency of the LO at the LO output. If a dead oscillator is the only problem, this should restore operation.

If the oscillator is operating, but off frequency, a multitude of spurious responses will appear. A simple signal injector that produces many frequencies simultaneously is not suitable for this test. Use a well-shielded signal generator set to an appropriate level at the LO frequency.

#### Divide and Conquer

Both signal tracing and signal-injection

procedures may be speeded by application of a technique known in computer programming as a binary search. Rather than check each stage sequentially, check a point halfway through the nonfunctioning section. As an example:

A surplus 18-tube receiver is not working. All of the filaments light, but there is absolutely no response from the speaker.

First, substitute a suitable speaker — still no sound. Next, check the high-voltage supply — no problem there. No clues indicate any particular stage. Signal tracing or injection must provide the answer.

Get out the signal generator and switch it on. Once the signal is stable, set the generator for a low-level RF signal, switch the RF OFF and connect the output to the receiver. Switch the RF ON again and place a high-Z signal-tracer probe at the lug of the antenna connection. Instantly, the tracer emits a strong audio note. Good; the test equipment is functioning.

Now, move the probe to the input of the receiver detector. As the tracer probe touches the circuit the familiar note sounds. Next, set the tracer for audio and place the probe halfway through the audio chain. It

is silent! Move the probe halfway back to the detector, and the note appears once again. Yet, no signal is present at the output of the stage. The third audio stage is faulty.

### Saving Time

Under certain conditions, the block search may be speeded by testing at the middle of successively smaller circuit sections. Each test limits the fault to one half of the remaining circuit (see Fig. 24). The receiver has 18 stages and the fault is in stage 12. This approach requires only four tests to locate the faulty stage, a substantial saving of time.

The divide-and-conquer tactic cannot be used in equipment in which the signal path splits during processing. Test readings taken inside feedback loops are misleading unless you understand the circuit and the waveform to be expected at each point in the test circuit. It is best to consider all stages within a feedback loop as a single block during the block search.

### TESTING WITHIN A STAGE

The search is now nearing an end. A few dc measurements will usually pinpoint one or more specific components that need adjustment or replacement. First, check the active device. If the device can be tested easily in the circuit, do so; otherwise, go on to check dc voltages.

Look in the service manual to determine if the circuit is controlled by AGC. The service manual should either give test procedures for the stage with the AGC active, or have instructions for disabling the AGC.

Check the parts in the circuit against the schematic diagram to be sure that they are reasonably close to the design values (someone may have changed them during repairs). Next, make some calculations to see what the voltage should be. It is important to consider the effect of the meter in these calculations. Remember, however, that the calculated voltages are nominal; measured voltages may vary from the calculations. When making measurements, remember the following points:

- Make measurements at device leads, not at circuit-board traces or socket lugs.
- Use small test probes to prevent accidental shorts.
- Never connect or disconnect power to solid-state circuits with the switch on.

### Symptoms and Faults in a Typical Amplifier Circuit

Fig. 25 is a schematic of a common-emitter transistor amplifier. The emitter, base and collector leads are labeled e, b and c, respectively. Important dc voltages are measured at these points and designated  $V_e$ ,  $V_b$  and  $V_c$ . Similarly, the important currents are  $I_e$ ,  $I_b$  and  $I_c$ .  $V+$  indicates the supply voltage. Emitter-base internal resistance,  $R_b$ , is approximated by the formula:

$$R_b = \frac{26 \beta}{I_e} \quad (\text{Eq. 2})$$

Fig. 25 — A typical common-emitter amplifier (audio).

where  $I_e$  is expressed in milliamperes. The "junction drop,"  $V_j$ , is the potential measured across a semiconductor junction that is conducting.  $V_j$  is typically 0.6 V for silicon and 0.2 V for germanium transistors.

$R1$  and  $R2$  form a voltage divider that supplies dc bias ( $V_b$ ) for the transistor. Normally,  $V_e$  will be equal to  $V_b$  less the e-b junction drop.  $R4$  provides degenerative dc bias, while  $C3$  provides a low-impedance path for the signal. From this information, normal operating voltages can be calculated:

$$V_b = \frac{(V+)R2}{(R1 + R2)} = 1.09 \text{ V} \quad (\text{Eq. 3})$$

$$V_e = V_b - V_j = 0.49 \text{ V} \quad (\text{Eq. 4})$$

$$I_e = \frac{V_e}{R4} = 0.001 \text{ A} \quad (\text{Eq. 5})$$

$$I_c = \frac{I_e \beta}{(\beta + 1)} = 0.001 \text{ A} \quad (\text{Eq. 6})$$

$$V_c = (V+) - (I_c \times R3) = 7.14 \text{ V} \quad (\text{Eq. 7})$$

Refer to Fig. 25 while reading the symptoms associated with failure of various components in the circuit.

#### • $R1$ open:

$$V_b = 0, V_e = 0, V_c = 12$$

$V_b$  drops to ground potential because current through the voltage divider stops. When  $V_b < V_e + V_j$ , the transistor stops conducting.  $V_c$  rises to  $V+$ .

#### • $R1$ short:

$$V_b = 12, V_e = 11.4, V_c < V_b$$

Since the resistance of  $R1$  is zero,  $V_b = V+$ . This biases the transistor into saturation (full on), usually resulting in destruction of the transistor,  $R3$  or  $R4$ .

#### • $R2$ open:

$$V_b = 1.7, V_e = 1.1, V_c < V_b$$

The voltage divider becomes  $R1$  in series with  $R4$  and  $R_b$ . The combination of  $R1$ ,  $R4$  and  $R_b$  sets  $V_b$  at saturation, so that  $V_c$  is approximately equal to  $V_e$ .

#### • $R2$ short:

$$V_b = 0, V_e = 0, V_c = 12$$

A short in  $R2$  has the same effect as an open  $R1$ .

#### • $R3$ open:

$$V_b = 0.62, V_e = 0.02, V_c < V_b$$

No output. Since  $R3$  is open there is no  $I_c$ . This reduces  $I_e$  and  $V_e$ . The difference between  $V_e$  and  $V_b$  forward biases the e-b junction and the series combination of  $R4 + R_b$  appears in parallel with  $R2$  divider. The circuit stabilizes with  $V_e$  close to zero and  $V_b$  equal to  $V_e$  plus  $V_j$ .  $V_c$  is approximately equal to  $V_e$ .

#### • $R3$ short:

$$V_b = 1.09, V_e = 0.49, V_c = 12$$

No output. If  $R3 = 0$ , then the output voltage  $V_c = (V+) - (I_c \times 0) = V+$ .

#### • $R4$ open:

$$V_b = 1.09, V_e = 0, V_c = 12$$

No  $I_e$  can flow, therefore  $I_b = I_c = 0$ .  $V_c$  rises to  $V+$ .  $V_b$  changes imperceptibly. Attempts to measure  $V_e$  will indicate  $V_e$  slightly less than  $V_b$  because the meter provides a high-Z path for a small  $I_e$ .

#### • $C1$ or $C2$ open:

$$V_b = 1.09, V_e = 0.49, V_c = 7.14$$

Bias is normal; but the signal is gone. Loss of signal with normal bias can only be caused by a coupling capacitor. A scope or signal tracer can be used to show presence of signal and locate the faulty capacitor.

#### • $C3$ open:

$$V_b = 1.09, V_e = 0.49, V_c = 7.14$$

When  $C3$  opens, impedance to the signal is increased and gain is reduced. The voltage gain becomes  $R3/R4$ .

#### • $C3$ short:

$$V_b = 0.7, V_e = 0, V_c < V_b$$

This shorts  $R4$ , so  $V_e$  becomes 0 V.  $I_b$  increases until  $V_b$  is equal to  $V_j$ . The transistor is saturated, so  $V_c$  is approximately equal to  $V_e$ .

#### • c-b junction open:

$$V_b = 0.62, V_e = 0.02, V_c = 12$$

No  $I_c$  flows, so  $V_c$  rises to  $V+$ . Other symptoms simulate an open  $R3$ .

#### • c-b short:

$$V_b = 1.64, V_e = 1.04, V_c = 1.64$$

$V_c = V_b$  because of the short.

$$I_e = V+ / (R3 + R4); V_e = R4 \times I_e$$

$$V_b = V_e + V_j$$

#### • e-b open:

$$V_b = 1.09, V_e = 0, V_c = 12$$

No  $I_b$  and, therefore, no  $I_e$  can flow.  $V_c = V+$ ;  $V_e = 0$ .  $V_b$  is normal.

#### • e-b short:

$$V_b = 0.05, V_e = 0.05, V_c = 12$$

$V_b = V_e$ ;  $V_e$  is at a low value because  $R4$  is in parallel with  $R2$ , thus lowering  $V_b$ . Since the e-b junction is shorted,  $R_b$  is 0; all emitter current flows through the base.

There is no  $I_c$ ;  $V_c = V_+$ .

- e-c short:

$V_b = 1.09$ ,  $V_e = 1.09$ ,  $V_c = 1.09$ ,  $V_c = V_e$ . Since the emitter-collector path has no resistance, all  $I_e$  flows to the collector and there is no  $I_b$ .  $V_b$  is normal, but  $V_e = V_c$  as determined by the R3/R4 voltage divider.

#### Voltage Levels

There are two voltage levels in most cir-

cuits. Most component failures (opens and shorts) will force one of the dc measurements very close to one of these levels. Typical failures that show up as incorrect dc voltages include: open coupling transformers; shorted capacitors; open, shorted or overheated resistors and open or shorted semiconductors.

For example, consider the circuit of Fig. 25. If R2 failed open, the voltage-

divider action at the base would stop.  $V_b$  would rise to 12 V (R1 becomes a pull-up resistor) and bias the e-b junction on. With the e-b junction conducting, a new divider network is formed of R1 in series with the internal base resistance of the transistor and R4.  $V_b$  will stabilize based on this new divider — if the transistor is not destroyed while saturated. Now proceed to test the suspected parts and make the repair.

## Components

Each electronic component has a function. This section acquaints you with the functions, failure modes and test procedures of resistors, capacitors, inductors and other components. Test the components implicated by symptoms and stage-level testing. In most cases, a particular faulty component will be located by these tests. If a faulty component is not indicated, check the circuit adjustments. As a last resort, use a shotgun approach. Replace all parts in the problem area with components that are known to be good.

### Wires and Connectors

Short circuits are caused by physical damage to insulation or by conductive contamination. Damaged insulation is usually apparent during a close visual inspection of the conductor or connector. Look carefully where conductors come close to corners or sharp objects. Consider areas where wires and connectors are subject to stress.

Conductive contaminants range from water to metal filings. Most can be removed by a thorough cleaning. Any of the residue-free cleaners can be used, but remember that the cleaner may also be conductive. Do not apply power to the circuit until the area is completely dry. Keep the cleaners away from the variable-capacitor plates, transformers and parts that may be harmed by the chemical. The most common conductive contaminant is solder.

Increased resistance and open connections are most often the outgrowth of repeated flexing. Nearly everyone has broken a wire by bending it back and forth, and broken wires are usually easy to detect. Connector failure is more insidious. Most connectors maintain contact as a result of spring tension that forces two conductors together. As the parts age, they become brittle and lose tension.

Any connection may deteriorate because of nonconductive corrosion at the contacts. Solder helps prevent this problem but even soldered joints suffer from corrosion when exposed to weather.

Since poor connections increase joint resistance, the dissipated power ( $I^2R$ ) in

the joint increases. Signs of excess heat often surround poor connections in circuits that carry moderate current.

Check for short and open circuits with an ohmmeter or continuity tester. Repair worn insulation by replacing the wire or securing an insulating sleeve (spaghetti) or heat-shrink tubing over the worn area. Clean those connections that short as a result of contamination. Replace broken wires. Occasionally, corroded connectors may be repaired by cleaning, but replacement of the conductor/connector is usually required. Solder all connections that may be subject to harsh environments and protect them with acrylic enamel, RTV compound, or a similar coating.

When replacing conductors, use the same material and size, if possible. Substitute only wire of greater cross-sectional area (smaller gauge number) or material of greater conductivity. Insulated wire should be rated at the same, or higher, temperature and voltage as the wire it replaces. Replacement connectors should be chosen with consideration given to voltage and current ratings. Use connectors with symmetrical pin arrangements only where correct insertion is not critical.

### Resistors

Resistors are used to limit or divide current and to divide voltage. They fail by increasing resistance (often becoming an open circuit) or developing leakage. Excessive heat causes most resistors to permanently change value. Such heat may come from external sources or from power dissipated within the resistor. Sufficient heat burns the resistor until it becomes an open circuit. Resistors also fracture (become an open circuit) as a result of physical shock.

Leakage is only a problem with resistors of very high value (100 k $\Omega$  or more). Leakage current actually flows through dirt paths on the outside of the resistor body, mounts or circuit board, not through the resistor itself.

Resistors that have permanently changed value may be replaced, or repaired by connecting an appropriate resistor in parallel

with the faulty part. Leakage is cured by cleaning the resistor body and surrounding area.

Potentiometers suffer from noise (especially in dc circuits) in addition to the problems of fixed-value resistors. Dirt often causes intermittent contact between the wiper and resistive element. To cure the problem, spray cleaner into the potentiometer (through holes in the case) and rotate the shaft a few times. The resistive element in wire-wound potentiometers eventually wears and breaks from the sliding action of the wiper.

Replacement resistors should be of the same value, tolerance, type and power rating as the original. The value should stay within tolerance: Suppose a 10-k $\Omega$  resistor with a 20% tolerance, fails. Resistors of closer tolerance need not have the same nominal value as the original, as long as their value, plus or minus their tolerance, falls within the tolerance range ( $10,000 \times 0.8 = 8000 \Omega$  to  $10,000 \times 1.2 = 12,000 \Omega$ ) of the original. A 9100- $\Omega$ , 5%-tolerance resistor should have a value between  $9100 \times 0.95 = 8645 \Omega$  and  $9100 \times 1.05 = 9555 \Omega$ . Thus, the 5% resistor is a suitable replacement.

Replacement resistors may be of a different type than the original, if the characteristics of the replacement are consistent with circuit requirements. Some resistor families and their characteristics are:

- Carbon composition — Carbon composition resistor values are moderately stable from 0° to 60° C (their resistance increases above and below this temperature range). They are not inductive, but they are relatively noisy, and have wide tolerances.

- Wire wound — These resistors are very stable in value, and are made to close tolerances. They are, however, small coils of wire and exhibit inductance when used in ac circuits.

- Metal film — Metal film resistors are exceptionally stable in value. They are made to close tolerances, are noninductive and create little noise. High-power (above 3 W) versions are not available.

- Carbon film — Carbon film resistors

are not as stable, nor are their tolerances as close, as those of metal-film resistors. They are noninductive. Carbon-film resistors are especially useful because they have a *negative* temperature characteristic. That is, their resistance decreases with temperature. They are often used in temperature-compensation circuits.

Substitute resistors may have a greater power rating than the original, except in high-power emitter circuits where the resistor also acts as a fuse.

Potentiometers should be replaced with the same type (carbon or wire wound) and taper (linear, log, reverse log, and so on) as the original. Keep the same, or better tolerance, but be mindful of the power rating. Potentiometer power ratings are specified for the entire resistive element. A 10-W potentiometer can dissipate 10 W only when set for maximum resistance. The allowable dissipation for a segment of the resistor is proportional to the resistance of that segment, depending on taper. If the wiper of a 10-W unit were set to 30% of the total resistance, it could only dissipate 3 W in that portion of the element.

In all cases, mount high-temperature resistors away from heat-sensitive components. Also, keep carbon resistors away from heat sources. This will extend their life and assure minimum resistance variations.

## Fuses

Always use exact replacement fuses. It is important for maximum safety that the current, voltage and timing (fast-, normal- or slow-blow) be identical to the original. Also, the replacement fuse should be the same physical size. Never attempt to force a fuse that is almost the right physical size to fit into the fuse-holder. The substitution of a bar, wire or penny for a fuse invites a "smoke party."

## Capacitors

Capacitors are used to store energy (in the electrostatic field between the plates) or block the flow of dc. They fail as a result of excess current, voltage or temperature. Dielectric failure or a permanent shift of capacitance are symptoms of current overload. Voltage overload may produce internal corona or puncture the dielectric. Excess heat may come from nearby heat-generating components, excessive current, an operating frequency well beyond the capacitor design frequency or a lossy dielectric. Leakage occurs directly, through the dielectric, or through leakage paths (dirt) across the component body or chassis surface.

## Testing

The easiest way to test capacitors (out of circuit) is with an ohmmeter. In this test, the resistance of the meter forms a timing circuit with the capacitor to be checked. Capacitors from 0.01  $\mu\text{F}$  to 1.0  $\mu\text{F}$  can be tested with common ohmmeters. Set the meter to its highest range and connect the test leads across the discharged capacitor. When the leads are connected, current

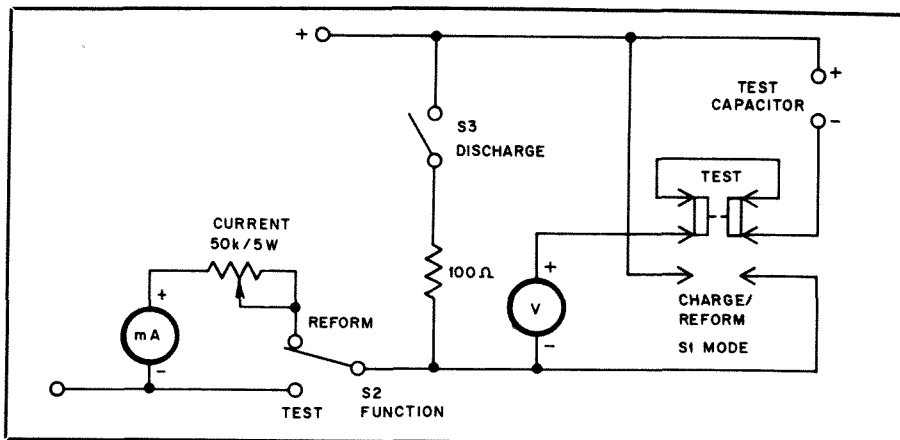

Fig. 26 — Fixture for testing capacitors and reforming the dielectric or electrolytic capacitors. Use 12 V for testing and the capacitor working voltage for reformation.

begins to flow. The capacitor passes current easily when discharged, but less easily as the charge builds. We see this on the meter as a low resistance that builds, over time, to infinity. The speed of the resistance build up corresponds to capacitance, small capacitance values seem to achieve infinite resistance instantly. A 0.01- $\mu\text{F}$  capacitor checked with a 11-M $\Omega$  FETVOM would increase from zero to a two-thirds scale reading in 0.11 second, while a 1- $\mu\text{F}$  unit would require 11 seconds to reach the same reading. If the tested capacitor does not reach infinity within five times the period taken to reach the two-thirds point, it has excess leakage. If the meter reads infinite resistance immediately, the capacitor is open. (Aluminum electrolytic capacitors cannot be measured by this method because they often give erroneous high-leakage readings.)

Fig. 26 shows a circuit that may be used to test capacitors. Make sure that the power supply is off, set S1 to CHARGE and S2 to TEST, then connect the capacitor to the circuit. Switch on the power supply and allow the capacitor to charge until the voltmeter reading stabilizes. Next, switch S1 to TEST and watch the meter for a few seconds. If the capacitor is good, the meter will show no potential. (In fact, there will be some voltage drop, but the meter will not be able to measure it.) Any appreciable voltage indicates excess leakage. After testing, set S1 to CHARGE, switch off the power supply, and press the DISCHARGE button until the meter shows 0 V, then remove the capacitor from the test circuit.

Capacitance can be measured with a dip meter, an RX bridge or a dip meter. An RX bridge (see "A Noise Bridge for 160 through 10 Meters," Chapter 25) can be used to measure capacitance by placing a 50- $\Omega$  resistor in series with the capacitor. The procedure is similar to that explained for calibrating the bridge.

To determine capacitance with a dip meter, a parallel-resonant circuit should be constructed using the capacitor of unknown value and an inductor of known value. Measure the resonant frequency of the circuit, and calculate the value of the

Fig. 27 — Partial view of an air-dielectric variable capacitor. Apply cleaning fluid where the wiper contacts the rotor plates.

unknown component, using the formula:

$$\text{unknown} = \frac{\left(\frac{1000}{2\pi f_o}\right)^2}{\text{known}} \quad (\text{Eq. 9})$$

where

$f_o$  = resonant frequency in MHz  
known = the value (L in  $\mu\text{H}$ , C in pF) of the known component

This formula works for unknowns of either C or L.

It is best to keep a collection of known components that have been measured on accurate L or C meters. Alternatively, a "standard" value might be taken as the average value of several (10 or more) components with the same marked value (disregard parts with values that differ greatly from the rest), or that of a section of coaxial cable. (Capacitance per unit length is usually specified.) Prewound, air-dielectric coils, such as Miniductor®, Polycoil®, and Air-dux® are high-Q inductors with reliable values. The accuracy of tests made with any of these alternatives depends on the accuracy of the "standard" value component. Further information on this technique appears in Bartlett's article, "Calculating Component Values," in the Nov. 1978 QST.

## Cleaning

The only variety of common capacitor that can be repaired is the air-dielectric variable capacitor. Electrical connection to the moving plates is made through a spring-wiper arrangement (see Fig. 27). Dirt nor-

mally builds on the contact area, and cleaning is occasionally required.

Before cleaning the wiper/contact, use gentle air pressure and a soft brush to remove all dust and dirt from the capacitor plates. Then use a screwdriver blade to lift the wiper gently from the rotor plate and apply some cleaning fluid. Rotate the shaft quickly several times to work in the fluid and establish contact. Use the cleaning fluid sparingly, and keep it off the plates except at the contact point.

### Replacement Capacitors

Replacement capacitors should match the original in value, tolerance, dielectric, working voltage and temperature coefficient. If exact replacements are not available, substitutes may vary from the original part in the following respects.

Bypass capacitors may vary from one to three times the capacitance of the original. Coupling capacitors may vary from one-half to twice the value of the original. Capacitance values in tuned circuits (especially filters) must be held constant, and any replacement will probably require circuit alignment.

If the same type of capacitor is not available, use one with better dielectric characteristics; however, do not use mica capacitors to block high dc voltages. Also, do not substitute polarized capacitors for nonpolarized parts. Capacitors with a higher working voltage may be used, unless the replacement is an electrolytic. When choosing substitute capacitors, consider the characteristics of each type:

- **Air dielectric** — Air-dielectric capacitors are large when compared to other types of the same value. They are very stable over a wide temperature range. Losses are low, and a high Q can be obtained. Humidity and atmospheric pressure can cause arcing. Consider plate shape when choosing replacement air variable capacitors; correct plate shape assures proper dial tracking.

- **Ceramic** — There are two types of ceramic capacitors. Those with a low dielectric constant are relatively large, but very stable and nearly as good as mica capacitors at HF.

High dielectric constant ceramic capacitors are physically small for their capacitance, but their value is not as stable. Their dielectric properties vary with temperature, applied voltage and operating frequency. Use them only in coupling and bypass roles. Tolerances are usually +100% and -20%.

Ceramic capacitors are produced with values from 100 pF to 0.1  $\mu$ F. They are not polarized.

- **Electrolytic** — Electrolytic capacitors are popular because they provide high capacitance values in small packages at a reasonable cost. Leakage is high, as is inductance, and they are polarized. Internal inductance restricts foil electrolytics to low-frequency applications. They are available

with values from 1 to 500,000  $\mu$ F.

A dielectric is "formed" by the voltage applied to the capacitor. As a consequence, electrolytics should not be used where the dc potential is well below the capacitor working voltage. It is best to slowly walk the voltage up, increasing about 10% every 10-15 minutes.

The dielectric must be re-formed when the capacitor has been stored, or operated at low voltage for long periods (two years or more). Re-formation is accomplished by applying full working voltage to the capacitor, with current limited, until the dielectric strength is restored.

The circuit shown in Fig. 26 can be used for this purpose. Set S2 to REFORM, S1 to REFORM and R2 to maximum resistance. Place the capacitor in the circuit, turn on the power supply and set it to the capacitor working voltage. Adjust CURRENT for a 10-mA reading and leave the power on until the voltmeter shows the full supply voltage across the capacitor. It may take several days to complete the re-formation; if full supply voltage is not achieved, the capacitor must be replaced.

Tantalum electrolytic capacitors perform better than aluminum units but their cost is higher. They are smaller, lighter and more stable, with less leakage and inductance than their aluminum counterparts. Re-formation problems are less frequent, but working voltages are not as high as with aluminum units.

- **Paper dielectric** — Paper capacitors are inexpensive; capacitances from 500 pF to 50  $\mu$ F are available. High working voltages are possible, but paper-dielectric capacitors have high leakage rates and tolerances are no better than 10 to 20%.

Paper-dielectric capacitors are not polarized; however, the body of the capacitor is usually marked with a color band at one end. The band indicates the terminal that is connected to the outermost plate of the capacitor. This terminal is represented by a curved line in the schematic symbol for a capacitor; it should be connected to ground, or the side of the circuit with least potential, as a safety precaution.

- **Plastic film** — Capacitors with plastic-film (polystyrene, polyethylene or Mylar) dielectrics have the same characteristics as paper capacitors in most respects. They are more expensive than paper capacitors, but have much lower leakage rates (even at high temperatures). Capacitance is more stable than that of paper capacitors; low temperature coefficients are possible. Plastic-film capacitors are not polarized.

- **Mica** — The capacitance of mica capacitors is very stable with respect to time, temperature and electrical stress. Leakage and losses are very low. Values range from 1 pF to 0.1  $\mu$ F, with tolerances from  $\pm 1\%$  to  $\pm 20\%$ . High working voltages are possible, but they must be derated severely as operating frequency increases. Mica capacitors are not polarized.

Fig. 28 — Dip-meter coupling to inductors.

Silver mica capacitors are made by depositing a thin layer of silver on the mica dielectric. This makes the value even more stable, but it presents the possibility of silver migration through the dielectric. The migration problem worsens with increased dc voltage, temperature and humidity. Avoid using silver-mica capacitors under such conditions.

### Inductors and Transformers

Inductors store energy (in a magnetic field) or restrict the flow of ac. They can fail in several ways. The most common failure is a broken conductor. A short circuit across one or more turns of a coil will impair operation. Inductors that are used to block ac signals may "leak." (The ac signal may couple magnetically or capacitively through a faulty shield can, poor lead dress or distributed capacitance in the inductor.) Inductance may change as a result of shorted turns or physical damage to the coil or core material. Excessive tank-circuit current generates enough heat to melt plastics used as coil forms.

Inductors may be checked for open-circuit failure with an ohmmeter. Dc resistance will rarely exceed a few ohms. Shorted turns and other changes in inductance show only during alignment or inductance measurement. The procedure for measurement of inductance with a dip meter is the same as that given for capacitance measurement, except that a capacitor of known value is used in the resonant circuit. Fig. 28 shows the proper dip-meter orientation with respect to various coil configurations.

Replacement inductors must have the same inductance as the original, but that is only the first requirement. They must also carry the same current, withstand the same voltage and present nearly the same Q as the original part. Given the original as a pattern, the amateur can duplicate these qualities for many inductors. Note that inductors with cores are frequency-sensitive, so the replacement must have the same core material.

If the coil is of simple construction, with the form and core undamaged, carefully observe (and record) the number of turns and their placement on the form. Also note how the coil leads are arranged and connected to the circuit. Then determine the wire size and insulation used. (There is little hope of matching coil characteristics unless the wire is duplicated exactly in the new part.) Next, remove the old winding (be careful not to damage the form) and apply a new winding in its place. Be sure to dress all coil leads and connections in exactly the same manner as the original. Apply Q dope to hold the finished winding in place. Follow the same procedure in cases where the form or core is damaged, except that a suitable replacement form or core (same dimensions and permeability) must be found.

Ready-made inductors may be used as replacements if the characteristics of the original and the replacement are known and compatible. Unfortunately, many inductors are poorly marked. Thus, some comparisons and measurements are necessary.

Wire diameter, insulation and turn spacing are critical to the current and voltage ratings of an inductor. Next, eliminate those parts that bear no physical resemblance to the original part. This may seem an odd procedure, but the Q of an inductor depends on its physical dimensions and the permeability of the core material. Inductors of the same value, but of vastly different size or shape, will likely have a great difference in Q.

The Q of the new inductor can be checked by installing it in the circuit, aligning the stage and performing the manufacturer's passband tests. Although this practice is all right in a pinch, it does not yield an accurate Q measurement.

A better measurement of effective, unloaded Q can be made with a dip meter and an RF voltmeter (or a dc voltmeter with an RF probe). Make a parallel-resonant circuit using the replacement inductor and a capacitance equal to that of the tuned circuit under repair. Connect the voltmeter across this parallel combination and measure the resonant frequency. Adjust the dip-meter/circuit coupling for a convenient reading on the voltmeter, then maintain this dip-meter/circuit relationship for the remainder of the test. Vary the dip-meter frequency until the voltmeter reading drops to 0.707 times that at resonance. Note the frequency of the dip meter and repeat the process, this time varying the frequency on the opposite side of resonance. The difference between the two dip meter readings is the test-circuit bandwidth. This can be used to calculate the circuit Q:

$$Q = \frac{f_o}{Bw} \quad (\text{Eq. 10})$$

where

$f_o$  = operating frequency

Bw = measured bandwidth in the same units as the operating frequency.

Fig. 29 — Test circuits to determine the winding "sense" of transformers. Observe the sense dots.

Once the replacement inductor is found, install it in the circuit. Duplicate the placement, orientation and wiring of the original. Ground-lead length and arrangement should not be changed.

Isolation and magnetic shielding can be improved by replacing solenoid inductors with toroids; however, it is likely that many circuit adjustments will be needed to compensate for reduced coupling and mutual inductance. Alignment is required whenever a tuned-circuit component is replaced.

A transformer consists of two inductors that are magnetically coupled. Transformers are used to change voltage and current levels (this changes impedance also). Failure usually occurs as an open circuit or short circuit of one or more windings.

Amateur testing of power transformers is limited to ohmmeter tests for open circuits and voltmeter checks of secondary voltage. Make sure that the power-line voltage is correct, then check the secondary voltage against that specified. There should be less than 10% difference between open-circuit and full-load secondary voltage.

Replacement transformers must match the original in voltage, volt-ampere (VA), duty cycle and operating frequency ratings. (All transformer windings should be insulated for the full power-supply voltage.) Transformer windings are color coded; see Chapter 35 for more information. If it is necessary to determine the phase relationship of transformer leads, the tests illustrated in Fig. 29 can be used.

### Relays

Although relays are being replaced by

semiconductor switching in low-power circuits, they are still used extensively for control of high-power RF in transceivers and amplifiers. Relay action may become sluggish. Ac relays can buzz (with adjustment becoming impossible). A binding armature or weak springs can cause intermittent switching. Excessive duty cycle ruins contacts and shortens relay life.

Relays can be tested with a voltmeter or by jumping across contacts with a test lead (power on, in circuit) or with an ohmmeter (out of circuit). Look for erratic readings across the contacts, open or short circuits at contacts or an open circuit at the coil.

Most failures of simple relays can be repaired by a thorough cleaning. Clean contacts and mechanical parts with a residue-free cleaner. Keep it away from the coil and plastic parts that may be damaged. Dry the contacts with lint-free paper, such as a business card; then burnish them with a smooth steel blade. Do not use a file to clean contacts.

Replacement relays should match or exceed the original specifications for voltage, current, switching time and impedance (impedance is significant in RF circuits only). Many relays used in transceivers are specially made for the manufacturer. Substitutes may not be available from any other source.

Before replacing a multicontact relay, make a drawing of the relay, its position, the leads and their routings through the surrounding parts. This drawing allows you to complete the installation properly, even if you are distracted during the delicate operation. RF leads must be dressed exactly

Fig. 30 — A diode conduction, leakage and Zener-point test fixture. The ammeter should read mA for conduction and Zener-point,  $\mu$ A for leakage tests.

as they were on the original part, or alignment may be required.

## SEMICONDUCTORS

### Diodes

The primary function of a diode is to pass current in one direction only. Zener diodes are made with a predictable reverse-breakdown voltage and used as voltage regulators. Varactor diodes are specially made for use as voltage-controlled variable capacitors. (Any semiconductor diode may be used as a voltage-variable capacitance, but the value will not be as predictable as of a varactor.) A Diac is a special-purpose diode that passes only pulses of current in each direction.

Rectifier diodes fail by becoming an open circuit, a short circuit, by developing excess reverse leakage or by losing the ability to switch on and off quickly. Zener diodes may also fail by shifting their avalanche (reverse-breakdown) point. Varactor diodes fail in the same fashion as capacitors.

There are three basic tests for most diodes. First, is it a diode? That is, does it conduct in one direction and block current flow in the other? An ohmmeter is suitable for this test in most cases.

Before tests begin, make sure the meter uses a voltage of more than 0.7 V and less than 1.5 V to measure resistance. Next, use a good diode to determine the meter polarity: Set the meter to read ohms  $\times 100$  and connect the test probes across the diode. When the negative terminal of the ohmmeter battery is connected to the cathode, the meter will show 200 to 300  $\Omega$  (forward resistance) for a good silicon diode, 200 to 400  $\Omega$  for a good germanium diode. Reverse the lead polarity and set the meter to ohms  $\times 1M$  (times one million, or the highest scale available on the meter) to measure diode reverse resistance. Good diodes should show 100- to 1000-M $\Omega$  and 100-k to 1-M $\Omega$  for silicon and germanium, respectively. When done, mark the meter lead polarity for future reference.

To check a suspected diode, disconnect one end of the diode from the circuit, then measure the forward and reverse resistance. Diode-quality is shown by the ratio of reverse to forward resistance. A ratio of

100:1 is typical for small-signal diodes. The ratio may go as low as 10:1 for power diodes.

This procedure measures the junction resistances at low voltage. If the Zener point of a rectifier diode has shifted to a low value, it may not show in this test. The defect might show in the leakage-current measurement, but substitution is the only dependable test.

The second diode test measures the forward voltage drop across the diode junction. This measurement is made while the diode is conducting. Use a test circuit like that shown in Fig. 30, connect the diode, adjust the supply voltage until the current through the diode matches the manufacturer's specification and compare the junction drop to that specified. Silicon junctions usually show about 0.6 V, while germanium is typically 0.2 V. Junction voltage drop increases with current flow. The results of this test can be used to choose diodes that are matched with respect to forward resistance at a given current level.

The final simple diode test measures diode leakage current. Place the diode in the circuit used above, but with reverse polarity. Set the specified reverse voltage and read the leakage current on the ammeter. (The currents and voltages measured in the junction voltage-drop and leakage tests vary by several orders of magnitude.)

The major criterion of Zener diodes is the Zener voltage. The Zener-voltage test also uses the circuit of Fig. 30. Place the diode in the circuit (so that it is reverse biased), increase the voltage until there is a large increase in current flow, then read the Zener voltage from the voltmeter.

Replacement rectifier diodes should have the same current and peak inverse voltage (PIV) as the original. Series combinations of diodes are often used in high-voltage rectifiers. Good engineering practice demands that the voltage be distributed equally across each diode. This is accomplished by placing a resistor and capacitor across each diode. When a diode fails, check the associated components also.

Switching diodes may be replaced with diodes that have equal or greater current ratings and a PIV greater than twice the peak-to-peak voltage of the signal they switch. Switching time requirements are not critical except in logic and some keying circuits. RF switching diodes used near resonant circuits must have exact replacements, as the diode resistance and capacitance will affect the tuned circuit. Logic circuits require exact replacements to assure compatible switching and load characteristics.

Voltage, current and capacitance characteristics must be considered when replacing varactor diodes. Once again, exact replacements are best.

Zener diodes should be replaced with parts having the same Zener voltage and equal or better current, power, impedance and tolerance specifications. Check the associated current-limiting resistor when

replacing a Zener diode.

### Bipolar Transistors

The fundamental purposes of transistors are to switch and to amplify. Transistor failures occur as an open junction, a shorted junction, excess leakage or a change in amplification performance.

Transistor tests are not performed at the planned operating frequency. Tests are made at dc or a low frequency (usually 1000 Hz). This practice is based on the assumption that the semiconductor meets all of its specifications equally well. That is, if it functions at low frequencies, it functions equally well at high frequencies. When special RF circuits (such as oscillators) are planned, build a circuit to test prospective devices at the operating frequency. The circuit under repair is the best test of a potential replacement part.

The simplest and probably the most telling of bipolar-transistor tests is performed with a test lead, a 10-k $\Omega$  resistor and a voltmeter, while the transistor is in a circuit with the power on. Connect the voltmeter across the emitter/collector leads and read the voltage. Then use the test lead to connect the base and emitter leads (Fig. 31A). Under these conditions, conduction of a good transistor will be cut off and the meter should show nearly the entire supply voltage across the emitter/collector leads. Next, remove the clip lead and connect the 10-k $\Omega$  resistor from the base to the collector. This should bias the transistor into conduction and the emitter/collector voltage should drop. (Fig. 31B) (This test indicates transistor response to changes in bias voltage.)

Transistors can be tested (out of circuit) with an ohmmeter in the same manner as diodes. Look up the device characteristics before testing and consider the consequences of the ohmmeter-transistor circuit. Limit junction current to 1 to 5 mA for small-signal transistors. Transistor destruction or inaccurate measurements may result from careless testing.

Use the ohms  $\times 100$  and ohms  $\times 1000$  ranges for small-signal transistors. For high-power transistors use the ohms  $\times 1$  or ohms  $\times 10$  ranges. The reverse-to-forward resistance ratio for good transistors may vary from 30:1 to 100:1. Germanium transistors sometimes show low reverse resistance when tested with an ohmmeter.

Bipolar transistor leakage may be specified from the collector to the base, emitter to base or emitter to collector (with the junction reverse biased in all cases). The specification may be identified as  $I_{cbo}$ ,  $I_{ebo}$ , collector cutoff current or collector leakage for the base-collector junction,  $I_{ebo}$ , and so on for other junctions.<sup>4</sup>

<sup>4</sup>The term, " $I_{cbo}$ " means, "Current from collector to base with emitter open." The subscript notation indicates the status of the three device terminals. The terminals concerned in the measurement are listed first, with the remaining terminal specified as "s," shorted, or "o" open.

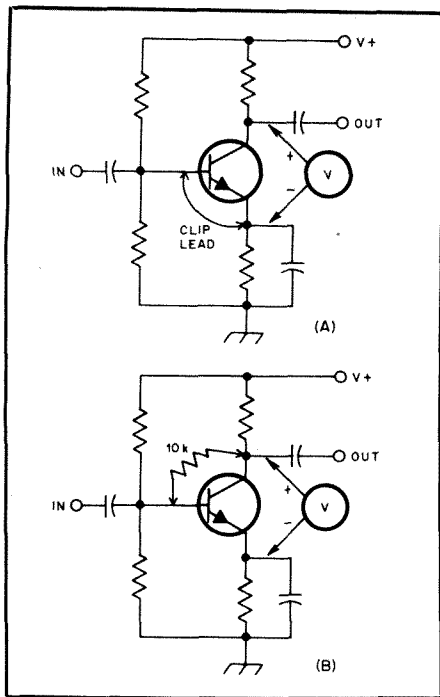

Fig. 31 — An in-circuit semiconductor test with a clip lead, resistor and voltmeter. The meter should read V+ at (A), and anything from a slight variation to 0 V at (B).

Fig. 32 — A test circuit for measuring collector-base leakage with the emitter shorted, open or shorted through a (variable) resistance, depending on the setting of S1. See the transistor manufacturer's instructions for test conditions and the value of R1 (if used). Reverse battery polarity for PNP transistors.

Manufacturers may require that tests be made with the emitter lead unconnected, shorted to the base or connected to the base through a resistor. Temperature is critical to this test. Allowable leakage current increases with junction temperature.

A suitable test fixture for base-collector leakage measurements is shown in Fig. 32. Make the required connections and set the voltage as stated in the transistor specifications and compare the measured leakage current with that specified. Small-signal germanium transistors exhibit  $I_{cbo}$  and  $I_{ebo}$  leakage currents of about 15  $\mu A$ . Leakage increases to 90  $\mu A$  or more in high-power

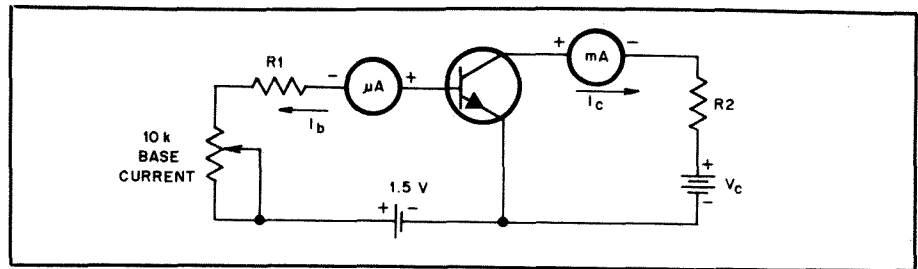

Fig. 33 — A test circuit for measuring transistor beta. Values for R1 and R2 will vary widely with the transistor tested. Reverse the battery polarities for PNP transistors.

components (germanium power transistors can develop excess leakage while sitting on the shelf.) Leakage currents for silicon NPN transistors are seldom more than 1  $\mu A$ . Leakage current tends to double for every 10° C increase above 25° C.

Breakdown-voltage tests actually measure leakage at a specified voltage, rather true breakdown voltage. Breakdown voltage is known as  $BV_{cbo}$ ,  $BV_{ces}$  (emitter shorted to base) or  $BV_{ceo}$ . Use the same test fixture shown for leakage tests, adjust the power supply until the specified leakage current flows, and compare the junction voltage against that specified.

A circuit to measure dc current gain is shown in Fig. 33. Current gain is also known as:

$$\bullet (\alpha) = \frac{\Delta I_c}{\Delta I_e}$$

in a common-base amplifier

$$\bullet (\beta) = \frac{\Delta I_c}{\Delta I_b}$$

in a common-emitter amplifier; "collector-to-base current gain," "forward current-transfer ratio,"

- $h_{FE}$  = (ac current gain).
- $h_{fe}$  = (dc current gain).

Conditions for gain testing are dictated by the manufacturer's data sheet. When testing, do not exceed the voltage, current (especially in the base circuit) or dissipated-power rating of the transistor. Make sure that the load resistor is capable of dissipating the power generated in the test. When  $I_c$  is high, measure the emitter-collector leakage current (with emitter shorted to base) first, and subtract the leakage from  $I_c$  before calculating gain. Do not neglect the effect of the meter resistance on the circuit.

RF devices should be tested at RF. Most component manufacturers include a test-circuit schematic on the data sheet. The test circuit is usually an RF amplifier that operates near the high end of the device frequency range.

Semiconductor failure is nearly always the result of environmental conditions. Open junctions, excess leakage (except with germanium transistors) and changes in amplification performance result from overload or excessive current. Shorted junctions are caused by voltage spikes.

Fig. 34 — Ohmmeter tests of a JFET. The junction is reverse biased at A and forward biased at B.

Check surrounding parts for the cause of the transistor's demise, and correct the problem before installing a replacement.

## JFETs

Junction FETs can be tested, out of circuit, with an ohmmeter in much the same way as bipolar transistors (see Fig. 34). Connect the negative ohmmeter lead to the gate of an N-channel JFET and check the resistance to both source and drain. The JFET is reverse biased by the ohmmeter battery, and resistance across each junction should be several megohms or more (using the ohms  $\times 1M$  scale). Then reverse the lead polarity to measure the forward resistance of each junction, which should be 500 to 1000  $\Omega$ . P-channel JFETs can be checked in the same manner with the test-lead

polarity reversed for both tests.

## MOSFETs

MOS (metal-oxide semiconductor) layers are extremely fragile. Normal body static is enough to puncture this delicate insulator. Even gate-protected (a diode is placed across the MOS layer to clamp voltage) MOSFETs may be destroyed by 6 V. Make sure the power is off, capacitors discharged and the leads of a MOSFET are shorted together before installing or removing it from a circuit. Use a voltmeter to be sure the chassis is near ground potential, then touch the chassis before and during MOSFET installation and removal. This assures that there is no difference of potential between your body and the MOSFET leads. Follow this equalization procedure whenever a MOSFET may contact another object. Ground the soldering-iron tip with a clip lead when soldering MOS devices. The source should be the first lead connected and the last disconnected to a circuit.

The insulating layers in MOSFETs prevent testing with an ohmmeter. They can be checked for operation with the transistor tester shown in Chapter 25. The test, however, is only a general check for operation, substitution is the only practical means for amateur testing of MOSFETs.

## FET Considerations

Replacement FETs should be of the same kind as the original part. That is, JFET or MOSFET, P-channel or N-channel, enhancement or depletion characteristics should be chosen to match the original.

Next consider the breakdown voltage required by the circuit. Always allow for twice to four times the signal voltage in amplifiers. Provision should be made for transients of 10 times the line voltage in power supplies. Breakdown voltages are usually specified as  $V_{(BR)GSS}$  or  $V_{(BR)GDO}$ .

Gate-voltage specifications indicate the bias or signals required for operation. The specification usually gives the gate voltage required to cut off or initiate channel current (depending on the mode of operation). Gate voltages are usually listed as  $V_{GS(OFF)}$ ,  $V_p$  (pinch off),  $V_{TH}$  (threshold) or  $I_D(ON)$  or  $I_{TH}$ .

Gate leakage is a measure of FET input impedance. MOSFET gate leakage is extremely small; JFET leakage is greater. Leakage does not increase appreciably with temperature in either device. The characteristic may be called  $I_{GSS}$  (leakage from gate to source with drain shorted to source),  $I_{GSO}$  or  $I_{GDO}$ . (The first term is the preferred measurement, as the GSS configuration results in greater leakage.)

Dual-gate MOSFET characteristics are complicated by interaction of the two gates. Cutoff voltage, breakdown voltage and gate leakage are the important traits of each gate.  $V_{GIS(OFF)}$  is the cutoff voltage designation for gate 1, while  $V_{(BR)G1SS}$  and  $I_{G1SS}$  are the gate-1 breakdown

voltage and leakage current designators, respectively.

## Semiconductor Substitution

In all cases try to obtain exact replacement semiconductors. Specifications vary slightly from one manufacturer to the next. Also, device specifications are minimums; some units far exceed them. Obtain replacements for PA devices (and others that are not common) from the equipment manufacturer. Some parts are specially selected for a particular characteristic by the maker.

Crossover equivalents are useful, but not infallible. Before using an equivalent, check the specifications against those for the original part. When choosing a replacement, consider:

- Is it silicon or germanium?
- Is it a PNP or an NPN?
- Operating frequency and input/output capacitance.
- Dissipated power (often less than  $V_{max} \times I_{max}$ ).
- Will it fit the original mount?
- Unusual circuit demands (low noise and so on).
- The gain-bandwidth product.

Remember that crossover equivalents are listed without testing, and manufacturer's numbers are not necessarily unique. Derate power specifications, as recommended by the manufacturer, for high-temperature operation.

## INTEGRATED CIRCUITS

The basics of integrated circuits are covered in Chapter 4. Amateurs seldom have the sophisticated equipment required to test ICs. Even a multitrace 'scope can view only their simplest functions. We must be content to check every other possible cause, and only then assume that the problem lies with an IC.

There are two major classes of ICs: Linear and digital. Linear ICs are best replaced with identical units. Do not overlook equipment manufacturers as a source of replacements; they are the only source with a reason to stockpile obsolete or custom-made items. If substitution of an IC is unavoidable, look in one of the many books written about ICs, their use and traits. Understanding and assessing the necessary characteristics can be as difficult as redesigning the entire circuit. In fact, extensive modifications of the coupling circuits and wiring may be required to conform to the new device connections. The concept of the electronic building block, which implies some degree of interchangeability, is fundamental to IC production, but the intricacies of comparison make substitution difficult.

Substitution of digital and array ICs is somewhat easier than that of linear ICs because there are fewer significant characteristics to consider. Digital signals, because of their on/off nature, demand only speed and slight power, not fidelity,

from a device.

First, review the explanation of the various logic families and their electrical characteristics in Chapter 8. Interface circuits and their limitations are covered there also. Consider interface and logic requirements, switching time and fan-out when choosing substitute parts. Check supply voltages, at the lead to the IC pin, once again before installing any new IC. It is a good idea to check the potential on each trace to the bad component. The old IC may have "died" as a result of a lethal voltage. Measure twice — repair once! Of course, in-circuit performance is the final test of any substitution.

## TUBES

The most common tube failures in amateur service are cathode depletion and gas contamination. Whenever a tube is operated, the coating on the cathode loses some of its ability to produce electrons. It is time to replace the tube when electron production (cathode current,  $I_c$ ) falls to 50 to 60% of that exhibited by a new tube. This kind of tube failure is accelerated by exceeding the recommended duty cycle, as is often the case when sweep tubes are pressed into amateur service. High-gain power-amplifier tubes often fail from cathode depletion when filament voltage is not adequately regulated.

A gas-contaminated tube can be spotted because there is often a glow *between* the elements during operation. The gas reduces tube resistance and leads to runaway plate current evidenced by a red glow from the anode, interelectrode arcing or a blown power-supply fuse. Runaway plate current is most likely to occur during long transmissions at higher operating frequencies.

Less common tube failures include an open filament, broken envelope and interelectrode shorts. Use an ohmmeter to check for an open filament (remove the tube from the circuit first). A broken envelope is visually obvious, although a cracked envelope may appear as a gassy tube. Interelectrode shorts are evident during voltage checks on the operating stage. Any two elements that show the same voltage are shorted. (Remember that some interelectrode shorts, such as the cathode-suppressor grid, are normal.) Confirm that the tube is shorted, and not the circuit, by removing the tube.

Substitution is the best test of a tube. First, check the tube for opens and shorts on a tester. If the tube has an open element, check the surrounding circuits for shorts, then try a new tube. When you suspect that tubes are weak, check them by substitution. Place a new tube in the circuit and leave it in place only if there is a noticeable improvement. In power-supply circuits, measure the B+ with the old tube in place. If a new tube increases the B+ by 10% or more, leave the replacement in the circuit. Remember that no tube tester can adequately test a tube for use as an oscillator.

The "life test" is meant to determine if a tube will fail in the near future. Connect the tube to an emission tester and reduce the filament voltage by 20% from normal. If the plate current drops below that of a good tube, the service life of the tube is nearly over. Also, the cathodic emission of a strong tube falls slowly when filament voltage is removed; emission in a weak tube stops immediately.

Tube testers are covered earlier in this chapter. Look there for more information about testers and tips on their use.

Generally, a tube may be replaced with another that has the same basic model number, but look at data sheets for the respective tubes to verify their compatibility. Consider the base configuration and pinout, interelectrode capacitances (a small variation is okay except for tubes in oscillator service), dissipated power ratings of the plate and screen grid and current limitations (both peak and average).

For example, the 6146A may be replaced with a 6146B (heavy duty), but the B-suffix tube should not be replaced with an A-suffix version. (See the tetrode and pentode transmitting tube specifications in Chapter 35: A 6146B can dissipate 35 W safely, while a 6146A is rated at only 25 W.) In some cases, the difference denotes differences in filament voltages, or even base styles, so check *all* specifications before making a replacement.

As usual, the best course is an exact replacement from the equipment manufacturer; especially for tubes used in RF-power and oscillator circuits. (These are sometimes hand-picked or close-tolerance versions of standard models. Even tubes of the same model number, prefix and suffix vary slightly, in some respects, from one supplier to the next.)

## CHECKOUT

Inspect each circuit visually when repairs are complete. Look for cold solder joints and signs of damage incurred during the repair. Use a bright light close behind printed circuit boards to check for breaks in the copper foil. Double check the position, leads and polarity of diodes, transistors and electrolytic capacitors that were removed or replaced. Make sure that all ICs have pin 1 in the proper spot. Test fuse continuity with an ohmmeter and verify that its current rating matches the circuit specification.

Observe the lead dress. Place wires clear of screw points and sharp edges. Separate the leads that carry dc, RF, input and output as much as possible. Plug-in circuit boards should be firmly seated with screws tightened and star washers installed if so specified. Shields and ground straps should be installed just as they were on the original.

### For Transmitters Only

Since the signal produced by an HF transmitter can be heard the world over,

a thorough check is demanded after any service. Follow the procedure below to make sure the transmitter operates properly. Do not exceed the transmitter duty cycle while testing. Limit transmissions to 10 to 20 seconds unless otherwise specified by the owner's manual.

- 1) Set all controls as specified in the operation manual, or at mid scale.

- 2) Connect a dummy load and a power meter to the transmitter output.

- 3) Set the drive or carrier control for low output.

- 4) Switch the power on.

- 5) Transmit and quickly set the final-amplifier bias to specifications.

- 6) Slowly tune the output network through resonance. The current dip should be smooth and repeatable. It should occur simultaneously with the maximum power output. If these characteristics are not present, the amplifier is unstable. Adjust the neutralization circuit (see details in Chapter 15) if one is present or check for oscillation. An amplifier requires neutralization whenever active devices, components or lead dress (that affect the output/input capacitance) are changed.

- 7) Check to see that the output power is consistent with the amplifier class used in the PA (efficiency should be about 25% for Class A, 50 to 60% for Class AB or B, and 70 to 75% for Class C.)

- 8) Repeat steps 4 through 6 for each band of operation from lowest to highest frequency.

- 9) Check the carrier balance (in SSB transmitters only) and adjust for minimum power output with maximum RF drive and no microphone gain.

- 10) Adjust the VOX controls.

- 11) Measure the passband and distortion levels if equipment (wide-bandwidth 'scope or spectrum analyzer) is available.

### All Other Repaired Circuits

After completing all of the preliminary checks, remove any test equipment, set the circuit controls per the manufacturer's specifications (or to midrange if specifications are not available), and switch the power on. Watch and smell for smoke, and listen for odd sounds such as arcing or hum. Operate and observe the circuit for a few minutes, consistent with allowable duty cycle. Vary all operating controls through their full range (consistent with operating instructions); see that they have the desired effects. Measure the gain and distortion of repaired amplifiers.

If the circuit appears to be operating normally, vary the power-supply voltage  $\pm 10\%$  while checking for intermittent connections. Check for intermittents by subjecting the circuit to heat, cold and slight flexure. Also, tap or jiggle the chassis lightly with an alignment tool or other insulator. If the equipment is meant for mobile or portable service, operate it through an appropriate temperature range. Many mobile radios do not work on cold

Fig. 35 — Ship equipment packed securely in a box within a box.

mornings, or on hot afternoons, because a temperature-dependent intermittent was not found during repairs.

## FACTORY REPAIRS

This chapter does not tell how to perform all repairs. Those repairs that deal with very complex and temperamental circuits, or that require sophisticated test equipment, should be passed on to a professional.

You should have opened a dialog with the manufacturer early in the repair work: If you did not, do so now. Notify the repair center before shipping any equipment. Get authorization for shipping and an identification name or number for the package.

Begin the packing procedure by blocking and tying down all heavy components. Large vacuum tubes should be wrapped in packing material or shipped separately. Make sure that all circuit boards and parts are firmly attached. Enclose a statement of the trouble, a short history of operation and any test results that may help the service technician.

Use a box within a box for shipping. (See Fig. 35) Place the equipment and some packing material inside a box. Seal the box with tape, address it, and mark it "Fragile — Electronic Equipment." Place that box inside another that is at least six inches larger in each dimension. Fill the gap with packing material, seal, address and mark the outer box. Choose a good freight carrier and insure the package.

### Used Equipment

There is a certain thrill we all feel as we enter the flea market at our favorite hamfest. Vikings, "Gooney birds," Warriors and the venerable S-Line appeal to almost everyone. Equally tempting is the allure of a bargain; few hams can resist one.

Keep an eye on the classified section of radio magazines. Know the going price for radios that interest you and never pay that price without a demonstration. Try to buy equipment that was of high quality when it was new. It will serve you well when it is old.

Any gear that has been in storage may need repair. When you are looking for a

bargain, gear that needs repair is usually the best buy unless:

- It is heavily damaged.
- Expensive test gear is needed for repair.
- No manual or parts are available.

### Recently Built Equipment

First, do not buy unless you know the manufacturer. Know the equipment and whether parts and manuals are available. See that the manual is included in the sale — manuals are difficult to locate and expensive.

When a good prospect is found, open the cabinet. Look for missing parts, evidence of fire or damage. Purchase modified equipment if you trust the seller, or if the modifications can be easily removed. Modifications are as good as the skill of the person who installed them. Check the meter functions; the readings can tell you much.

### Older Gear

Gear made before 1970 is usually suitable only for CW operation. Once again, do not overpay, watch for modifications and get the manual. Check for missing parts, and do not waste time on equipment that was inferior when new.

Beware of power supplies that do not use an isolation transformer. Such gear is difficult to modify. Connection of accessories, such as a keyer, keyboard or Q multiplier, is dangerous.

### Restoration

First, open the cabinet and replace any parts that show signs of physical damage. Electrolytic capacitors often fail with age. Visual failure signs include bulges and leakage of a thick fluid or a white, gray or brownish paste or powder. Even if none of these signs are present, an electrolytic capacitor may be destroyed when power is first applied after long disuse. This may be prevented by re-forming the dielectric layer before applying power (see earlier section of this chapter).

Paper capacitors (wax or plastic coated) fail by leakage. They exude fluid or develop cracks in their coating. Replace faulty paper capacitors with dipped-Mylar units of the same, or higher, working voltage.

Mica and ceramic capacitors survive storage better than their tubular counterparts, but they require more exact replacements. Replacements must match not only the capacitance and working voltage of the original, but also the tolerance and temperature coefficient in all but bypass applications.

Remove dust and dirt with a small brush and a vacuum cleaner while inspecting the circuitry. Use extreme care around variable capacitors, inductors and rotary switches. Clean potentiometers and rotary switches with residue-free spray cleaner. Service air-dielectric variable capacitors as described earlier in this chapter. An eraser will clean stubborn dirt from rotary switch contacts,

but be very gentle and do not disturb lead dress around the switch. If leads to RF circuits are disturbed during cleaning, alignment may be affected.

After all visible problems have been corrected, disconnect one of the transformer secondary leads and measure the dc resistance from the power-supply output to ground. If the resistance is not consistent with the power ratings of the supply, locate the reason before applying power. If all is well, reconnect the transformer secondary and use a variable-voltage transformer to apply power gradually to the circuit. Listen and watch for arcs in the circuit as power is applied. Equipment that has been in storage should be "burned in" before proceeding. Operate the circuit (within duty-cycle limits) several hours each day for a week. Stay near the gear during this period to make sure that the "burn in" does not become a "burn down."

Once the basic clean up is completed, note any troubles as instructed earlier in this chapter and begin the normal repair routine. Once the equipment is repaired, clean the cabinet, instrument panel and knobs with household or automotive cleaner and a small brush. Smooth surfaces may be brightened by an application of automotive wax.

### A SPECIAL CASE — NEW CONSTRUCTION

In most repair work, the technician is aided by the knowledge that the circuit once worked. It is only necessary to find the faulty part(s) and replace it. This is not so with newly constructed equipment. Repair of equipment with no working history is a special, and difficult, case.

Try to tackle the project one stage at a time. Consider each stage as two halves: Input and output. Look for any active device that is either saturated or cut off. Problems with the bias circuit are usually evident even with no input signal.

Use this procedure to set the bias of a high-gain amplifier. Set up the amplifier with a suitable dummy load and an oscilloscope on the output. Feed the input with a sine wave through an appropriate matching network. Increase the drive until the output waveform is clipped to a nearly square wave (See Fig. 36). Adjust the bias so that the positive and negative sections of the wave have equal duty cycles. Decrease the drive level slowly while making fine bias adjustment to maintain the duty cycle.

If equal clipping is not possible, suspect the component values or design. Nonlinear operation can be cured by adjusting values in the bias network, unless the active device is unsuitable for the circuit. When the circuit will only operate near saturation or cut off, try reducing positive feedback.

Once the bias is adjusted, check carefully for oscillations or noise. Oscillations are most likely to start with maximum gain and the amplifier input shorted. Any noise that

Fig. 36 — Waveforms seen while adjusting amplifier bias. The amplifier is overdriven at A, adjusted for proper duty cycle at B and operating normally at C.

is induced by 60-Hz sources can be seen with a 'scope synchronized to the ac line. Test with the supply voltage varied by  $\pm 10\%$  (high-gain circuits are sensitive to supply-voltage changes).

RF oscillations should be cured with changes of lead dress or circuit components. Separate input leads from output leads; use coaxial cable to carry RF between stages; neutralize inter-element or junction capacitance. Ferrite beads on the control element of the active device often stop unwanted oscillations.

Low-frequency oscillations ("motor-boating") indicate poor stage isolation or inadequate power-supply filtering. Try a better lead-dress arrangement and/or increase decoupling capacitance. Use larger capacitors at the power-supply lead, increase the number of capacitors or use separate decoupling capacitors at each stage.

Coupling capacitors that are too low in value cause poor low-frequency response. Poor response to high frequencies is frequently caused by transistor input capacitance. The input capacitance of a transistor decreases with frequency; this lowers stage gain. Reducing the stage gain at lower frequencies will help, as will using a better transistor.

## Chapter 27

# Power Supply Projects

**C**onstruction of a power supply can be one of the most rewarding projects undertaken by a radio amateur. Whether it's a charger for the NiCds in a VHF hand-held transceiver, a low-voltage, high-current monster for a new 100-watt solid-state transceiver, or a high-voltage supply for a new linear amplifier, a power supply is basic to all of the radio equipment we enjoy and operate. Power-supply projects are especially inviting to amateurs new to rolling their own. Unlike transmitters and receivers, layout and wiring of power supplies is not particularly important to proper operation. Parts for many power-supply projects are readily available in many areas, either through local retail outlets or at flea markets and hamfests. The power-supply project requiring a special, hard-to-find part is the exception, rather than the rule. In addition, final testing and adjustment of most power-supply projects requires only a voltmeter, and perhaps an oscilloscope — tools commonly available to most amateurs.

Additional information on power-supply design and theory may be found in Chapter 6. General construction techniques that may be helpful in building the projects in this chapter are outlined in Chapter 24. Chapters 2, 3, 4 and 5 contain basic information on the components that make up power supplies.

Safety must always be carefully considered during design and construction of any power supply. Power supplies contain potentially lethal voltages, and care must be taken to guard against accidental exposure. For example, electrical tape, in-

sulated tubing (spaghetti) or heat-shrink tubing is recommended for covering exposed wires, component leads, component solder terminals and tie-down points. Whenever possible, connectors used to mate the power supply to the outside world should be of an insulated type designed to prevent accidental contact.

Connectors and wire should be checked for voltage and current ratings. Always use wire with an insulation rating higher than the working voltages in the power supply. Special high-voltage wire is available for use in B+ supplies. Chapter 35 contains a table showing the current-carrying capability of various wire sizes. Stripping on wire and connectors to save money could result in a flashover, meltdown or fire.

All fuses and switches should be placed in the hot leg(s) only. The neutral leg should not be interrupted. Use of a three-wire (grounded) power connection will greatly reduce the chance of accidental shock. The proper wiring color code for 117-V circuits is: black — hot; white — neutral; and green — ground.

### Power Supply Primary Circuit Connector Standard

The International Commission on Rules for the Approval of Electrical Equipment (CEE) standard for power supply primary circuit connectors for use with detachable cable assemblies is the CEE-22 (see Fig. 1). The CEE-22 has been recognized by the ARRL and standards agencies of many countries. Rated for up to 250 V, 6 A at 65° C, the CEE-22 is the most commonly used three-wire (grounded), chassis-mount

Fig. 1 — CEE-22 connectors are available with built-in line filters and fuse holders.

primary circuit connector for electronic equipment in North America and Europe. It is often used in Japan and Australia as well.

When building a power supply requiring 6 A or less from the primary supply, a builder would do well to consider using a CEE-22 connector and an appropriate cable assembly, rather than a permanently installed line cord. Use of a detachable line cord makes replacement easy in case of damage. CEE-22 compatible cable assemblies are available with a wide variety of power plugs including most types used overseas.

Some manufacturers even supply the CEE-22 connector with a built-in line filter. These connector/filter combinations are especially useful in supplies that are operated in RF fields. They are also useful in digital equipment to minimize conducted interference to the power lines.

CEE-22 connectors are available in many styles for chassis or PC-board mounting. Some have screw terminals; others have solder terminals. Some styles even contain built-in fuse holders.

## A 5-A Switching Supply

This section describes a practical 13.8-volt, 5-ampere switching power supply suitable for use with transceivers in the 25-watt-output class. Circuit simplicity and easy parts acquisition were the major design goals. The supply was built and tested in the ARRL laboratory by Greg Bonaguide, WA1VUG. A 10-watt-output 220-MHz FM transceiver was used as a load with no apparent degradation of the RF output spectral purity. The line and load regulation are acceptable, and the unit

is slightly more efficient than an equivalent linear supply. With the heat sink specified, the unit can withstand 3-minute FM transmissions interspersed with 1-minute listening periods. Because of the simple circuit configuration, conventional preregulation components are used. Therefore, this

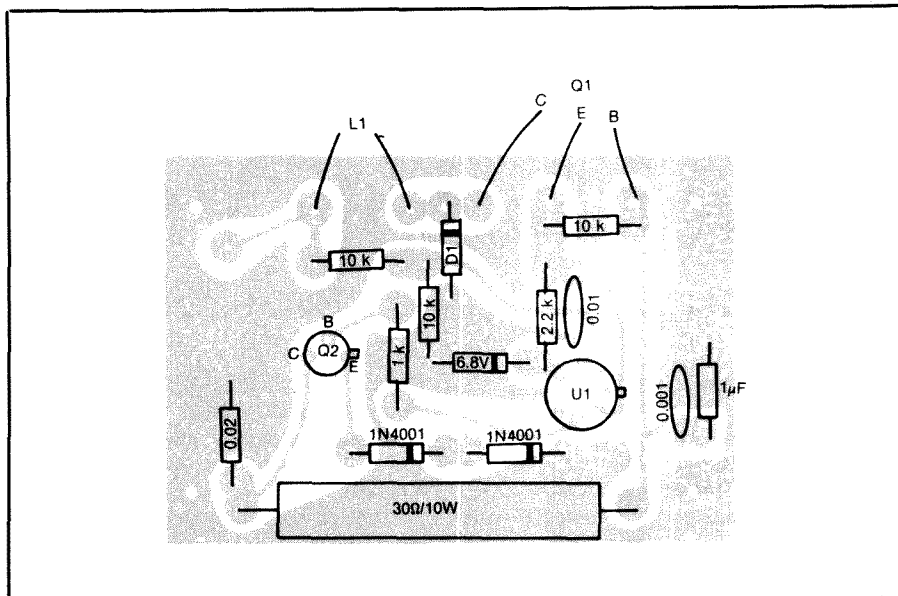

Fig. 2 — Front panel of the switching power supply. The cabinet is by Apollo and has a built-in power switch.

**Fig. 3 — Interior view of the switching power supply. The main switch transistor heat sink and fuse are mounted on the rear panel.**

power supply offers no particular economic advantage over one using linear regulation. This project was intended to demonstrate the switching principle as applied to voltage regulation, and it serves that purpose well. However, it is not in any way represented to be a state-of-the-art design.

**Fig. 5 — Parts-placement guide for the PC board of the switching-regulator supply control board.** The component side is shown with an X-ray view of the foil. A full-size etching pattern can be found at the back of this book.

A more nearly technically correct name for this project might be "A 5-A Power Supply Using a Switching Regulator." However, it's not necessary to belabor the distinction between supplies and regulators in casual work.

Fig. 2 shows the cosmetic aspects of the front panel, while Fig. 3 reveals one satisfactory arrangement of internal com-

ponents. The schematic diagram is given in Fig. 4. Stud-mount rectifiers are used in a full-wave bridge. A PC board for the diodes is visible in Fig. 3, but the etching pattern is not printed here because of its simplicity. The component-placement guide for the electronics board is given in Fig. 5. A full-size etching pattern can be found at the back of this book.

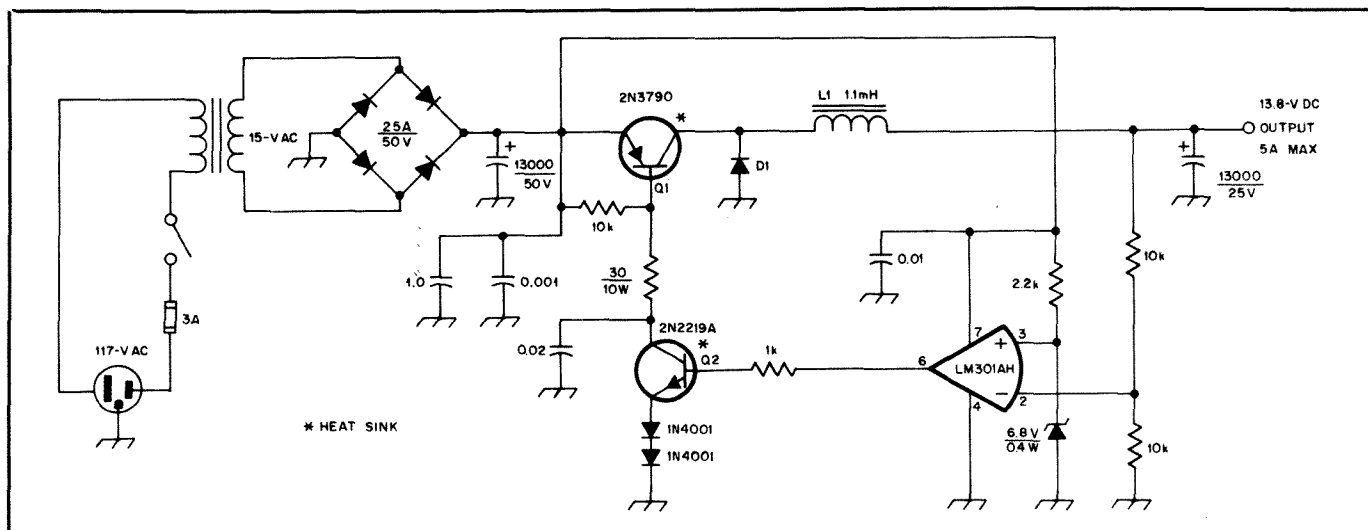

Fig. 4 — A switching power supply suitable for use with medium-power amateur transceivers. At full load the switching rate is approximately 50 kHz. Resistance values are in ohms, and capacitance values are in microfarads.

# An RF-Proof 30-Amp Supply

Solid-state technology has made possible circuit miniaturization that was only dreamed about 20 years ago. This new technology has afforded the amateur community medium-power equipment compact enough to use in even the most cramped mobile environment. This equipment is normally designed to operate from a source of 13.8-V dc and is well-suited for direct connection to the automobile electrical system. In the interest of size and weight conservation, however, an ac-operated power supply (necessary for fixed-station operation), is not often built in. If home operation from the ac mains is contemplated, an external source of 13.8-V dc is required. Matching commercial units are often costly and are not normally designed for high-duty-cycle modes, such as RTTY or SSTV.

The power supply described here (Figs. 6 through 13), designed by George Woodward, W1RN, and built in the ARRL lab by Mark Wilson, AA2Z, boasts a 30-A continuous current rating. Cost of construction will depend on the builder's junk box, but should be significantly less than commercially available units. This design features complete output metering, over-voltage shutdown and foldback current limiting. Additionally, this supply exhibits excellent immunity to RF fields, even with the cover removed. During testing, a 5-W, 2-meter transceiver was keyed with the antenna just inches from the regulator circuitry, with no loss of regulation. Also, a 100-W HF transceiver was loaded into a piece of wire that was attached to a fluorescent bulb. There was enough RF present to illuminate the bulb, but the power supply performed perfectly when the bulb was brought near the output terminals.

## Design Information

The schematic diagram of the RF-proof supply is given in Fig. 7. A custom transformer, available from Avatar Magnetics, is used in this design. The hefty 25.4-V center-tapped secondary, wound with a pair of no. 11 wires, is continuous-duty rated at 34 A. At full load, the secondary voltage is down only 100 mV from nominal. Transformer output voltage is an important consideration in high-power applications: If the transformer voltage is too high, the pass transistors dissipate excessive power because of the large voltage drop across each device. Conversely, low transformer output voltage can cause loss of regulation because of insufficient voltage differential across the regulator circuitry. A separate 15-V, 1.5-A secondary winding (connected to U3) powers the regulator and associated circuitry so that the high-current secondary voltage can be kept lower.

In high-current applications, a low-voltage condition can also be caused by marginal transformer current ratings.

Fig. 6 — The completed RF-proof power supply features voltage and current metering and remote sensing.

Under no-load conditions, the current through the transformer is low, hence the  $I \times R$  drop through the secondary (from the dc winding resistance) is small. When the transformer is called upon to deliver more current, however, the voltage drop through the secondary increases, causing insufficient voltage at the rectifier and regulator circuits. This is not a problem with the AV-399 transformer used here!

CI, a 190,000- $\mu$ F electrolytic capacitor, provides a clean dc waveform to the regulator and pass transistors. This high value is necessary to keep ripple to a minimum. The filtered secondary voltage is close to the desired output voltage to keep pass-transistor dissipation to a minimum. This, however, means that ripple must be minimized so that under load the input voltage remains above the desired regulated output voltage. The energy stored in this capacitor is tremendous, so a bleeder resistor must be used even though the voltage is low. The 1-k $\Omega$  resistor here draws 14 mA — not enough to heat up the inside of the already-warm cabinet, but enough to safely discharge CI.

The large value chosen for CI places a high peak-current demand on the rectifiers. To charge this capacitor, several hundred amperes of peak current will flow through the rectifiers over short periods of each cycle. Peak-current demands must be considered carefully when selecting rectifiers and wiring for this portion of the circuit. D1 and D2 have surge-current ratings of 500 A and can handle 40 A continuously. These are stud-mounted rectifiers, and they require a substantial heat sink.

Voltage regulation is handled by a 723-type IC regulator, U1. This IC generates the reference voltage for the regulated output. R3, a 25-turn potentiometer, is used to set the output voltage to the desired value; the supply shown here

was set to precisely 13.80 V.

U1 is capable of supplying about 150 mA — not enough to drive the high-current pass transistors. In this circuit, the output of U1 drives a control loop consisting of U2B and Q1. Almost any NPN Darlington that can handle 5 A or more will work for Q1. The 15-A 2N6576 used here was chosen because it was available locally.

Q1 drives four 2N3055 NPN power transistors (Q3-Q6). For best current balance and efficiency, these pass transistors should all be from the same manufacturing lot. A 0.1- $\Omega$ , 5-W spreading resistor is placed in series with the emitter lead of each 2N3055 to help balance current distribution. The emitter resistor values should be within 1% of each other. Matching can be accomplished by placing low-value (1.0- to 2.2- $\Omega$ ),  $\frac{1}{4}$ -W resistors in parallel with each 0.1- $\Omega$  unit until the desired tolerance is obtained.

If you use a different heat sink or a higher input voltage, you will probably have to use additional pass transistors to keep the junction temperature to an acceptable level. See Chapter 6 for complete information on how to calculate the proper heat sink and number of pass transistors needed for your application.

Current limiting, provided by U2A, U2D and associated components, protects the supply from overcurrent damage. An operational amplifier, U2A, monitors the voltage across the current-sense resistor (R2) and reduces the regulator drive when output current exceeds 32 A. If a short circuit should appear across the supply output terminals, the overcurrent circuit activates, reducing output voltage to next to nothing at a current level selected by the fold-back resistor, R1.

R1 is actually made from two separate resistors in series. This makes it possible to change the value slightly (by experimenting with the smaller resistor) until the desired foldback current is obtained. With the value shown, fold-back current is limited to 3 A. This value was chosen so that the M1 deflects slightly so that the operator can tell that the problem is overcurrent of some kind rather than a loss of input voltage, yet it is low enough that wires won't melt. When the supply folds back, the OVER-CURRENT lamp turns on, warning the operator of an overload.

A change in the value R1 as small as a few hundred ohms will make a significant difference, so resistor tolerances can affect the foldback current of your version of this supply. You may have to experiment with different resistors to get an acceptable foldback current. Of course, you can set the foldback current to any value you wish. Also, the value of  $V_{IN}$  has a profound effect, so if you use a different transformer and  $V_{IN}$  is much different from 20.5 V (the measured value of  $V_{IN}$  on the ARRL lab version), you should recalculate the

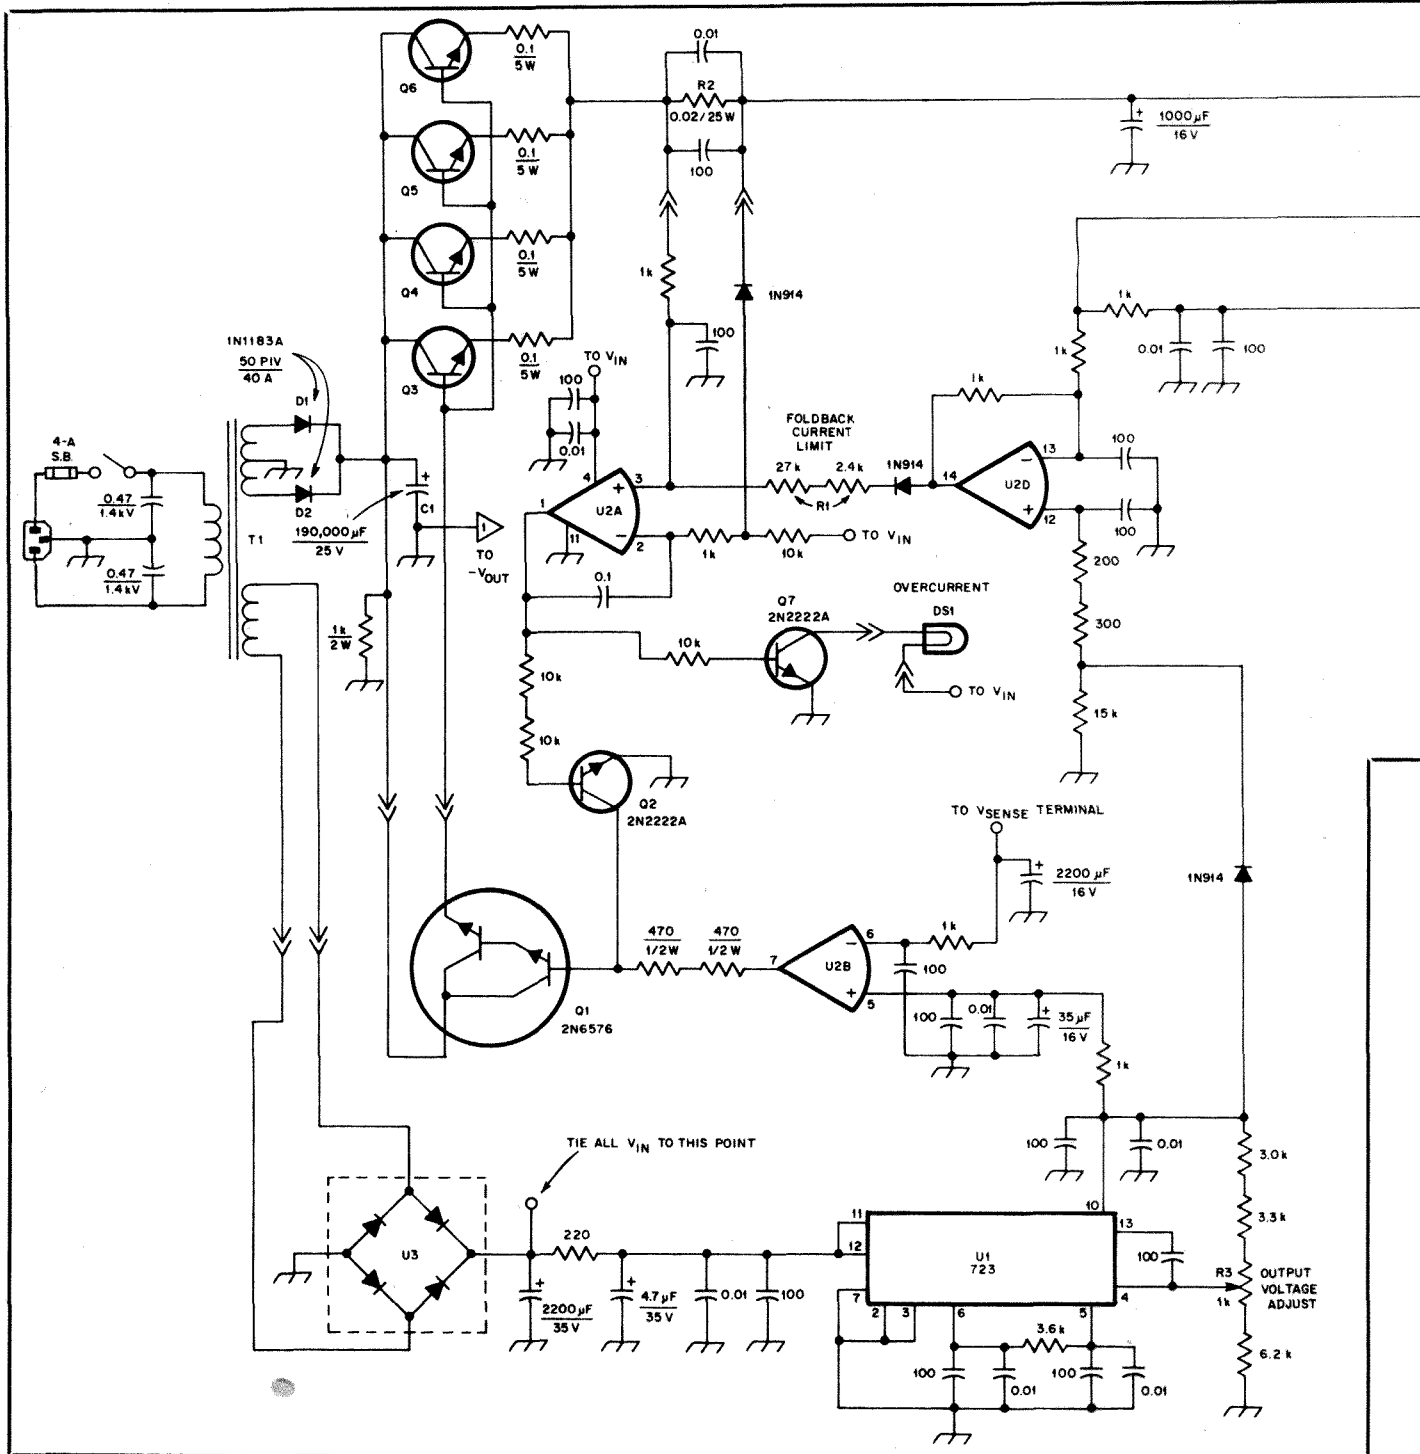

Fig. 7 — Schematic diagram of the high-current, RF-proof power supply. All resistors are  $\frac{1}{4}$ -W, 5% types unless noted. Capacitors are monolithic ceramic types unless noted. Capacitors marked with polarity are electrolytic. Numbered components not appearing in the parts list are for text reference.

C1 — Electrolytic capacitor, 190,000  $\mu$ F, 25 V (Sprague 194G025DJ2A or equiv.).

D1, D2 — Rectifier diode, 50 PIV, 40 A (1N1183A or equiv.).

DS1 — 12-V pilot light or LED with 680- $\Omega$  dropping resistor.

M1 — Dc ammeter, 0-30 A.

M2 — Dc voltmeter, 0-15 V.

Q1 — 5 A or greater Darlington transistor (see text).

Q3-Q6 — NPN power transistor (2N3055, 2N5303 or equiv.).

Q8 — 25-A SCR, TO-220 package (ECG-5550 or equiv.).

R2 — Five 0.1- $\Omega$ , 5-W resistors in parallel (see text).

R3 — Multiturn PC-mount potentiometer, 1 k $\Omega$ , 0.5 W.

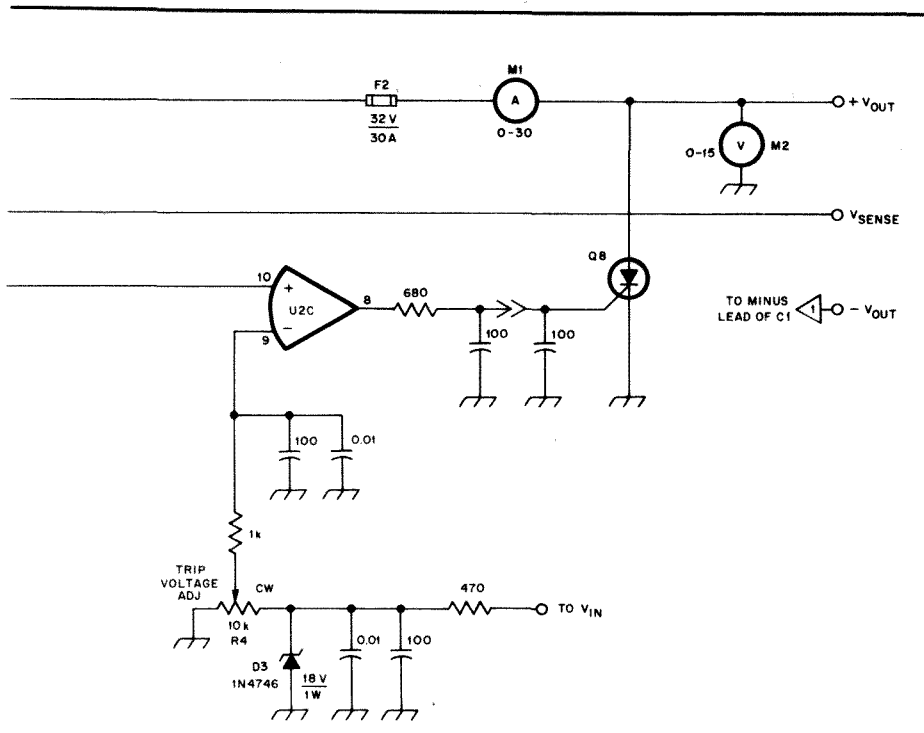

R4 — Multiturn PC-mount potentiometer, 10 k $\Omega$ , 0.5 W.

T1 — Power transformer. Primary, 117-V ac; secondary, 25.4-V CT, 34 A and 15 V, 1.5 A (Avatar AV-399 or equiv. Available from Avatar Magnetics, 1147 North Emerson, Indianapolis, IN 46219).

U1 — Adjustable voltage regulator IC, 14-pin DIP package (LM723, MC1723 or equiv.).

U2 — Quad 2-input operational amplifier (LM324).

U3 — Bridge rectifier, 50 PIV, 1.5 A.

value of R1 from the equation

$$R_{FB} = \frac{V_{IN}}{0.7 - (I_{FB} \times 0.02)} - 1$$

where

$R_{FB}$  = the value of the foldback resistor in k $\Omega$

$V_{IN}$  = the regulator board supply voltage in volts

$I_{FB}$  = the desired foldback current in amperes

This supply also includes a crowbar over-voltage protection circuit, consisting of U2C, Q8 and associated circuitry. Should the output voltage exceed the threshold — somewhere slightly above the desired output voltage — set by the parallel combination of D3/R4, Q8 will conduct, short-circuiting the output terminals of the supply. R4, a multi-turn potentiometer, is used to set the trip voltage. This lights DS1 and triggers the previously described over-current protection circuitry.

F2 is included in case of a drastic supply failure. Normally, the supply would fold back if a short circuit appeared at the output. Should something happen to the regulator board and the foldback current limiting circuitry fail to function, full supply current — in excess of 30 A — would be available at the output terminals. This is enough current to do serious damage to the load and/or interconnecting wires. F2 should blow if this happens.

Remote sensing, another important feature in high-current supplies, is included. When heavy loads are connected through long cables, the voltage drop

degrades load regulation. Remote sensing allows the drop associated with long cable runs to be included in the regulator feedback loop. For normal operation, a jumper wire must be connected between the +V<sub>OUT</sub> and V<sub>SENSE</sub> terminals to complete the regulator feedback loop. The supply will not regulate if this jumper is omitted! To use the remote-sensing feature, remove the jumper wire between the +V<sub>OUT</sub> and V<sub>SENSE</sub> terminals, and connect a wire between the V<sub>SENSE</sub> terminal and the positive side of the load.

Care has been taken to make this design immune to the RF that floats around most amateur stations. Each RF-sensitive component is heavily bypassed with both 100-pF and 0.01- $\mu$ F capacitors to ensure radio-frequency energy a low-impedance path to ground. In some places, several resistors are used in series, rather than a single unit, to break up long leads and potential “antennas” for RF.

### Construction

One possible assembly method can be seen in Fig. 12, although other methods should perform just as well. The supply is built in a Hammond enclosure. T1, C1 and the regulator circuit board mount inside the cabinet. The heat sinks for Q3-Q6 and D1 and D2 mount on the exterior of the rear panel, with the fins vertical, to take advantage of natural convection cooling. Do not mount the heat sinks with the fins horizontal! See Chapter 6 for complete information on thermal design considerations.

Components that don't generate appreciable heat are contained on a double-sided

PC board (Figs. 9 and 10). One side of this board is etched. The foil on the remaining side is unaltered, to act as a ground plane. All component leads that go to ground are soldered to the ground plane. Where a component lead is to pass through the board, the hole is drilled from the etched side, and foil around the hole on the component side removed to prevent shorting to ground. The foil can be cleared away with a 1/8-inch drill bit turned by hand. Do not clear away foil from holes for component leads that go to ground. A parts-placement guide for this circuit board is shown in Fig. 10.

To avoid ground loops, this supply uses a single-point ground. PC board common does not contact the cabinet; instead, all power supply grounds (except those on the primary) are tied to the minus terminal of C1.

The pass transistors, Q3-Q6, inclusive, are mounted on a Wakefield model 441K heat sink. In this version, the transistors are mounted directly to the heat sink with thermal compound, but without insulating hardware. The transistor case is tied to the collector, so the dc potential of the heat sink is 13.8 V. Wakefield insulating stand-offs are used between the sink and the cabinet. The emitter current-spreading resistors are placed on terminal strips that are mounted on the heat sinks adjacent to each pass transistor. Connections are made by soldering directly to the transistor pins. Another builder may wish to use insulating hardware and/or TO-3 sockets. A full-size drilling template for mounting four TO-3 transistors on the Wakefield 441 is given in Fig. 11, and the wiring for the pass transistors is shown in Fig. 8.

D1 and D2 are mounted on a Wakefield 421K heat sink that bolts to the rear panel. The rectifiers used in the prototype have the cathode connected to the stud. The rectifiers are mounted “upside down” on the heat sink; that is, the anode pins point toward the chassis. See Fig. 13. To avoid exposed wiring, a copper strip is mounted between the cathodes of D1 and D2 and the heat sink. Connection to the cathodes is made to this strip. Use heat sink compound between the diodes and the copper strip and between the copper strip and the heat sink. As before, these devices are not insulated from the heat sink, so the heat sink is mounted on insulating standoffs manufactured by Wakefield for this purpose.

Q8 is mounted to the chassis on a small heat sink. Because the foldback current in this supply is limited to 3 A, only a small heat sink is required. If, however, you change the foldback current to a higher value, you must use a larger heat sink.

R2, the 0.02- $\Omega$ , 25-W current-sense resistor consists of five 0.1- $\Omega$ , 5-W resistors in parallel. The resistors used here have built-in mounting brackets, so long no. 4 machine screws are used to mount them to the chassis. The sand-type power resistors

Fig. 8 — Connections to Q3-Q6 are made on the underside of the heat sink.

Fig. 9 — The regulator circuitry is mounted on a double-sided PC board. Component leads that connect to ground are soldered to the ground plane on top of the board. Copper foil is removed from the component side of the board where leads pass through to traces on the other side. See text and Fig. 10.

(like those used at the emitters of Q3-Q6) are much more common; the best way to mount sand-type resistors is between two terminal strips.

Liberal use of terminal strips simplifies the wiring and troubleshooting, should it be necessary. In a supply of this current capability, it is imperative that you use wire heavy enough for the job. If you choose a different cabinet and/or layout from the one shown here, try to keep the high-

current runs between T1, D1, D2, C1 and Q3-Q6 as short as possible. Even no. 12 wire is rated for only 23 A continuous in applications such as this, so no. 10 is in order here. No. 10 wire can be difficult to obtain and work with, so you can do what we did in the prototype supply: Use several pieces of smaller wire for each run. The high-current secondary wires from T1 connect directly to the anodes of D1 and D2; the center tap connects directly to the C1

minus terminal. Three pieces of no. 12 wire are used between the rectifiers and C1. A separate length of no. 14 wire is used between the collector of each pass transistor and C1. Likewise, a separate piece of no. 14 is used between the emitter of each pass transistor and R2. Three no. 12s are used between R2 and M1, and between M1 and the positive output terminal. Likewise, three no. 12s are used between C1 and the negative output terminal. This may seem like overkill, but at 30 or more amperes,  $I \times R$  losses in even short lengths of hookup wire are significant. The rest of the wiring is low current, so any no. 22 or larger hookup wire may be used.

### Testing and Setup

After construction has been completed, it will be necessary to adjust the output voltage and crowbar threshold point before using the supply as a power source. All that is needed is an accurate voltmeter (preferably a digital voltmeter, if available) and a screwdriver to turn the OUTPUT VOLTAGE and TRIP VOLTAGE potentiometers. Remember to install the jumper between +V<sub>OUT</sub> and V<sub>SENSE</sub>.

For initial setup, temporarily replace R2 with a resistor of approximately 0.5  $\Omega$ . This resistor can be made from several low-value, 1-W resistors in parallel. The actual value is not critical; the purpose is to prevent unnecessary fireworks by limiting supply current to around 1 A for initial testing and setup. Also, disconnect the gate of Q8 from U2C.

Before applying power to the regulator board and pass transistors, verify the operation of T1, D1, D2 and C1. No-load voltage on C1 should be approximately 18 V. Remove power and connect the pass transistors and the regulator board. Begin with R4 fully counterclockwise (for maximum trip voltage) and R3 fully clockwise (for minimum output voltage).

Turn the supply on. M2 should deflect upscale 10 to 12 V. If the voltmeter does not indicate any output voltage, or if the OVERCURRENT lamp is illuminated, quickly turn the supply off, unplug the line cord and check for wiring errors. If all is well, connect a voltmeter across the supply output terminals and slowly rotate R3 clockwise until the meter reads 13.8 V. Do not be surprised if you have to turn R3 many turns; the adjustable voltage range of this supply has been preset by the fixed resistors, and R3 is intended for trimming the supply voltage to the desired output, rather than for large voltage excursions. Connect a resistive load of approximately 15- $\Omega$  across the supply output terminals. This should draw approximately 1 A, and M1 should deflect slightly. Short-circuit the supply output terminals through a meter capable of reading approximately 0-1 A. Supply voltage should drop drastically, the foldback current through the ammeter should be less than 500 mA and DS1 should light to indicate OVERCURRENT. The

**NOTE: SOLDER ALL LEADS  
MARKED "X" TO THE  
GROUND PLANE**

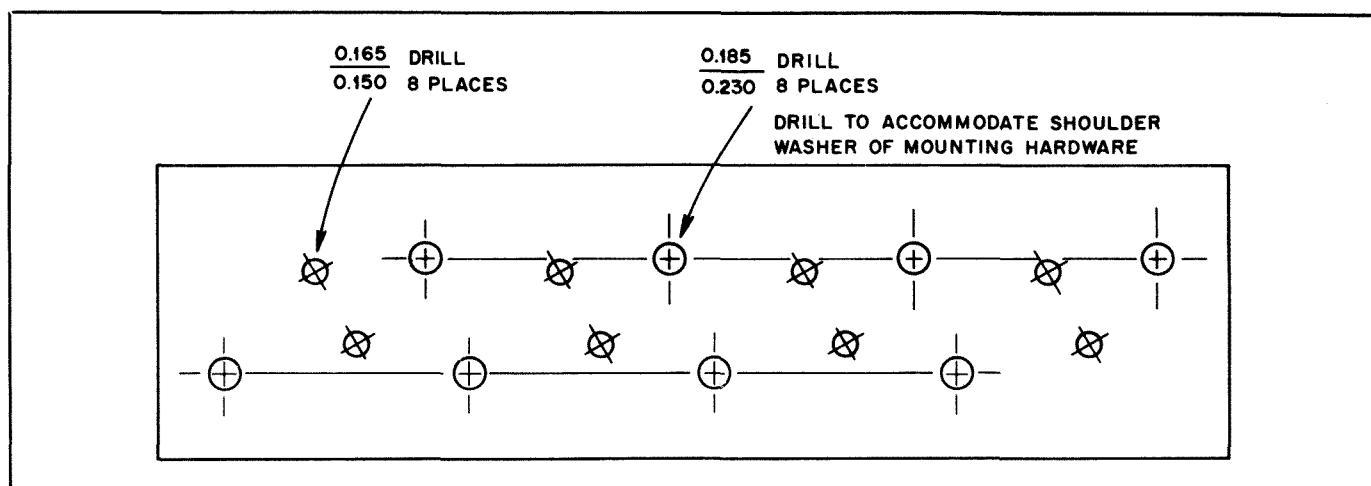

Fig. 10 — Parts-placement guide for the regulator board. A full-size etching pattern appears at the back of this book.

**Fig. 11 — Full-size drilling template for the Wakefield 441K heat sink. See text for details.**

foldback current should be less than half of the maximum supply current (set to approximately 1 A by the temporary R2).

Next, set the crowbar to fire at the desired voltage. Connect a voltmeter to the lead that will be used to connect the 680- $\Omega$  resistor on the regulator board to the gate of Q8. Set the voltmeter to a convenient range above 20 V (the value of  $V_{IN}$ ). There should be no voltage present at this point until the crowbar trips. Rotate R3 until the supply output voltage reaches the desired trip voltage. A trip voltage of

14.5 V was selected for the prototype supply. Next, adjust R4 until the crowbar trips and the voltmeter indicates the value of  $V_{IN}$ . The crowbar is now set to fire at 14.5 V. Turn R3 until the supply voltage drops below the trip voltage (the voltmeter will return to zero) and connect the gate lead to Q8. Turn R3 to increase supply voltage until the crowbar trips. This time, Q8 will fire, shorting the supply output. The supply should go into foldback current limiting and behave as it did when you shorted the output terminals as described

above. Remove power and turn R3 to reduce the supply output voltage below the trip point. Apply power again and adjust R3 until supply output voltage returns to 13.8 V, or whatever you want the output voltage to be for normal operation. This completes initial testing.

Now it's time for the real smoke test. Turn off the supply and remove the temporary resistor used at R2; install the 0.02- $\Omega$  unit. Locate some low-value resistors to test the supply at various current levels. We started testing the prototype with a 5- $\Omega$ ,

Fig. 12 — An internal view of the high-current power supply. The rectifiers and pass transistors are mounted to heat sinks on the rear panel. Parts are arranged to keep the high-current runs as short as possible.

200-W resistor (approximately a 3-A load) and added additional similar resistors in parallel until we reached the desired current level. To make a full-current test of the supply, you'll need a combination of resistors that totals approximately  $0.5\ \Omega$  at 450 W. If you don't have access to suitable

power resistors, automobile headlights are an excellent, commonly-available high-current 13.8-V load. At some point in your testing, you'll notice that although the supply voltage at the output terminals of the supply is still holding steady at 13.8 V, the voltage at the load will be somewhat less

Fig. 13 — D1 and D2 are mounted to the heat sink with the anode posts pointing toward the chassis. The cathodes are connected by a copper strip that is sandwiched between the devices and the heat sink. Connection to the cathodes is made to a lug that is soldered to the copper strip. See text.

than that because the drop in the connecting wires is not included in the regulator feedback loop. This is where remote sensing comes into play. Disconnect the jumper between the  $+V_{OUT}$  and  $V_{SENSE}$  terminals and connect the  $V_{SENSE}$  terminal directly to the load. The voltage at the load should now be within a few hundred millivolts of the no-load supply output voltage.

After you have verified supply performance under load, you should verify that the foldback current level is indeed the desired value. Reconnect the jumper wire between the  $+V_{OUT}$  and  $V_{SENSE}$  terminals. Screw up your courage and briefly short the  $+V_{OUT}$  terminal to the  $-V_{OUT}$  terminal. M1 should indicate the selected value of foldback current (in this case, 3 A) and M2 should indicate almost no voltage. If this is not the case, you will have to experiment with different values for the smaller of the two resistors that make up R1. Try changing the value a few hundred ohms at a time until you reach the desired foldback current.

Congratulations! The supply is now ready to use.

## A 28-V, High-Current Power Supply

Many modern high-power transistors used in RF power amplifiers require 28-V dc collector supplies, rather than the traditional 12-V supply. By going to 28 V (or even 50 V), designers significantly reduce the amount of current required for an amplifier in the 100-W or higher output class. The power supply shown in Figs. 14 through 18 is conservatively rated for 28 V at 10 A (enough for a 150-W output amplifier) — continuous duty! It was designed with simplicity and readily-available components in mind. Mark Wilson, AA2Z, built this project in the ARRL lab.

Fig. 14 — The front panel of the 28-V power supply sports only a power switch, pilot lamp and binding posts for the voltage output. There is room for a voltmeter, should another builder desire one.

### Circuit Details

The schematic diagram of the 28-V supply is shown in Fig. 15. T1 was designed by Avatar Magnetics specifically for this project. The primary requires 117-V ac, but a dual-primary (117/234 V) version is available. The secondary is rated for 32 V at 15 A, continuous duty. The primary is bypassed by two 0.01- $\mu$ F capacitors and protected from line transients by an MOV.

U1 is a 25-A bridge module available

from Radio Shack or a number of other suppliers. It requires a heat sink in this application. Filter capacitor CI is a computer-grade 22,000- $\mu$ F electrolytic. Bleeder resistor R1 is included for safety because

of the high value of  $C_1$ ; bleeder current is about 12 mA.

There is a trade-off between the secondary voltage of the transformer and the value of the filter capacitor. To maintain regulation, the minimum supply voltage to the regulator circuitry must remain above approximately 31 V. Ripple voltage must be taken into account. If the voltage on the bus drops below 31 V in ripple valleys, regulation may be lost.

In this supply, the transformer secondary voltage was chosen to allow use of a commonly-available filter value. The builder found that 50-V electrolytic capacitors of up to about 25,000  $\mu\text{F}$  were common and the prices reasonable; few dealers stocked capacitors above that value, and the prices increased dramatically. If you have a larger filter capacitor, you can use a transformer with a lower secondary voltage; similarly, if you have a transformer in the 28- to 35-V range, you can calculate the size of the filter capacitor required. Chapter 6 contains the formulas needed to calculate ripple for different filter

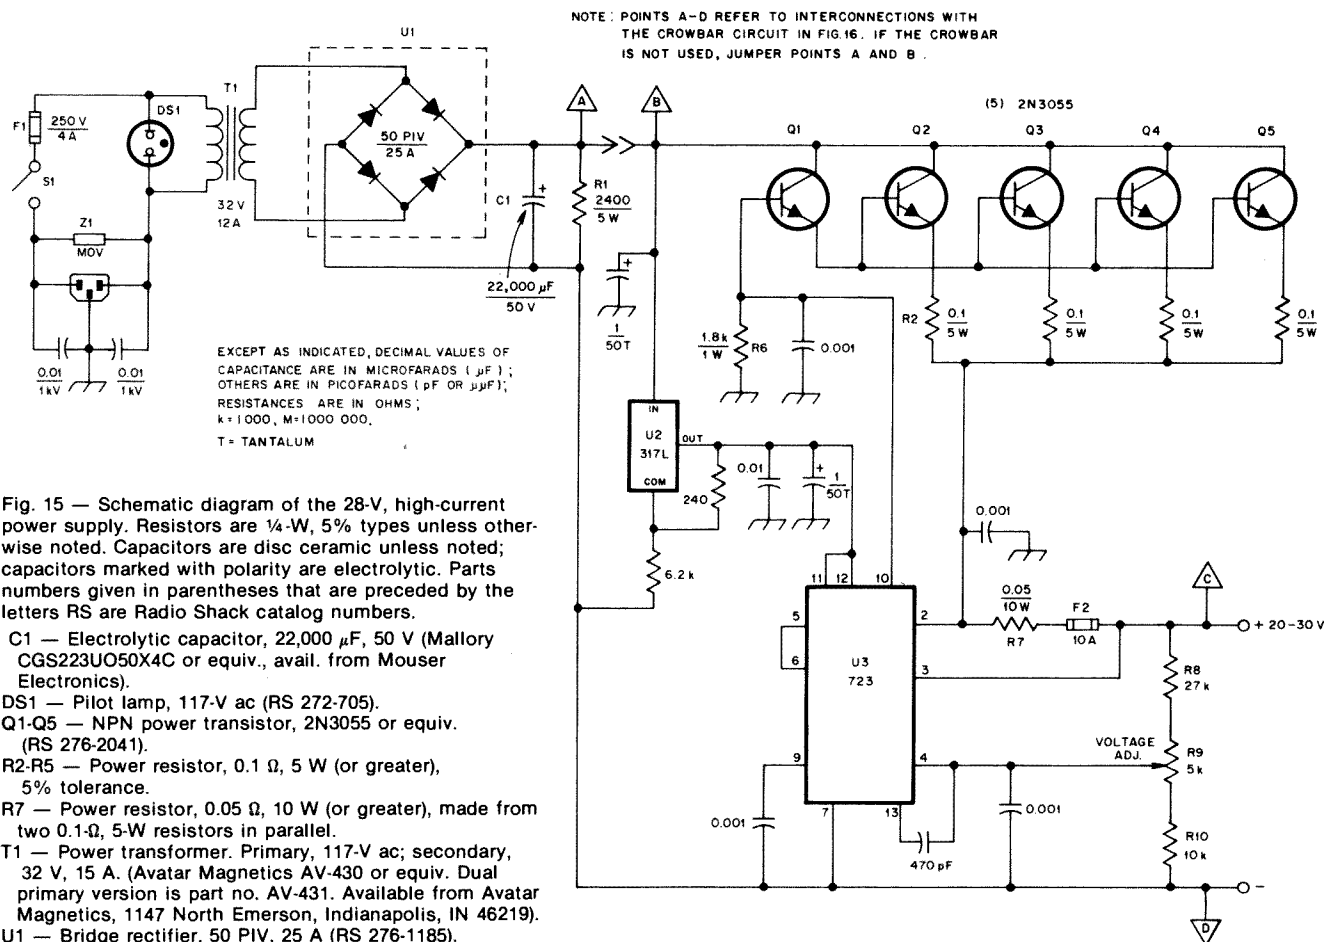

Fig. 15 — Schematic diagram of the 28-V, high-current power supply. Resistors are  $\frac{1}{4}$ -W, 5% types unless otherwise noted. Capacitors are disc ceramic unless noted; capacitors marked with polarity are electrolytic. Parts numbers given in parentheses that are preceded by the letters RS are Radio Shack catalog numbers.

C1 — Electrolytic capacitor, 22,000  $\mu$ F, 50 V (Mallory CGS223U050X4C or equiv., avail. from Mouser Electronics).

DS1 — Pilot lamp, 117-V ac (RS 272-705).

Q1-Q5 — NPN power transistor, 2N3055 or equiv.  
(RS 276-2041).

R2-R5 — Power resistor, 0.1  $\Omega$ , 5 W (or greater), 5% tolerance.

R7 — Power resistor, 0.05  $\Omega$ , 10 W (or greater), made from two 0.1- $\Omega$ , 5-W resistors in parallel.

T1 — Power transformer. Primary, 117-V ac; secondary, 32 V, 15 A. (Avatar Magnetics AV-430 or equiv. Dual primary version is part no. AV-431. Available from Avatar Magnetics, 1147 North Emerson, Indianapolis, IN 46219).

U1 — Bridge rectifier, 50 PIV, 25 A (RS 276-1185).

U2 — Three-terminal adjustable voltage regulator, 100 mA (LM-317L or equiv.). See text.

U3 — 723-type adjustable voltage regulator IC, 14-pin DIP package (LM-723, MC1723, etc., RS 276-1740).

Z1 — 130-V MOV (RS 276-570).

and transformer values.

The regulator circuitry takes advantage of commonly-available parts. The heart of the circuit is U3, a 723 voltage regulator IC. The values of R8, R9 and R40 were chosen to allow the output voltage to be varied from 20 to 30 V. The 723 has a maximum input voltage rating of 40 V, somewhat lower than the filtered bus voltage. U2 is an adjustable 3-terminal regulator; it is set to provide approximately 35 V to power U3. U3 drives the base of Q1, which in turn drives pass transistors Q2-Q5. This arrangement was selected to take advantage of common components. At first glance, the number of pass transistors seems high for a 10-A supply. Input voltage is high enough that the pass transistors must dissipate about 120 W (worst case), so thermal considerations dictate the use of four transistors. See Chapter 6 for a complete discussion of thermal design. If you use a transformer with a significantly different secondary potential, refer to the Chapter 6 thermal tutorial to verify the size heat sink required for safe operation.

R9 is used to adjust supply output voltage. Since this supply was designed primarily for 28-V applications, R9 is a "set and forget" control mounted internally. A 25-turn potentiometer is used here to allow precise voltage adjustment. Another builder may wish to mount this control, and perhaps a voltmeter, on the front panel to easily vary the output voltage.

The 723 features current foldback if the load draws excessive current. Foldback current, set by R7, is approximately 14 A, so F2 should blow if a problem occurs. The output terminals, however, may be shorted indefinitely without damage to any power-supply components.

If the regulator circuitry should fail, or if a pass transistor should short, the unregulated supply voltage will appear at the output terminals. Most 28-V RF transistors would fail with 40-plus volts on the collector, so a prospective builder might wish to incorporate the overvoltage protection circuit shown in Fig. 16 in the power supply. This circuit is optional. If you choose to use the "crowbar," make the interconnections as shown. Note that R11 and F3 of Fig. 16 are added between points A and B of Fig. 15. If the crowbar is not used, place a wire jumper between points A and B of Fig. 15.

This crowbar circuit is taken from Motorola application notes for the MC3423 overvoltage sensor IC. The chip contains a 2.5-V reference and two comparators. When the voltage at pin 2 (sense terminal) reaches 2.5 V, the output goes high (from 0.0 V to the positive bus voltage) to drive the gate of Q6, a high-current SCR. Q6 turns on, shorting the supply output terminals. This circuit is inexpensive and easy to implement, yet it allows the builder to precisely set the trip voltage. It provides excellent gate drive to the SCR, and is somewhat quicker and more reliable than

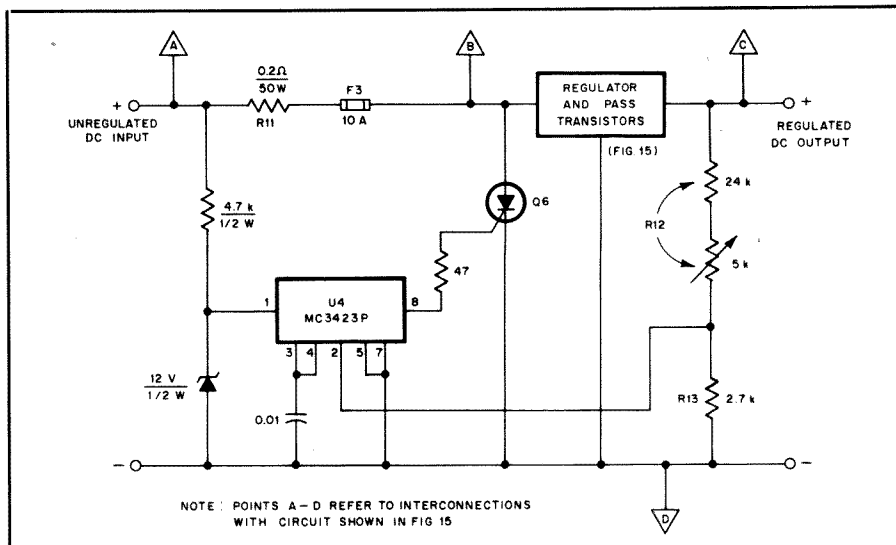

Fig. 16 — Schematic diagram of the over-voltage protection circuit. Resistors are 1/4-W, 5% carbon types unless noted.

Q6 — 20-A, 100-V stud-mount SCR (RCA SK6502 or equiv.).  
R12 — 5-kΩ, 10-turn potentiometer in series

with a 24-kΩ, 1/4-W resistor.  
U4 — Overvoltage sensor IC, Motorola MC3423 (RS 276-1717).

Fig. 17 — Interior of the 28-V, high-current power supply. The cooling fan is necessary only if the pass transistors and heat sink are mounted inside the cabinet. See text.

crowbar circuits that use Zener diodes. R11 and F3 protect the pass transistors from damage in case of high-current transients.

The trip voltage is determined from the equation

$$V_{TRIP} \approx 2.5 \left( 1 + \frac{R11}{R12} \right)$$

The application notes recommend that R13 be less than 10 k $\Omega$  for minimum drift and suggest a value of 2.7 k $\Omega$ . In this version, R12 is preset with a 24-k $\Omega$  resistor, and a 5-k $\Omega$ , 10-turn potentiometer dials in the precise trip point.

### Construction

Fig. 17 shows the interior of the 28-V supply. It is built in a Hammond 1401K enclosure. All parts mount inside the box. The regulator components are mounted on a small PC board that is attached to the rear of the front panel. See Fig. 18. Most of the parts were purchased at local electronics stores or from suppliers listed in Chapter 35. Many parts, such as the heat sink, pass transistors, 0.1- $\Omega$  power resistors and filter capacitor can be obtained from scrap computer power supplies found at flea markets.

Q2-Q5 are mounted on a Wakefield model 441K heat sink. A drilling template can be found in Fig. 11. The transistors are mounted to the heat sink with insulating washers and thermal heat-sink compound to aid heat transfer. Radio Shack TO-3 sockets make electrical connections easier. The heat sink surface under the transistors must be absolutely smooth. Carefully deburr all holes after drilling and lightly sand the edges with fine emery cloth.

A five-inch fan circulates air past the heat sink inside the cabinet. Forced-air cooling is necessary only because the heat sink is mounted inside the cabinet. If the heat sink was mounted on the rear panel with the fins vertical, natural convection would provide adequate cooling and no fan would be required.

U1 is mounted to the inside of the rear panel with heat-sink compound. Its heat sink is bolted to the outside of the rear panel to take advantage of convection cooling.

U2 may prove difficult to find. The 317L is a 100-mA version of the popular 317-series 1.5-A adjustable regulator. The 317L is packaged in a TO-92 case, while the normal 317 is usually packaged in a larger TO-220 case. Many of the suppliers listed in Chapter 35 sell them, and RCA SK7644 or Sylvania ECG1900 direct replacements are available from many local electronics shops. If you can't find a 317L, you can use a regular 317 (available from Radio Shack, among others).

R7 is made from two 0.1- $\Omega$ , 5-W resistors connected in parallel. These resistors get warm under sustained operation, so they

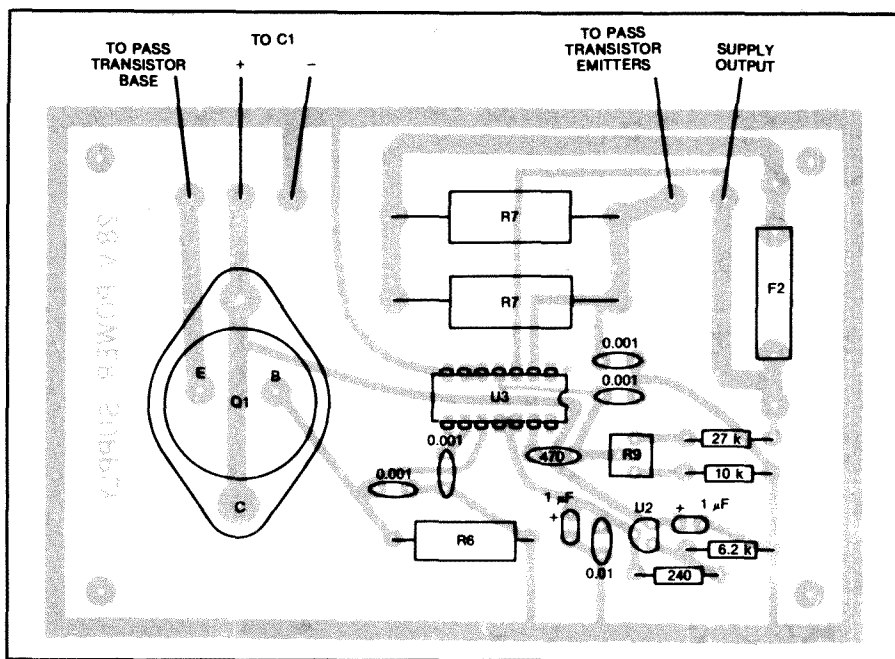

Fig. 18 — Parts-placement diagram for the 28-V power supply. A full-size etching pattern appears at the back of this book.

are mounted approximately 1/16 inch above the circuit board to allow air to circulate and to prevent the PC board from becoming discolored. Similarly, R6 gets warm to the touch, so it is mounted away from the board to allow air to circulate. Q1 becomes slightly warm during sustained operation, so it is mounted to a small TO-3 PC board heat sink.

Not obvious from the photograph is the use of a single-point ground to avoid ground-loop problems. The PC-board ground connection and the minus lead of the supply are tied directly to the minus terminal of C1, rather than to a chassis ground.

The crowbar circuit is mounted on a small heat sink near the output terminals. Q6 is a stud-mount SCR and is insulated from the heat sink. An RCA replacement SCR was used here because it was readily available, but any 20-A or greater SCR that can handle at least 50 V will work. The other components are mounted on a small circuit board that is attached to the heat sink with angle brackets. U4 is available from Radio Shack.

Although the output current is not extremely high, no. 14 or no. 12 wire should be used for all high-current runs, including the wiring between C1 and the collectors of Q2-Q5; between R2-R5 and R7; between F2 and the positive output terminal; and between C1 and the negative output terminal. Similar wire should be used between the output terminals and the load.

### Testing

First, connect T1, U1 and C1 and verify that the no-load voltage is approximately 44-V dc. Then, connect unregulated voltage to the PC board and pass transistors. Leave the gate lead of Q6 disconnected from pin 8 of U4 at this time. You should be able to adjust the output voltage between approximately 20 and 30 V. Set the output to 28 V.

Next, set the crowbar to fire at 29 V or whatever trip voltage you desire. Set the potentiometer of R12 for maximum resistance. Connect a voltmeter to U4, pin 8. The voltmeter should indicate 0.0 V. Increase supply voltage to 29 V and adjust R12 until pin 8 goes high, to approximately 28 V. Back off the supply voltage; pin 8 should go low again. Connect the gate lead of Q6 and again increase supply voltage to 29 V. The crowbar should fire, shorting the supply output. Slight adjustment of R12 may be necessary. Remove power and turn R9 to reduce supply voltage below the trip point. Apply power and reset the output voltage to 28 V.

Next, short the output terminals to verify that the current foldback is working. Voltage should return to 28 when the shorting wire is disconnected. This completes testing and setup.

The supply shown in the photographs dropped approximately 0.1 V between no load and a 12-A resistive load. During testing in the ARRL lab, this supply was run for four hours continuously with a 12-A resistive load on several occasions without any difficulty.

# A 1.2- to 15-Volt, 5-Ampere Supply

The power supply shown in Figs. 19 to 23 is intended for general-purpose, test-bench applications. The output is adjustable from 1.2 to 17 volts at currents up to 6 amperes. Metering is provided for voltage levels up to 15 volts and current levels up to 5 amperes. Most of the components used in this supply are of the junk-box variety with the possible exception of U2, the three-terminal voltage regulator. The circuit will tolerate fairly wide component substitutions and still offer good performance. The majority of the circuit components are mounted on a  $2\frac{3}{4} \times 4\frac{1}{2}$ -inch circuit board. All controls, including the

mains fuse are located on the front panel for easy access.

## The Circuit

As shown in Fig. 20, two power

transformers are used in parallel to feed U1, the full-wave bridge rectifier assembly. The transformers specified are rated at 2 amperes each. The prospective builder might question the wisdom of using only

Fig. 19 — A simple 1.2- to 15-volt, 5-ampere power supply. All controls are mounted on the front panel for easy access. The milliammeter reading is multiplied by 100 to obtain the true output current.

Fig. 21 — Inside view of the power supply. Component placement is not at all critical; however, the layout shown here provides a neat appearance.

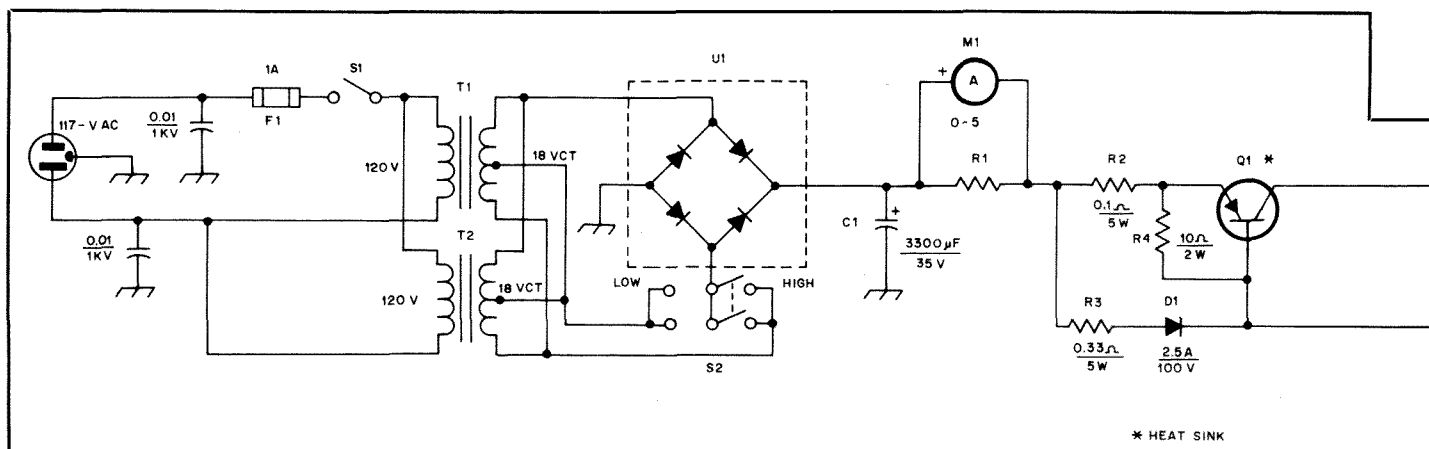

Fig. 20 — Schematic diagram of the 5-ampere power supply. Component designations on the schematic diagram but not shown in the parts list are for text or placement guide reference only.

C1 — 3300- $\mu$ F, 35-volt, axial leads.  
J1, J2 — Binding posts.  
M1 — 0-50 mA, Calectro DI-914 or equiv.  
M2 — 0-15 V, Calectro DI-920 or equiv.  
Q1 — Silicon PNP power, Radio Shack 276-2043 or equiv.

R1 — Meter shunt, 13 inches no. 22 enameled wire wound on a high-value, 1-watt resistor. (Resistor used only as a form for the wire.)

U2 — Regulator, LM-317K.

Fig. 22 — For voltage and current requirements that fall to the left of the diagonal line, the power supply may be operated in the LO mode. Pass-transistor dissipation will be reduced when the supply is operated in this manner.

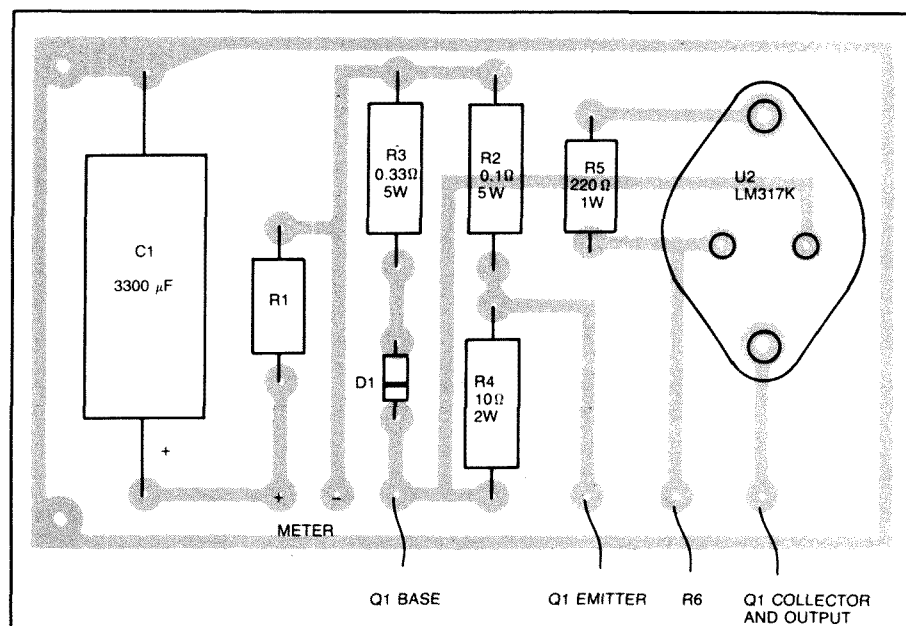

Fig. 23 — Circuit-board layout pattern as viewed from the component side of the board. A full-size etching pattern can be found at the back of this book.

4 amperes worth of transformer in a 5-ampere supply. This is a valid question. With a 5-ampere load connected to the output of the supply, the transformers deliver more than their rated secondary voltage and do not become unreasonably warm to the touch even after continuous-duty operation. If transformers of different manufacture are used, it might be wise to select units having a higher current rating — just to be sure.

S2 is included in the design so that either half or all of the secondary voltage may be applied to U1. This feature was included so that the dissipation of the pass transistor may be reduced when using the supply with low-voltage, high-current loads. The graph displayed in Fig. 22 can be used as a guide

in selecting the HI or LO mode of operation.

The regulator consists of a pass transistor "wrapped around" an adjustable voltage regulator. Circuit operation can be understood by noting the values of R3 and R2. The majority of the three-terminal regulator current will flow through R3 and D1. The offset voltage in D1 is approximately equal to the emitter-base potential of Q1. Because of this, the voltage drop across R3 will be the same as that across R2. Since the ohmic value of R2 is 0.33 of R3, three times as much current will flow in Q1 as in U2. The net result is that the current capability of the overall circuit is increased by a factor of four. In addition, the current-limiting characteristics of the three-terminal regulator are transferred directly to the composite circuit.

M1 and its associated shunt resistor are placed at the input to the regulator circuit so that the voltage drop across the resistor will not adversely alter the supply voltage regulation. The relatively small current drawn by the regulator circuitry does not seriously affect the meter accuracy. M2 measures supply output voltage.

#### Construction

The power supply is housed in a homemade enclosure that was fabricated from sheet aluminum. Fig. 21 shows the parts layout. Dimensions of the enclosure are  $5\frac{1}{2} \times 6 \times 8$  inches, although any cabinet that will house the components may be used. Circuit board layout information is given in Fig. 23. The completed circuit board is mounted vertically to the chassis using space lugs and no. 6 hardware. A small heat sink for the LM317K regulator was made from a scrap piece of aluminum. The pass transistor is mounted to a larger heat sink which is bolted to the rear panel of the power supply. Here, a Motorola MS-10 was used. Bear in mind that the transistor must be insulated from the sink. Use a small amount of heat-sink compound between the transistor and the sink for a good thermal bond.

Since the power supply can deliver up to 6 amperes, fairly heavy wire should be used for those runs carrying the bulk of the current. No. 18 wire was used in this unit and it appeared to be adequate.

The completed power supply may be "crowbarred" without worry of regulator or pass transistor destruction. Perhaps the only precaution that should be mentioned is that of the exposed collector of the pass transistor. Although no damage will occur if the case is shorted to ground, it will cause the loss of output voltage. This could occur if the power supply is mounted on a test bench with a number of leads dangling behind the unit. A simple fix for this would be to mount a plastic TO-3 transistor cover over the case.

# A Deluxe 5- to 25-Volt, 5-Ampere Supply

The power supply illustrated in Figs. 24 and 26 and schematically at Fig. 25 might

Fig. 24 — Front view of the deluxe 5- to 25-volt, 5-ampere power supply.

be termed a rich person's power supply. The unit shown can supply voltages from 5 to 25 at currents up to 5 amperes. With thermal and short-circuit protection, it is virtually destruction proof. A digital panel meter is used to monitor voltage and current, selectable by a front-panel switch. Although we termed this a "rich person's supply," it will cost far less to build than a ready-made supply with the same features. The most expensive single item in the supply is the digital panel meter, which sells in single lot quantities for around \$50 as this is written.

The digital readout, however, is not much more expensive than two high-quality meters. The prospective builder should consider this when choosing between the digital panel meter and two analog panel meters. Voltage measurements are read directly

from the panel meter in volts. Current is measured in amperes; a reading of 0.05 is equal to 50 mA.

## Circuit Details

The circuit diagram of the power supply is shown in Fig. 25. T1 is a 36-volt, center-tapped transformer rated at 6 amperes. D1 and D2 are used in a full-wave rectifier providing dc output to the filter capacitor, C3, a 34,000- $\mu$ F, 50-volt electrolytic of the computer-grade variety. The unregulated voltage is fed to U1, a National LM338 regulator, the heart of the supply. This chip is rated for 5-A continuous duty when used with an adequate heat sink. R1 and R2 form a voltage divider which sets the output voltage of the supply. R2 is a 10-turn potentiometer. U1 is bypassed with 2.2- $\mu$ F tantalum capacitors directly at

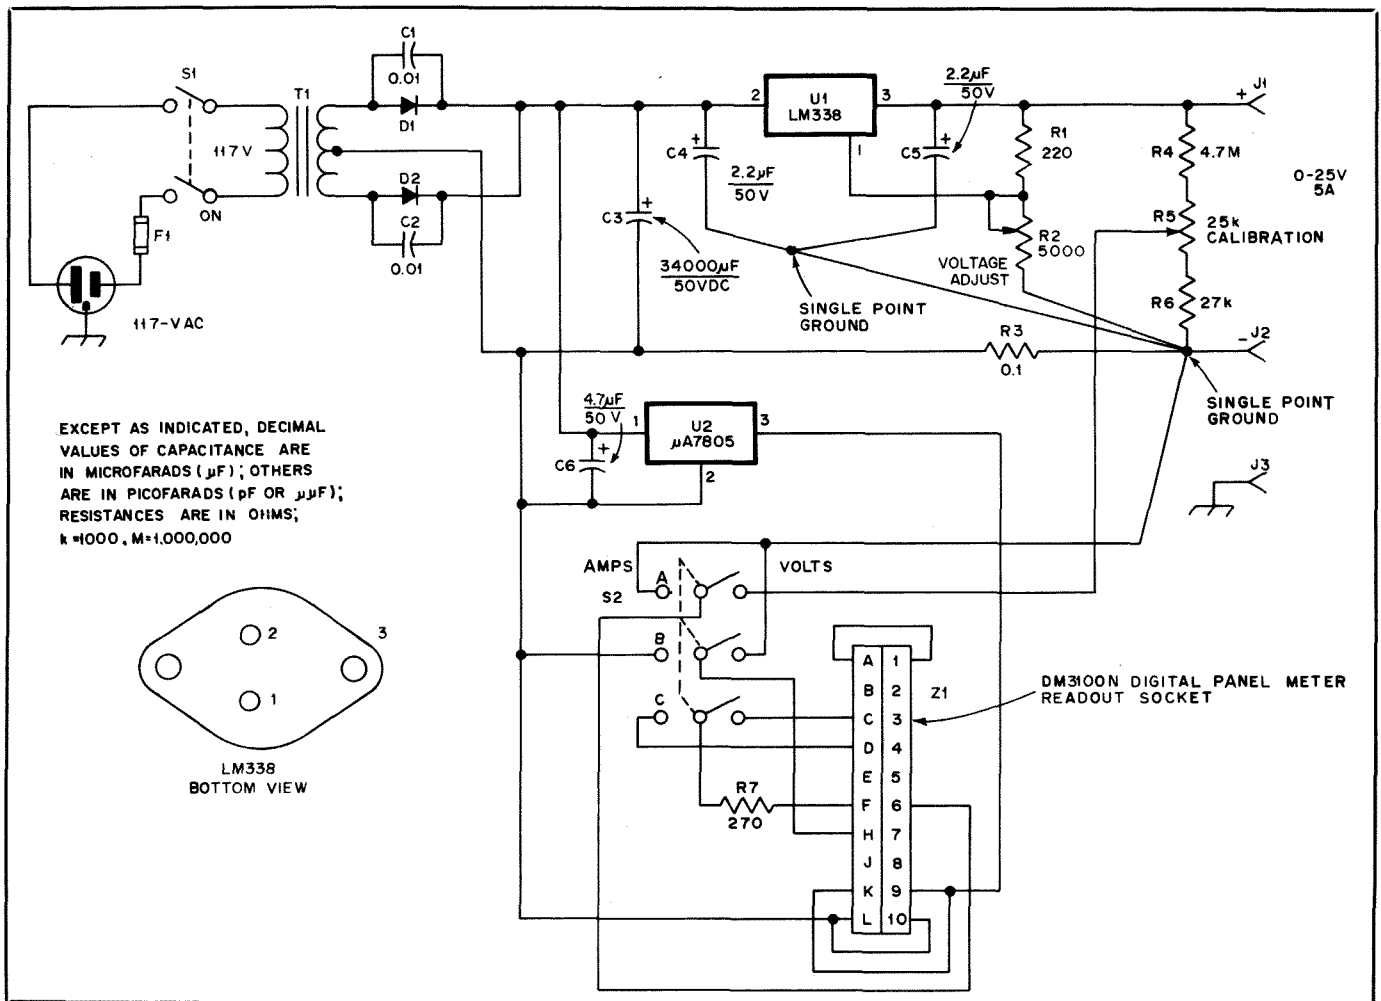

Fig. 25 — Schematic diagram of the deluxe power supply. All resistors are half-watt carbon types unless noted otherwise. Capacitors are disc ceramic unless noted otherwise. Numbered components not appearing in the parts list are for text reference only.

the input and output pins.

Z1, as outlined earlier, is a digital panel

meter. Connections to the meter are made through a special edge connector supplied with the readout. U2 is used to supply a regulated 5 volts for powering the digital panel meter. The input and ground leads of this regulator are attached to the input (non regulated) side of U1.

R4, R5 and R6 form a divider circuit to supply the digital meter with an output voltage reading. R5 is made adjustable so that the meter can be calibrated. R3 is a current-sensing resistor which is placed in the negative lead of the supply. This resistor is used on the input side of the regulator (U1) so as not to affect the voltage regulation of the power supply at high load currents. Any voltage dropped across the resistor will be made up by the regulator, so the output voltage will remain unchanged. Notice that U2 is placed to the left or at the input side of the regulator. This is so the current drawn by the readout will not affect current readings taken at the load. Sections A and B of S2 are used to switch the meter between the voltage and current sensors. S2C is used to switch the decimal point in the digital panel meter to read correctly for both voltage and current.

As shown in the schematic, a single-point ground is used for the supply. Used in

many commercial supplies, this technique provides better voltage regulation and stabilization than the "ground it anywhere" attitude. In this supply, the single-ground point is at the front panel binding post labeled MINUS. All leads that are to be connected to ground should go only to that point.

### Construction

The deluxe power supply is housed in a homemade enclosure that measures  $9 \times 11 \times 5\frac{1}{4}$  inches (Fig. 26). U1 is mounted to a large heat sink ( $3 \times 5 \times 2$  inches) attached to the rear apron of the supply. The front panel sports the digital-panel meter, power switch, binding posts, fuse holder, voltage-adjust potentiometer and meter-selector switch. Although a circuit board is shown in the photograph as supporting R4, R5, R6, R7, D1, D2, C1 and C2, these items could just as well be mounted on terminal strips. For this reason a board pattern is not supplied.

The front and rear panels are painted white, and the cover is blue. Dymo labels are used on the front panel to identify each of the controls. Cable lacing of the various leads adds to the clean appearance of the supply.

# A Multiple-Voltage Bench Supply

Meeting the voltage needs of today's electronic devices may pose more than a minor inconvenience to the experimenter. Having individual supplies available to power TTL, CMOS, ECL and MOSFET devices, as well as relay windings, can be annoying — particularly if the bread-boarded project requires them all simultaneously. The power supply shown in Figs. 27 through 32 provides eight popular fixed voltages ( $\pm 5$ , 12, 15 and 24 V), as well as two continuously variable voltages ( $\pm 1.3$  to 28 V) — enough to handle almost any electronic situation.

Simplicity, flexibility, low cost and ease of parts procurement were major design goals. By analyzing the transformer, rectifier/filter capacitor and regulator separately, a prospective builder should find enough information to confidently duplicate, modify or completely redesign this supply to fit his or her particular needs. The completed unit, shown in Fig. 27, was designed and built in the ARRL lab by Greg Bonaguide, WA1VUG.

## Design Overview

Fig. 28 is a block diagram of a power supply. The rectifier/filter block receives a stepped-down ac voltage from the transformer secondary and delivers a filtered positive or negative voltage to the bus lines. These lines in turn supply the regulators with positive or negative input voltages. Internal regulator circuitry then drops and stabilizes this input voltage at a particular value.

## Transformer Considerations

The transformer chosen for this supply, shown schematically in Fig. 29, features a 117-V primary and a 48-V, 4-A center tapped secondary. Both positive and negative voltages may be obtained by using a bridge rectifier and grounding the transformer center tap. The maximum dc voltage expected on either bus can be computed from the equation

$$V_{dc, \max} = \left( \frac{1.414 \times V_{RMS}}{2} \right) - V_f$$

where

$V_{RMS}$  = the transformer secondary RMS voltage

$V_f$  = the forward drop across a single rectifier diode (usually 0.8 V)

The transformer used for this project yields  $V_{dc, \max} = 33.14$  V, the peak voltage that the dc bus filter capacitors will charge to under no-load conditions. Any applied load will tend to discharge the capacitors, producing a periodic ripple voltage. The peak-to-peak ripple value will be determined by load current, capacitance and ripple frequency. A properly designed power supply should have little or no detectable output

Fig. 27 — The multiple-voltage bench supply features a number of popular voltages used in solid-state projects.

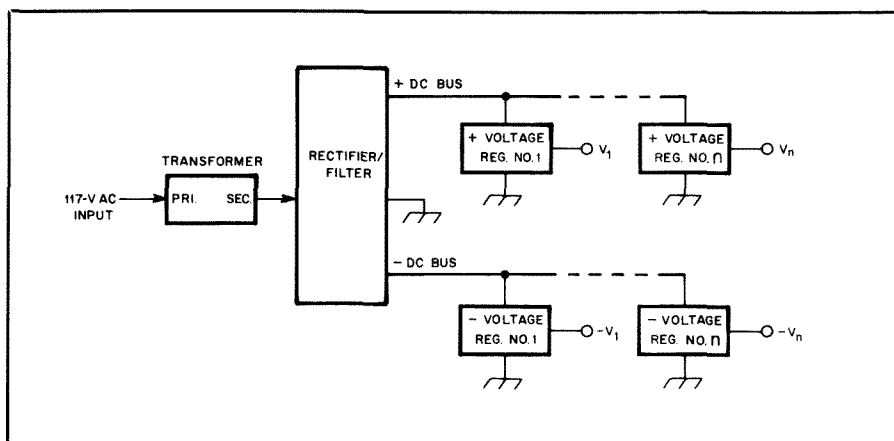

Fig. 28 — Block diagram of the multiple-voltage bench supply.

ripple, regardless of the regulator P-P input ripple voltage.

## Filter Capacitor/Rectifier

In general, a 3-terminal regulator requires an input voltage at least 3-V higher than its output voltage. This value, called dropout voltage, is the minimum input voltage that the device needs to regulate. In this design, the highest voltage any regulator is expected to deliver is 28 V, so the filter capacitor should never permit the bus to drop below 31 V ( $28 + 3$ ). From the earlier calculation, the no-load maximum bus voltage will never exceed 33.14 V. The difference, 2.14 V, represents the maximum peak-to-peak ripple voltage that can be allowed on either bus (Fig. 30). Additionally, each bus is expected to draw 2 A, half the available transformer current.

Equipped with the above information, the required filter capacitance may be calculated using the equation

$$C = \frac{I\sqrt{2}}{F_r V_{p-p}\sqrt{3}}$$

where

$C$  = filter capacitance in farads

$I$  = maximum current drawn from the bus in amperes

$F_r$  = ripple frequency in hertz (120 for full-wave rectification)

$V_{p-p}$  = peak-to-peak ripple voltage

In this case,  $C$  works out to be 6356  $\mu F$ . The next closest available combination of commercial values, 6500  $\mu F$ , is used.

The bridge rectifier is made from four 200-PIV, 3-A diodes. These devices provide necessary protection against the large surge current that initially charges the filter capacitors the instant the supply is switched on.

## Regulators

The 3-terminal regulators selected for this project are simple to work with and have several particularly attractive features. Built-in thermal shutdown, overvoltage protection and current foldback virtually guarantee destruction-proof operation — even in the event of accidental short-circuiting of power supply output terminals

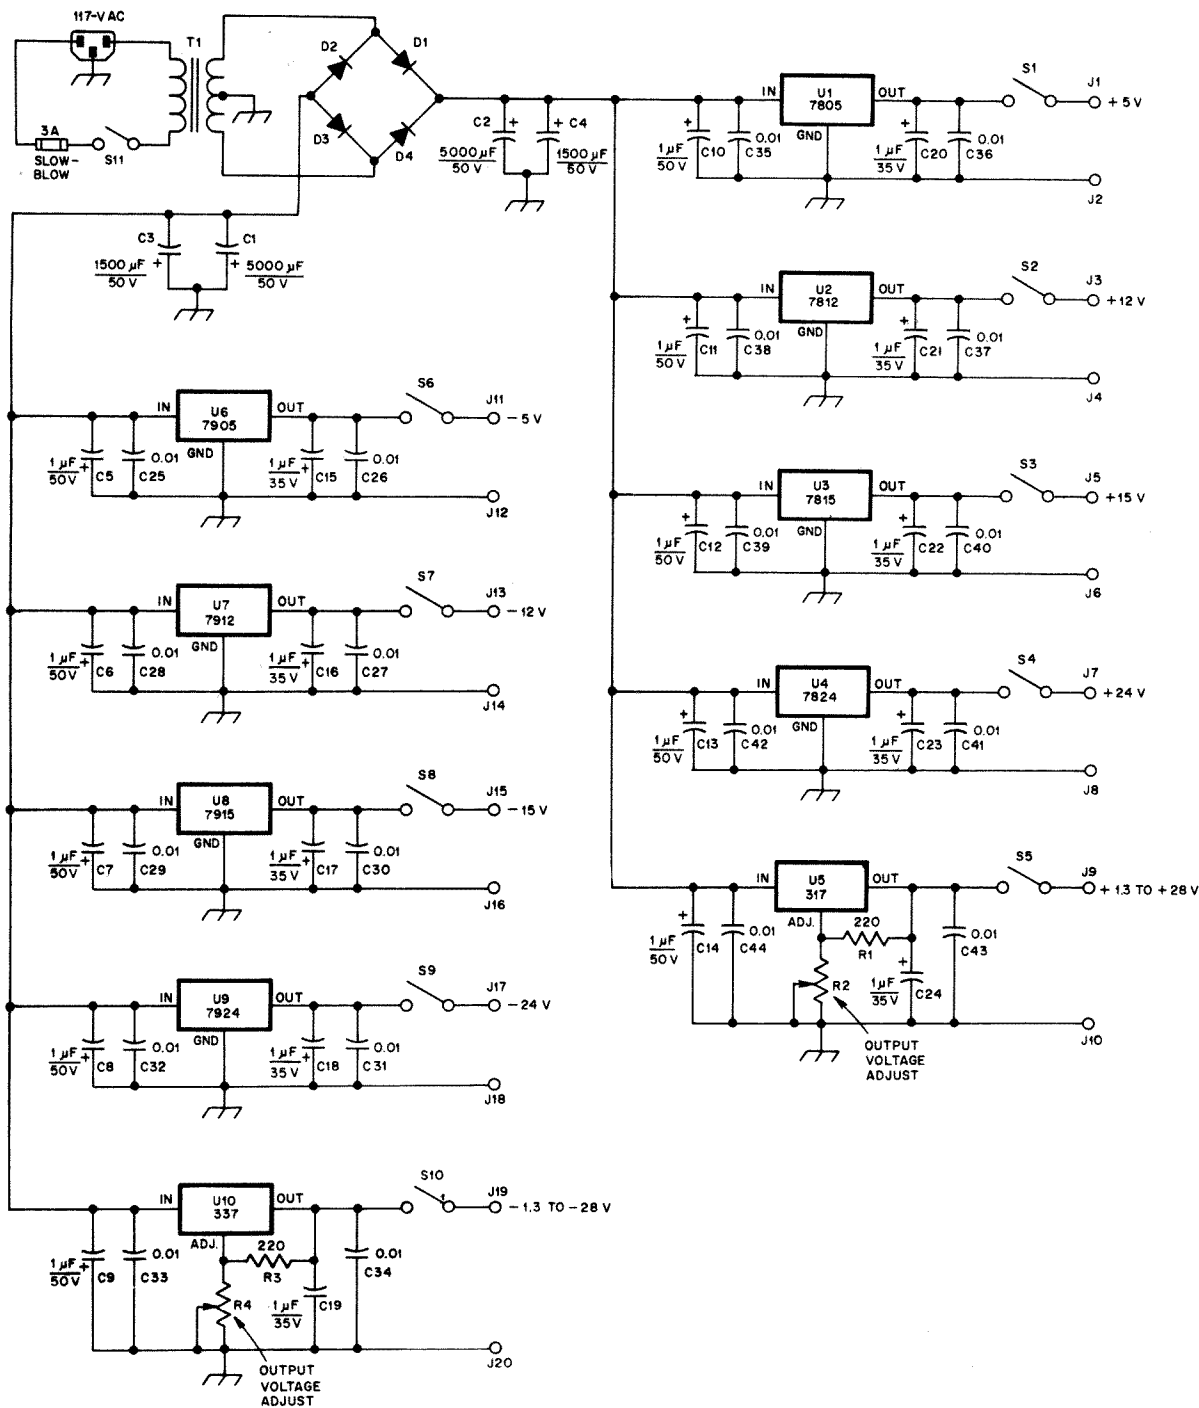

Fig. 29 — Schematic diagram of the multiple-voltage bench supply. All capacitor values are in microfarads and resistor values are in ohms. Resistors are  $\frac{1}{4}$  W.

 U10 — Voltage regulator, -1.2 to -37 V, 1.5 A (LM337 or equiv.).

Fig. 30 — Voltage relationships on the positive dc bus.

or excessive load demands. Three-terminal regulators are capable of supplying currents up to 8 A, simplifying construction and reducing overall cost by eliminating series-pass transistors and associated circuitry. The supply described here uses readily available 1.0-A regulators in TO-220-style packages.

Several design precautions must be taken when working with these regulators, however. Maximum input voltage, as well as maximum and minimum differential voltages, must conform to manufacturers' ratings for safe, trouble-free operation. Adequate heat-sinking must also be employed. In this supply, individual fin-type heat sinks cool each regulator. In some three-terminal devices, the case is also the input or output terminal, so care must be taken to ensure nothing contacts the heat sinks. The TO-220-style cases also permit installation against the side of the chassis, using it as a heat sink. However, if the regulator case isn't also the ground connection, appropriate mica washers, thermally

conductive silicone heat-sink compound and nonconductive fasteners must be used.

### Bypassing

Three-terminal regulators are active devices containing high-gain error-sensing amplifiers, so great care is necessary to keep them stable over a wide range of load impedances. Input and output leads should be bypassed with both 0.01- $\mu$ F disc-ceramic and 1.0- $\mu$ F tantalum capacitors. All bypassing should be performed as close to the regulator as possible to keep RF from

Fig. 32 — Interior view of the multiple-voltage bench supply.

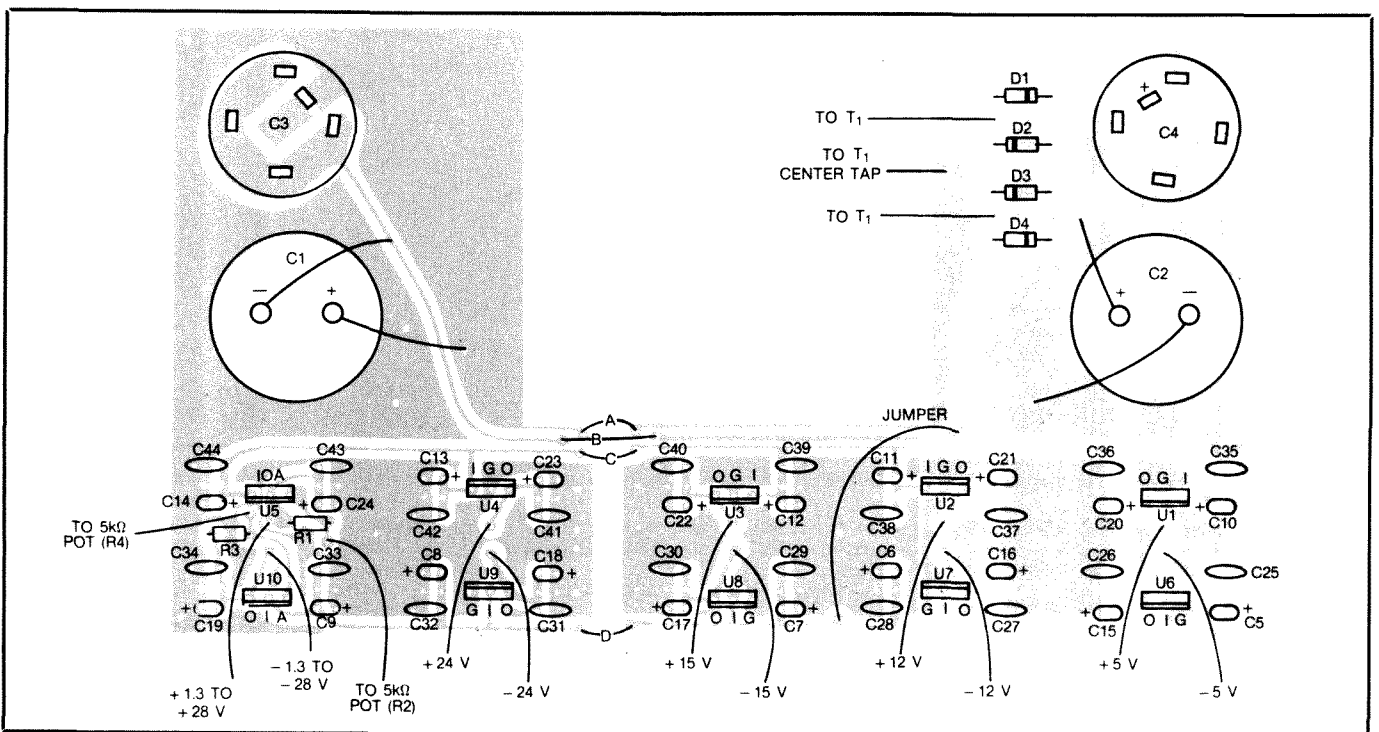

Fig. 31 — Parts placement for the multiple-voltage bench supply. A full-size etching pattern appears at the back of this book.

entering the device. Generally, use of double-sided circuit board material is recommended. The unetched component side acts as a ground plane. All component leads should be kept as short as possible. Ferrite beads on all lines leading to and from the regulators may be necessary in some cases.

### Construction

Most of the components in this supply are mounted on two single-sided PC

boards. Parts placement is given in Fig. 31. The boards are mounted just above the bottom of the  $4 \times 6\frac{3}{4} \times 12$ -inch cabinet (Fig. 32) and are cut to clear the transformer. Individual heat sinks are used for each regulator to ensure adequate cooling.

Output voltages from the regulators are fed to binding posts via toggle switches. The potentiometers for the two adjustable voltages are also mounted on the front panel adjacent to the binding posts. Ac line voltage enters the supply through a standard CEE-22, 6-A connector.

The high initial surge current needed to charge the capacitors at turn-on will blow an ordinary fuse, so use of a 3-A slow blow fuse is necessary. This fuse will conduct 4 A for about five seconds, allowing the capacitors to charge while guarding against drastic circuit malfunction. No. 18 wire is used for the ac connections, while no. 22 is used for the dc interconnections. The cover of the enclosure has a black wrinkle finish that attractively complements the natural-aluminum front panel.

## A Smorgasbord Supply

A smorgasbord offers foods and dishes to suit a variety of tastes. Similarly, the circuits and techniques presented here cover a wide range of low-voltage amateur power-supply applications. This smorgasbord, shown in Figs. 33 to 45 was prepared by Greg Bonaguide, WA1VUG, in the ARRL lab.

### Anatomy of a Power Supply

There are four major building blocks to any linear dc supply: The transformer, rectifier, filter and output regulator. However, before components can be specified and parts ordered, certain information must be provided. The designer needs to know the line voltage he has to work with (typically either 117 V, as here, or 234-V ac) and the desired output voltage and current the supply will deliver.

### Defining Output Voltages and Currents

It's handy to have  $\pm 12$  and  $\pm 5$  V at the workbench. While negative voltages are called upon to provide small currents, the +5-V tap must be capable of supplying 5 A for power-hungry logic boards. Similarly, many medium-power VHF FM rigs, low-power amplifiers, and QRP HF transceivers require at least 5 A from a steady 12-V tap. There are also times when a continuously variable, *tracking* voltage source (single-knob adjustment of positive and negative voltages) is indispensable. The variable supply should have a range of approximately 2 to 28 V at half an amp. The smorgasbord supply was designed with these goals in mind. Enough information is presented here to enable the amateur to

Fig. 33 — Front-panel view of the Smorgasbord Supply.

adapt these circuits and techniques to his own needs.

### Examining Regulator Characteristics

A three-terminal adjustable voltage regulator, such as the LM317, is a natural choice for this supply. Besides providing excellent regulation of output voltage over the range of 1.5 to 28 V, it offers other attractive features such as thermal-overload protection and current-foldback limiting. To make any three-terminal regulator work well, however, the designer must operate the device above a minimum input voltage, called the dropout voltage (Fig. 34A). If the input voltage dips below this manufacturer-

specified minimum (usually 3.0 V above the regulator's specified output voltage), regulation is lost.

Given this information, one would be tempted to apply an input voltage well above dropout. However, as the input voltage increases, so does the amount of power that the regulator must dissipate for any given output voltage and current. Three-terminal regulators have dissipation ratings that must be observed. Power dissipation can be calculated by multiplying the input-to-output voltage differential by the load current (Fig. 34B). Fig. 34C shows how input-output differential affects maximum available current. Under extreme

Fig. 34 — Important three-terminal regulator operating characteristics. See text for details.

operating conditions, regulator power dissipation may become so great that the device shuts down to keep from burning up, a condition known as current foldback.

This leads to an important design consideration. To deliver 28 V at 1.0 A, the regulator needs 31 V at its input terminal to satisfy dropout requirements. But, when the regulator is adjusted to deliver only 2.0 V, (minimum output voltage), the input voltage will remain at 31 V, and the input-output differential will be  $31 - 2$ , or 29 V! From the chart in Fig. 34C, we see that this condition results in severe current limiting. Fortunately, we don't need much current from the supply at this low voltage level. We will, however, need to be able to draw appreciable current at 28 V (for powering relays, and so forth), where, fortunately, a 3-V input-output differential presents no dissipation problems.

### Choosing Filter Capacitors

Now that we have calculated the minimum permissible bus voltage (31 V), based on the dropout requirements of the supply's highest output voltage (28 V), we can investigate various transformer, rectifier and filter capacitor combinations.

There are several reasons for choosing designs that minimize filter capacitance. Electrolytic capacitors are bulky. They also tend to be expensive. Supplies that use large electrolytic capacitors sometimes require special turn-on sequencing to safely handle inrush current. Also, these large capacitors present a shock hazard unless they are properly discharged when the

supply is switched off. Fortunately, we can use an equation to find ways of minimizing filter capacitance requirements. It interrelates power-supply current, ripple amplitude, ripple frequency and filter capacitance:

$$C = \frac{I \sqrt{2}}{F_r V_{p-p} \sqrt{3}} \quad \text{Eq. 1}$$

where

$I$  = supply current in amperes  
 $F_r$  = ripple frequency in hertz  
 $V_{p-p}$  = peak-to-peak ripple in volts.

This equation immediately tells us that we can reduce the filter capacitance by increasing the ripple frequency or by allowing a greater peak-to-peak ripple voltage to exist on the regulator input line (the bus). If we increase the ripple frequency, we will permit rectified dc pulses to replenish the energy stored in the filter capacitor at a faster rate. This is important, because the load is constantly draining this stored charge from the capacitor.

The alternative is to allow more ripple. This may seem confusing, since we have an intuitive notion that *all* power supply ripple is undesirable. Keep in mind, however, that ripple is only undesirable when it shows up *after* the regulator, where the voltage should be steady, pure dc. Pre-regulator ripple is an entirely different consideration. Fig. 35 helps to illustrate this point. Imagine we have a dc source of 40 V, with a 4-V p-p sawtooth waveform superimposed. Using an oscilloscope, we'd see the waveform of Fig. 35A. The voltage

begins at 40 V and decreases to 36-V valleys. If we hooked this up to a 28-V regulator, it would regulate perfectly because the bus voltage valleys never drop below the 31-V dropout value. In fact, we could let this sawtooth ripple waveform increase in amplitude until it was 9 V p-p, and we'd still have a perfectly regulated output! (Fig. 35B). As soon as the input voltage dips below 31 volts on valleys, however, output regulation is lost (Fig. 35C).

In any linear power supply, pre-regulator ripple will increase if we remove some filter capacitance or increase the load. Here, we need only enough filter capacitance to ensure that the input voltage remains above the regulator dropout voltage under full load.

Returning to the power-supply design, we can cut filter capacitance requirements in half if we use full-wave (120-Hz ripple) rather than half-wave (60-Hz ripple) rectification. Also, the amount of capacitance required can be reduced through the use of a transformer with a higher secondary voltage. With a higher bus voltage, more ripple (deeper valleys) can exist on the dc bus without dropout problems. However, as mentioned before, power dissipation becomes a problem at higher bus voltages, so all trade-offs must be considered.

The transformer chosen for the supply has a 48-V RMS, center-tapped secondary winding. The maximum dc voltage that can be expected from this supply, using a full-wave bridge rectifier and capacitive-input filter, is found from

$$V_{dc, \max} = \sqrt{2} V_{RMS} - 2V_d \quad (\text{Eq. 2})$$

where

$V_{RMS}$  = transformer RMS secondary voltage in volts

$V_d$  = the voltage drop across a single rectifier diode, usually 0.7 V.

This equation gives 66.3 V as the maximum rectified voltage that can be expected across the full secondary. Since we want positive *and* negative voltages, divide this result by two, for 33.15 V. The peak-to-peak ripple on this line must be limited to  $33.15 - 31.0 = 2.15$  V, since the bus voltage must remain above dropout (31.0 V).

Since the total transformer is rated at 4 A, assume that the positive bus and negative bus will each require half that current. Using Eq. 1, each bus will require 6329  $\mu\text{F}$  of filter capacitance. The next greater standard value, 6800  $\mu\text{F}$  at 50-V dc, is used for each bus. Observe proper capacitor polarity!

### Controlling the Adjustable-Output Regulators

A builder could install a stand-alone negative adjustable voltage regulator, such as an LM337, in the negative bus. This is a simple, reliable method for obtaining an adjustable, regulated negative voltage.

The smorgasbord supply, however, uses

a different technique to give single-knob control of both positive and negative voltages. See Fig. 36. U4, U5, Q2 and Q3 work together in a feedback loop to keep the negative output locked to the positive output. The 3.9-k $\Omega$  resistors form a voltage divider which, under normal conditions, sets pin 2 of U5 at zero volts. If the negative supply should begin to rise towards zero (as might happen if the load suddenly increases), pin 2 becomes positive with respect to pin 3 (ground), forcing pin 6 of U5 low. This forces Q2 into harder conduction, supplying more base current to Q3. Then, more load current flows through Q3 and, consequently, the load. This condition continues until a suitably negative output voltage returns zero volts to U5, pin 2. If too much current flows through Q3, the output voltage becomes too negative, and the voltage at the op-amp input drops below zero volts. This condition forces the output (pin 6) high, turning Q2 off, and removing Q3 base drive until the correct output voltage is established. Proper regulation of the positive output ensures regulation of the negative output. Whatever happens on the positive side also happens on the negative side; for example, if U4 goes into current limiting and the positive voltage drops, the negative voltage changes by the same amount. U5 is located on the rectifier board (Fig. 37).

### Obtaining a High-Current 5-V Output

There are several ways to obtain regulation for the +5-V output. The simplest method requires only a three-terminal, 5-V regulator, such as the LM7805 1-A device or the LM323 5-A device. See Fig. 38. In this supply, the regulator could be fed from the 31-V bus or from the 25-V bus used for the high-current 12-V supply (described later). This arrangement is less than satisfactory because the input-output voltage differential is high enough to cause power-dissipation problems, as described earlier, which severely restrict maximum current. A larger heat sink or a heftier device might help, but output current would still be limited. Another option is to install yet another transformer/rectifier/filter combination for the 5-V circuit.

Instead, the smorgasbord supply uses a step-down switching regulator (Fig. 39). By chopping an input dc voltage the switcher converts the output to a desired lower voltage at high efficiency. In fact, the switching regulator used here operates at 80% efficiency. It draws only 1.2 A from the 31-V bus, yet provides 5 V at 5 A. The circuit is designed around a Lambda LAS6350 IC.

Because of the high switching rate (approximately 60 kHz), relatively small values of inductance and capacitance are used. D1 is a special Schottky diode specifically designed for high-speed switching applications. It is available from Varo Semiconductors, as noted in the parts list. Do

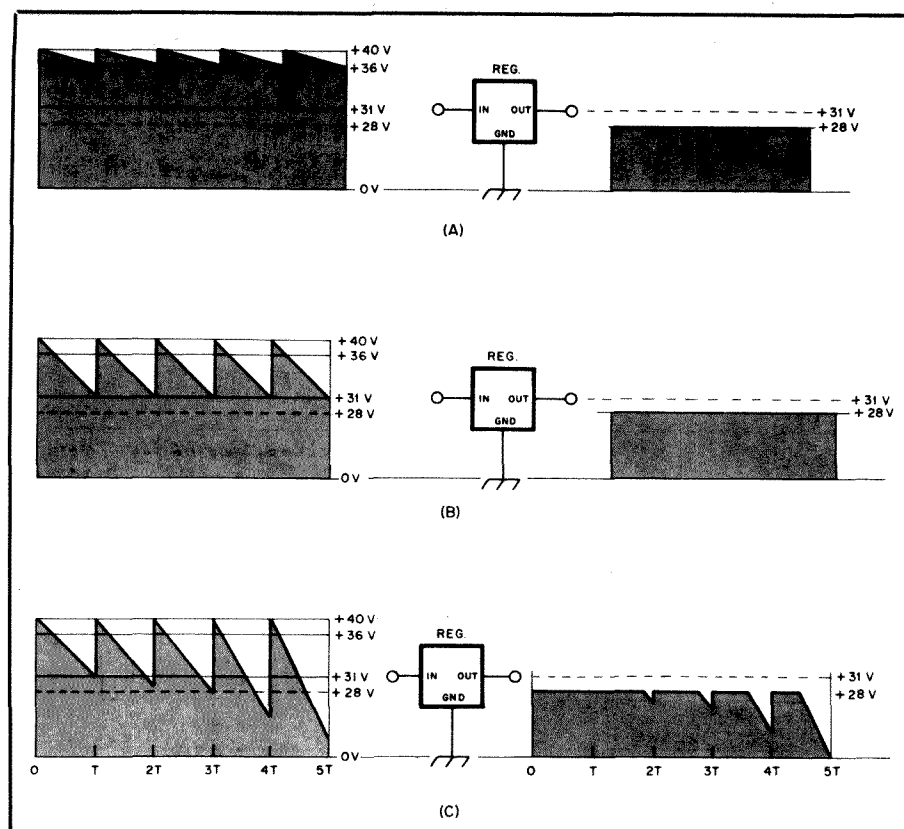

Fig. 35 — Effects of ripple on three-terminal regulator performance. See text.

not substitute an ordinary silicon diode!

In this switching regulator, care must be taken to prevent undesirable modes of oscillation. Bypassing is very important. Double-sided circuit board should be used with the layout pattern shown in Fig. 40.

### Negative 5- and 12-V Considerations

Since little current is required from the negative 5-V supply, a standard 7905 three-terminal -5-V regulator will suffice. Voltage input for the 7905 is taken from the output of the negative 12-V regulator, however, to reduce the 7905 input-output differential. The negative 12-V regulator is similar; a 7912 provides the -12-V regulated output.

### Designing a High Current, 12-V Regulator Subsystem

While a separate switching regulator could provide the higher current required for the positive 12-V output, a different method is used here. Switching regulators are fine for constant loads, such as heating logic chips, but they sometimes have trouble powering RF equipment. There are several reasons. First, most transceivers present widely varying loads — especially when switching between transmit and receive. Second, any RF that sneaks back into the switcher can raise havoc.

There is one other design goal that cannot be easily met by a switcher — high and

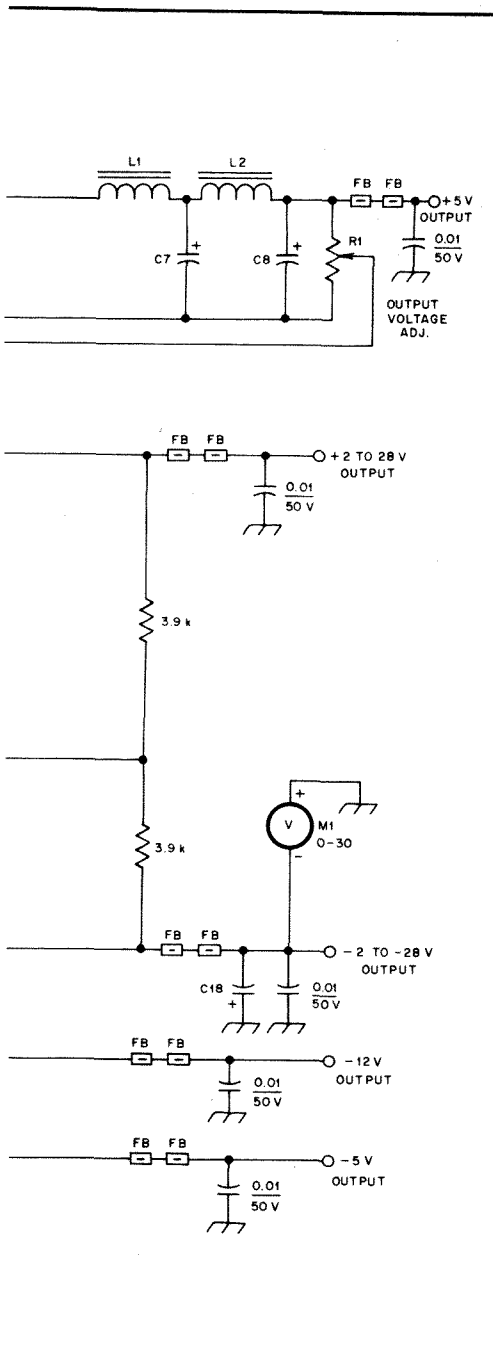

low current limiting. The smorgasbord supply includes provisions for high (5 A) and low (1 A) current settings for the 12-V supply. Shown in Figs. 36 and 41, this circuit consists of a standard three-terminal regulator with a current-boosting wrap-around pass transistor operating as a dc current amplifier for the high-current setting. U8 provides sensing and voltage-error correction and transfers these characteristics to Q1. As regulator current demands increase, more base current is drawn by the transistor. This causes the transistor to conduct harder, supplying greater collector current to the load.

Details of the design are presented here to allow the builder to calculate different current levels or to substitute a pass transistor with different characteristics. Refer to Fig. 41.  $I_c$  (collector current) is equal to  $I_2 - I_b$  (base current). The current through U8,  $I_a$ , is equal to  $I_1 + I_b$ . The total load current,  $I_L$ , is equal to  $I_c + I_a$ , or  $(I_2 - I_b) + (I_1 + I_b) = I_1 + I_2$ .

The voltage drop between  $V_{in}$  and  $V_b$  includes one diode drop, no matter which path ( $I_1$  or  $I_2$ ) is chosen:  $I_2$  flows through the internal base-emitter drop of Q1, while  $I_1$  flows through D1. This forces the same voltage drop across R1 and R2; so,  $I_1 R_1 = I_2 R_2$ , and

$$\frac{I_2}{I_1} = \frac{R_1}{R_2}$$

If we calculate the values for  $I_1$  and  $I_2$ , we can find the values needed for  $R_1$  and  $R_2$ . Assume that this circuit will be called upon to supply a worst-case maximum current of 8 A, to allow for momentary overloads. There will be two components of current through the regulator:  $I_b$  and  $I_1$ . Good design requires that  $U_8$  be run at somewhat less than its maximum rated current, so first assume  $I_a = 0.85$  A. Then,  $I_c = 8 - 0.85$ , or 7.15 A through the collector of  $Q_1$ . From the collector vs. base current curves for  $Q_1$  (Fig. 42), we find that

$I_b = 600$  mA for a collector current of 7.15 A. Thus, total current through  $R_1$  will be  $I_1 = I_a - I_b = 0.85 - 0.6 = 0.25$  A.

Because of the high current demand, a separate transformer is used for this output. It is rated at 18 V RMS at 8 A. The maximum dc bus voltage will be approximately 25 V. A 6800- $\mu$ F filter capacitor is also used on this bus, yielding a maximum ripple of 8 V (from Eq. 2). The minimum voltage on the bus will occur during ripple valleys ( $25 - 8 = 17$  V). The minimum regulator input voltage to avoid dropout is 15 V. A diode drops 0.7 V, so we must add this value to the minimum regulator requirement to make up for the drop across  $D_1$ . The voltage across  $R_1$  and  $R_2$  must be  $17 - 15.7 = 1.3$  V.

Thus,

$$R_1 = \frac{V_{R1}}{I_{R1}} = \frac{1.3 \text{ V}}{0.25 \text{ A}} = 5.2 \Omega$$

$$R_2 = \frac{V_{R2}}{I_{R2}} = \frac{1.3 \text{ V}}{7.75 \text{ A}} = 0.168 \Omega$$

The power dissipated by  $R_1$  will be

$$I^2 R_1 = 0.25^2 \times 5.2 = 0.325 \text{ W}$$

The power dissipated by  $R_2$  will be

$$I^2 R_2 = 7.75^2 \times 0.167 = 10.03 \text{ W}$$

The final design uses two 16-ohm, 1-watt resistors in parallel for  $R_1$ , and a 1-ohm, 25-watt adjustable wirewound resistor for  $R_2$ .

To implement high/low current limiting (Fig. 36),  $S_2$  shorts out the combination of  $R_1$  and  $D_1$ . This effectively sets the emitter and base of  $Q_1$  at the same potential, making it incapable of turning on and passing current. Thus, in the low current setting,  $U_8$  supplies all the current to the load.

### Other Design Features

The LED indicators (Fig. 43) are designed to turn on when the proper voltage appears at the power supply output terminals and to extinguish if the voltage falls by 1 V or more. For the two adjustable-output voltage regulators, the LEDs will stay lit unless a short-circuit condition occurs. Any or all of these indicators may be omitted, if desired.

### Precautions

Three-terminal regulators contain high-gain circuitry and may show signs of instability unless design safeguards are taken. Manufacturers urge that 0.1- $\mu$ F bypass capacitors be installed on all input and output leads, preferably right at the regulator pins. In practice, the amount of bypassing will vary from installation to installation. Additionally, all ground leads should be returned to a single point. This helps avoid difficult-to-cure ground loops.

Sometimes, one can actually hear regulator instability as a high-pitched whine. More often than not, however, the oscilla-

tions can only be detected with an oscilloscope. Different values and types of bypass capacitors should be tried until a combination is found that makes the oscillations disappear. A regulator may be considered stable when it can be operated at 10, 50 and 110% of maximum rated load without signs of oscillation, even when rapidly switched off and on.

Where wrap-around current-boosting regulators are used, oscillations can often be squelched by bypassing the base of the pass transistor to ground with several hundred ohms. In extreme cases, collector or emitter bypassing may be required.

Once the power supply passes these tests operating into resistive loads, it's time to power up the HF or VHF rig. Operating in the presence of strong RF fields can open up entirely new oscillation problems. One very important, yet basic cure is to enclose the supply in a metal cabinet. Wires leading into or out of the cabinet should be RF bypassed. Do not overlook the line cord when searching for potential sources of RF ingress. In most supplies, 0.02 to 0.05  $\mu$ F, 600-V capacitors across the line provide sufficient RF rejection. Ferrite beads on all outputs will also discourage RF from feeding back into the regulators.

$F_2$  is located at the output of  $U_2$ . It serves as a "safety valve" in case the regulator or pass transistor malfunctions. A 10-A automotive fuse may be used.

An 82-ohm,  $\frac{1}{4}$  W resistor placed across the  $Q_1$  emitter and base guards against transient operating conditions that could destroy the device. This is a very inexpensive form of semiconductor insurance!

### Construction

The interior of the smorgasbord supply can be seen in Fig. 44. A  $4\frac{1}{2} \times 15 \times 10$ -inch (HWD) steel cabinet (Bud model TV2155) houses the supply. The front panel slopes inward towards the top, making meter viewing easy. Half-height meter bezels for the Triplett meters further enhance the clean appearance of the front panel. The main power switch was primarily designed for computer applications and features a built-in pilot lamp. Power for the lamp comes from the +5 V switcher output.

For convenience, the rectifiers and filter capacitors, as well as  $U_5$ , are mounted on a single-sided PC board. A parts-placement diagram is shown in Fig. 37.

The 5-V switching regulator is mounted on its own PC board (Fig. 40). The component side of the board remains unetched. Those component leads that are connected to ground are soldered to the top of the board as well as the bottom. The copper foil on the top of the board must be cleared away from component leads that are not grounded. This can be accomplished with a countersink or a  $\frac{1}{8}$ -inch drill bit.

The LED drivers and associated circuitry

(Q4-Q9) mount on a small PC board that attaches to the rear of the front panel. Parts placement is shown in Fig. 43.

All regulators and power transistors mount on the back panel (Fig. 45). Individual heat sinks improve thermal dissipation. TO-3 sockets are used to facilitate device replacement. The transistors and regulators are electrically insulated from the heat sinks and chassis by mica washers; use silicone heat-sink grease for better thermal conductivity. Fig. 45A shows the location of regulators and transistors as viewed from the inside of the cabinet. Fig. 45B is a top view of the power supply showing layout of the major assemblies. Use point-to-point wiring to interconnect circuit board assemblies and regulators.

# The Perfect 10: A Battery Eliminator for FM Portables

In an effort to reduce the size of FM portable equipment, some manufacturers have opted to reduce the number of batteries in the battery pack. Now, a typical portable rig operates from a pack containing eight cells (nominal 9.6-V potential). Operating these rigs from an external supply, typically 12-V from an automobile electrical system or commonly-used home power supply, can be risky. Pete O'Dell, KB1N, presents the following solution for those amateurs wishing to power their portables from a source other than internal batteries. The "Perfect 10," shown in Figs. 46 through 50, was originally presented in March 1984 *QST*.

## The Regulator Circuit

Fig. 47 shows a circuit for use with the 12-V electrical system of an automobile (or any other 12-V dc source capable of supplying about 500 mA). Both the input and the output are fused for added safety. The mounting tab of U1 (internally connected to pin 2) is bolted to the metal cabinet that houses the circuit. Heat-sink compound is applied between the tab and the cabinet to aid heat transfer. The metal of the cabinet should be more than adequate as a heat sink because the input voltage is only 2 to 4 volts above the output voltage.

Two alternatives are available for U1. The 10-V fixed regulator is not very common, but is available from the source in the parts list. You could also use an LM317 adjustable regulator (available from Radio Shack and other sources). Adjust the 2-k $\Omega$  potentiometer for a supply output of 10 V.

D1 provides protection for the regulator chip in the event that the output terminal potential of U1 rises above that at the input terminal. Without D1, the regulator can be destroyed. That condition can occur easily. The capacitor on the input of U1 charges (assuming S1 is open). DS1 lights, then slowly extinguishes as the capacitor discharges. U1 may survive the small reverse current, but why take chances?

The two capacitors should be mounted as close to the regulator IC as possible.

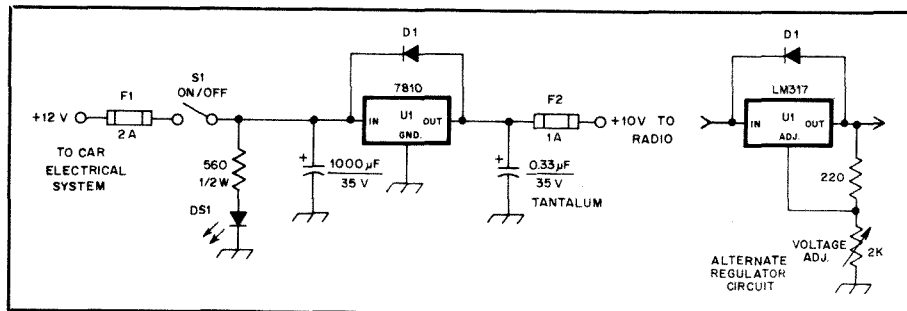

Fig. 47 — Schematic diagram of the regulator circuit. The resistor is a carbon-composition type. Capacitance is in microfarads. The input capacitor is electrolytic. Parts numbers in parentheses are from Radio Shack.

D1 — Silicon power diode, 1N4001 or equiv.  
DS1 — Green LED (276-022).  
F1, F2 — Fast-acting fuse, 1 A (270-1273).  
S1 — SPST toggle (275-602).  
U1 — 10-V, 1-A, three-terminal regulator, Texas

Instruments 7810 or equiv. (available from Active Electronic Sales Corp., P.O. Box 8000, Westboro, MA 01581, tel. 617-366-0500). Or 1-A adjustable three-terminal regulator (LM317 or equiv.).

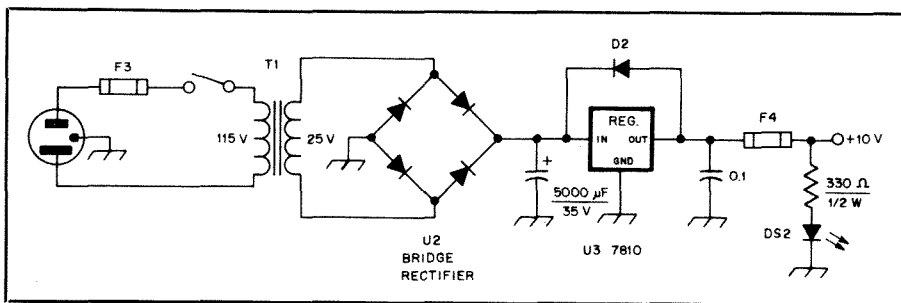

Fig. 48 — Schematic diagram of the base-station version of the battery eliminator. Components used in the regulator circuit are identical with those in Fig. 47. Consult the Fig. 47 parts list for component values.

T1 — Filament transformer; primary: 117-V ac, 60 Hz; secondary: 12.6-V ac, 1.2 A (173-1505).

U2 — Bridge rectifier, 4 A, 100 PIV (276-1171).

Fig. 49 — Internal view of the regulated supplies. Construction is straightforward; layout is not critical.

Fig. 46 — Two versions of the Perfect 10. The mobile unit bracket with ON/OFF switch attaches to a convenient spot on the dash-board, while the box housing the regulator mounts out of sight.

Some manufacturers recommend lead lengths no greater than 1/4 inch. U1, D1 and the capacitors mount in a small aluminum box. A mounting tab on the box permits it to be secured under the dash, out of sight. F1 and F2 are housed in in-line fuse holders. S1 and DS1 are

mounted on a small home-made bracket that is attached to the dash.

## A Base-Station Supply

Fig. 48 shows a version of the circuit that operates directly from 117-V ac. The regulator circuit is identical to that of Fig. 47. DS2 is located on the output and provides a quick visual check of the output status. The fuse holders are the panel-mounted variety instead of the in-line type. All the components are mounted inside a small aluminum box (Fig. 49). Again, the cabinet serves as the heat sink for the regulator chip.

Initially, a 1000- $\mu$ F capacitor was tried for the input of the regulator. No problems were encountered when using the supply with a 2.5-W portable. However, at the 5-W level, some hum was noticeable on the signal. A 5000- $\mu$ F unit cured the problem.

## Making Connections

Fig. 50 shows one method of connecting the battery eliminator to a portable rig. J1 is a miniature plastic-enclosed, closed-circuit phone jack (Radio Shack 274-296 or similar). P1 is a matching plug. As a phone

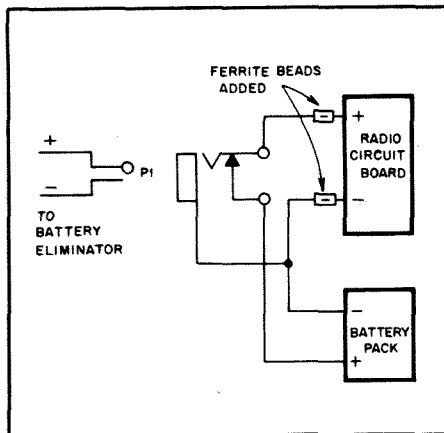

Fig. 50 — Block diagram of the connections between the battery pack, radio circuit board and battery eliminator for the Tempo S5 and similar portable units.

plug is inserted into a jack, the tip will cause a short, initially, between the elements of the jack. This results in a momentary short from the positive terminal of the battery to ground, which will not damage the battery pack (as long as the short is momentary). The event may cause a fuse in series with the battery to blow. If your radio incorporates a fuse in series with the battery pack, you should consider a different plug-and-jack system.

Finding a place to mount the jack in a small radio can be a chore. Carefully measure the openings and distances before drilling the mounting hole. Use liberal amounts of heat-shrink tubing to cover bare wires or terminals.

This method should work for most portables on the market — those that do not have slide-on battery packs. For rigs with

the slide-on packs, the easiest approach is to obtain an empty pack and construct the circuit inside it.

Two ferrite beads are added to the power leads near the circuit board in Fig. 50. These minimize the possibility of RF getting back into the portable-rig circuit through the battery eliminator. If the eliminator is constructed in a slide-on pack, the beads should be placed on the output wires that are soldered to the terminal inside the pack.

Before applying power, double check all wiring. With the radio ON/OFF switch in the OFF position, apply power to the eliminator circuit and check the voltage at the power input of the radio. If everything is all right, proceed with final assembly. There is nothing to adjust. Just use and enjoy.

## A Solid-State Regulator for Alternator-Battery Systems

Until very recently, automotive voltage regulators have been electromechanical devices. In some systems they can be reliable for many years, while in other systems they cause noise and fail frequently. Serious mobile operators should consider replacing their electromechanical regulator with an electronic one. Advantages of an electronic unit include greatly reduced hash and whine, tight load regulation independent of shaft speed, temperature stability and precise adjustment. Most modern radio equipment is powered from 13.8-V dc, so a battery-alternator system makes more sense for portable operation than does a 117-V ac generator and an accessory ac power supply.

The circuit shown in Fig. 51 is designed for alternators that are controlled in the positive (ungrounded) field lead. Alternator field current (up to 3 amperes) is regulated by Q1, which is driven by Q2 and U1. The "armature" terminal is also connected to the battery, so that when K1 is energized, the field becomes part of a feedback loop. U2 is a reference generator. When the alternator has sufficient speed, the loop maintains the armature/battery voltage at a level that causes no potential between the differential inputs of U1.

R1 sets the output voltage at which equilibrium is established. D1 absorbs negative-going transients generated by the field inductance that might otherwise damage Q1. In an automobile having a discharge indicator light the field is excited through the light when the ignition switch is turned on. As soon as the engine starts and the alternator stator (common connection of the 3-phase windings) develops about 5 volts, K1 closes and full alternator/battery voltage is available to drive the field. A system using an ammeter rather than an indicator light would have the "stator" ter-

minal connected to the ignition switch (through a current-limiting resistor if necessary) and the "indicator" terminal would not be connected.

The circuit can be built into a stock voltage regulator enclosure, which can serve as the heat sink for Q1. The remaining components can be mounted on a PC board or tie points. Vibration and shock can be severe in automotive service,

so clear silicone rubber compound is recommended as a cushion for the components and leads. R1 can be a PC-mount trimmer or a chassis-mount potentiometer with the bushing and shaft protruding through the regulator cover. Adjustment is greatly facilitated by the latter arrangement, but the knob should be anchored to the cover to prevent voltage changes caused by vibration or accidental contact.

U2 — 5-V, 1-A voltage regulator.

# The AA6PZ Power Charger

The battery charger shown in Figs. 52 through 58 combines the best features of constant-current and constant-voltage NiCd chargers. This charger was originally described by Paul Zander, AA6PZ, in December 1982 *QST*.

## The Power Charger

As shown in Fig. 53, when the battery voltage is low, the current available from the charger is high enough to keep the transmitter on the air. As the battery voltage increases, the charging current decreases in order to avoid overcharging the battery. Finally, as the battery approaches full charge the current tapers off more slowly with increasing voltage. This action provides a topping-off charge with some latitude for variations in battery voltage.

Fig. 54 shows what happens when a discharged battery is connected to the Power Charger. The initial current is high, charging the battery to 25 to 30% of its capacity in the first hour. The current drops off as the battery is charged. After approximately 6 hours the battery is fully charged. Then, as continued charging pushes the battery voltage higher, the current decreases to a few milliamperes. If you forget to disconnect the Power Charger after the battery is charged, the final charge rate is actually less stressful to the battery than if you were using a constant-current trickle charger.

What happens if you operate with the Power Charger connected? When the transmitter draws current from the battery the battery voltage drops, and more current is available from the Power Charger.

Fig. 52 — Interior view of the Power Charger. The three LEDs are mounted on long leads so they protrude through the top cover.

Fig. 53 — Output characteristics of the Power Charger circuit.

When the battery is less than three quarters charged the charger supplies most, if not all, of the transmitter current.

Rapid-charging capability, by itself, is of limited utility if the charger must be

plugged into a wall outlet. The Power Charger can be operated with a wide variety of sources that supply from 12 to 30 volts. For mobile operation the car battery can supply the power from the cigarette lighter. For extended portable or emergency operation, lead-acid storage batteries may be useful. For fixed-station use, a simple ac-operated supply can be used.

## Circuit Description

A simplified schematic diagram of the Power Charger is shown in Fig. 55. A full schematic is shown in Fig. 56. A PNP series-pass transistor, Q1, is used to control the charging current, and a 1- $\Omega$  resistor (R1) is used to monitor that current. When Q1 has enough base drive it will have 0.2 V or less between collector and emitter. This, combined with the voltage drop across R1, allows the circuit to have a minimal difference between the input and output voltages. Although it might be possible to use an IC voltage regulator in place of Q1 and some of the other parts, most IC regulators have a minimum of 2 or 3 V between the input and output. This makes them unsuited for mobile and portable operation where there is not much voltage to spare.

Q2 and Q3 control the base drive to Q1. Q3 receives input from Q4 if the charging current is too high — and from Q5 if the output voltage is too high. In response to either of these inputs, Q3 reduces the Q2 base current. This, in turn, reduces the base drive to Q1 so that the proper output voltage and current are maintained.

Q4 and the associated components monitor the output current. The base-

Fig. 54 — Typical charging performance of the Power Charger. Shown at A is the percentage of full charge obtained as a function of charging time. The charging current, as a function of time, is shown at B.

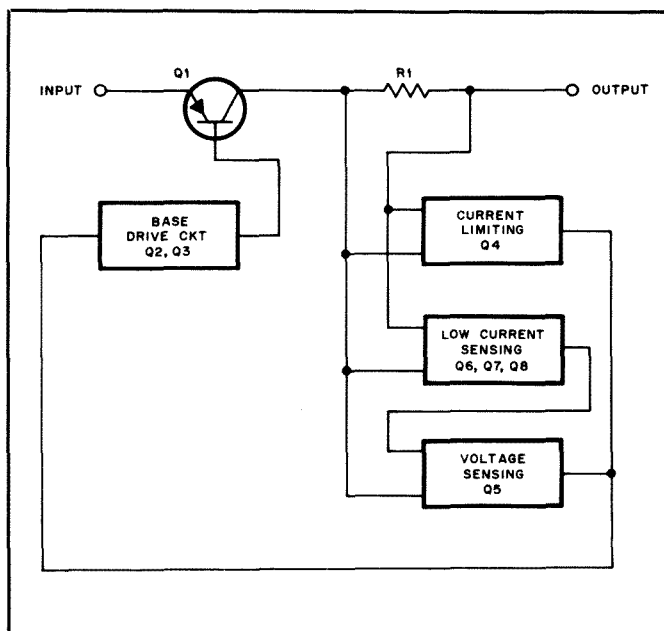

Fig. 55 — Block diagram of the Power Charger.

$$R5 = \frac{70}{R1 \times I_{MAX} - 0.7}$$

During most of the charging cycle Q5 and the 4.7-V Zener diode act as a voltage-sensing circuit. The combination of Q1, Q2, Q3 and Q5 regulate the collector voltage of Q1 at 11.2 V. There is, however, a resistor (R1) between that point and the battery. When the output current is 500 mA there is 0.5 V across R1, so the output is only 10.7 volts. At 200 mA, the drop across R1 is 0.2 volt, and the output is 11.0 volts. Viewed from the battery terminals, as the voltage increases the charging current decreases.

Using a 330- $\Omega$  resistor for R5 would give a maximum current of 500 mA.

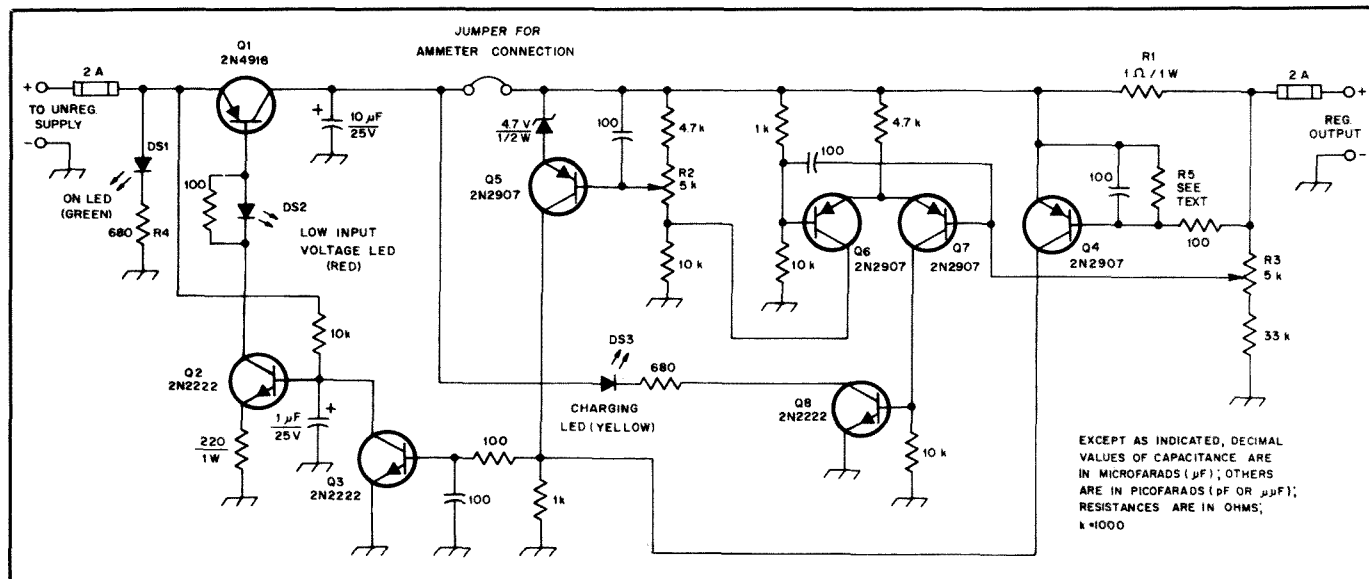

As the output voltage increases at the end of the charging cycle, the base drive to Q8 is reduced. This causes the CHARGING LED to dim and eventually go out when charging is complete.

**The last items in the schematic diagram**

## Construction

All of the components can be mounted on a 1.9- × 3.9-inch etched circuit board. An etching pattern for this board appears at the back of this book. This size fits comfortably inside a 2 × 4 × 1-inch aluminum box. A parts-placement diagram is shown in Fig. 58. Q1 is mounted with an insulating washer between it and the box. The mounting provides heat sinking for Q1 and mechanical support for one end of the circuit board. The other end of the board is supported by a no. 4-40 machine screw and three nuts. The first nut holds the screw securely to the box. The remaining nuts go above and below the board to hold it level in the box. The head of the same screw can be used to mount a rubber foot on the outside of the box.

Probably the only construction difficulty you will encounter is determining the proper charging connector for your transceiver. There seem to be as many different connectors as there are transceivers. Then there

**27-30 Chapter 27**

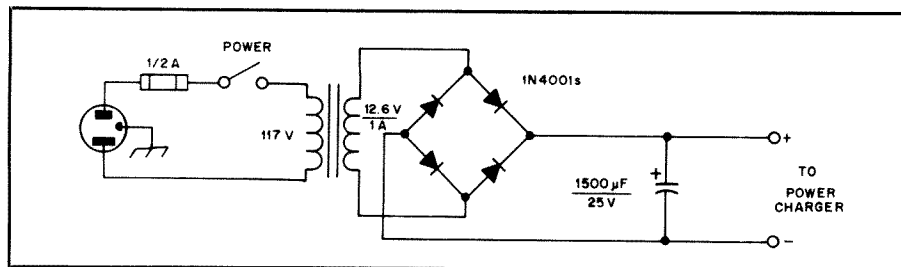

Fig. 57 — A simple ac adapter, such as the one shown here, can be used to power the charger for fixed-station use.

Fig. 58 — Parts-placement guide for the Power Charger. This view is from the component side of the board. Gray areas represent an X-ray view of the unetched foil. The etching pattern appears at the back of this book.

are several transceivers that are intended for use with a drop-in charger. A mating connector can be made from pieces of plastic and screws for the contacts. The challenge with the drop-in connector is to maintain contact when you transmit. Otherwise, the Power Charger cannot supply power directly to the transmitter, but can only recharge the battery when you set the transceiver back in the charger.

Another concern arises when you try to use one Power Charger with two transceivers. If the transceivers have a different number of cells in their battery packs, then the charging voltage must be different for each transceiver. It might be possible to build the Power Charger for the transceiver with the greater number of cells, and use an adapter containing two series silicon diodes for the other transceiver. The pair of diodes has a drop of approximately 1.4 V, which is similar to that of one charged NiCd cell. A compromise adjustment of the output voltage would then allow use of the Power Charger with either transceiver.

#### Adjustment

There are two variable resistors to adjust for proper operation of the Power Charger. Make sure the input voltage is high enough that the LOW INPUT VOLTAGE LED remains off while these adjustments are being performed. The initial adjustment procedure is based on voltage measurements. The

final adjustment procedure measures the specific charging current.

For the initial adjustment, turn R2 fully counterclockwise and R3 fully clockwise. Connect the Power Charger input to a convenient dc supply and the output to a dc voltmeter. Both the ON LED and the CHARGING LED should be lit. Adjust R2 for 11.2 volts (1.4 volts per cell). If your transceiver has an internal diode, increase the voltage by 0.7 volt to compensate for the voltage drop in the diode. If you are unsure about the accuracy of your voltmeter it is advisable to adjust R2 for a voltage reading that is a little on the low side. Next, slowly turn R3 counterclockwise. The CHARGING LED should become dim and go out. Adjust R3 to the point where the CHARGING LED is so dim you can barely see it. Then turn R3 a quarter turn counterclockwise. The output should increase by about 1 volt as R3 is adjusted.

The final adjustment takes care of small errors in setting the voltage, and adjusts the Power Charger to compensate for a diode or other components that may be between the transceiver charging connector and the battery.

Next, connect a milliammeter in place of the circuit board jumper between the CHARGING LED and R1. This is the best place to measure the charging current accurately. If, instead, the meter were connected directly to the output of the Power Charger, it is likely that the voltage drop

caused by the internal resistance of the meter would adversely affect the adjustment. A meter connected in place of the jumper will measure the current drawn by Q5, Q6, Q7 and the associated parts. This current, which is about 10 mA, can be measured when the Power Charger output is disconnected. When the battery is connected the true charging current can be found by subtracting the transistor current from the meter reading.

It may be tempting to measure the Power Charger input current instead, but an ammeter connected at the input would read the current drawn by the ON LED, the CHARGING LED and the base of Q1. This current could be from 20 to 100 mA, thus making an accurate determination of the charging current impossible.

Now, with the ammeter connected and the Power Charger turned on, it is time for the big moment. Connect the transceiver containing the charged NiCd battery to the Power Charger. The initial current surge may be 100 mA or more, but the current should fall quickly to less than 45 mA, which is the trickle-charge rate. Adjust R2 for a charging current between 20 and 30 mA. Adjust R3 until the CHARGING LED is so dim you can barely see it. Some interaction between these adjustments is normal, so you will probably have to repeat them several times until the current and the brightness of the CHARGING LED are correct.

Since continued charging will cause the current to decrease slowly with time, the adjustments should be completed within a minute or two of connecting the battery. If this can't be done disconnect the transceiver for a few minutes to allow the battery to recover, then try again. If you plan to use your Power Charger with more than one battery, a compromise adjustment of R2 may be necessary to compensate for construction differences in the batteries.

If you encounter difficulty with this adjustment you may have a bad component or a wiring error. Power resistors in values from 10 to 200 Ω may be used as loads to verify that your Power Charger has an output similar to that shown in Fig. 53.

Sam Bases, K2IUUV, offered these additional thoughts on calibration of the Power Charger in Technical Correspondence in September 1983 *QST*.

Calibration of the output voltage is extremely critical, and most inexpensive VOMs are definitely not accurate enough to do the job. Furthermore, typical milliammeters have a relatively high series resistance and will affect the charge current when removed from the circuit. Here's why: To charge the battery to 100% of capacity, the individual cell voltage must reach a minimum of 1.42 V at a charge rate of 0.1C, or 11.36 V for an 8-cell battery without an internal diode. A set point of 11.20 V, or 1.40 V per cell (as suggested), will result in only 15-37% of full charge. I experienced an apparent loss of battery

capacity, which was actually due to insufficient charge current at 11.20 V. Similarly, voltmeter errors as little as 0.16 V or milliammeter-induced voltage drops of the same amount will result in failure to charge the battery properly.

The charge rate must taper to the normal charge rate of 0.05C to 0.1C at 1.42 to 1.44 V per cell, or 22.5 to 45 mA for a 450-mAh battery. This charge rate may be left on indefinitely. A charge rate of 0.02C is a trickle charge, and it is used only to maintain a battery that previously has been fully charged. The power charger should not taper below 0.05C, or the battery will never reach 100% capacity; 0.1C is a better minimum value.

You may wish to calibrate the charger with a digital voltmeter as follows:

1) Using the slow-rate "wall charger," give your battery a 16-hour charge.

2) Connect the battery to the power charger for at least one-half hour. Monitor the current with a meter having a resistance of less than 0.2  $\Omega$ . You may use a current-sampling resistor of 0.1  $\Omega$  in series with the charger, and measure the voltage drop across it with a *good* DVM. For example, a reading of 0.0045 V indicates a charging current of 45 mA. (This measurement is usually beyond the means of anything but laboratory-grade instruments.)

3) If a laboratory-grade DVM is not available, connect the charger directly to the battery, without any series resistor or

ammeter, using the leads intended to be permanent. Measure the battery voltage with a DVM or laboratory-grade analog meter. Adjust R2 for a battery voltage of 1.42-1.44 V per cell, adding 0.7 V if your battery pack has an internal diode. Adjust R3 so the yellow LED barely glows, then readjust R2 (because of interaction). Alternatively, measure the voltage across R1 and adjust R2 and R3 to give a reading corresponding to 0.05C-0.1C.  $V = R1 \times 0.1C$ , so for a 450-mAh, 8-cell battery,  $V = 1.0 \times 0.045 \text{ A} = 0.045 \text{ V}$ .

As a final thought, I strongly suggest the use of a multifingered or other effective heat sink and thermally conductive grease together on Q1. Without them, excessive temperatures and thermal cycling will eventually damage the transistor, possibly damaging your battery from overcharge.

### Operation

Operation of the Power Charger is simple. Connect it to a convenient power source between 12 and 30 V dc. If the polarity is correct, the ON LED will light. If the voltage is high enough, the LOW INPUT VOLTAGE LED will be off. Connect the transistor and the CHARGING LED will come on. When charging is complete the CHARGING LED will go out. Disconnect the Power Charger first from the transceiver and then from the power source. Fig. 57 shows a suggested supply if you don't have a suitable ac power supply. It has some ac ripple, but that is

no problem since the charger acts as an electronic voltage regulator.

If a supply of 20 V or more is used to power the charger, an external 10- or 20- $\Omega$  power resistor should be used to reduce the power dissipation in Q1. The value of R4 should also be increased to keep the current through the ON LED below 20 mA.

The Power Charger can be used to charge the battery or to maintain the charge in the battery while the transceiver is being used. It is recommended that the latter mode of operation not be used on an exclusive basis, however. If the NiCd batteries are not allowed to cycle occasionally between a fully discharged and fully charged condition, they will suffer a temporary reduction in capacity. Although it is not necessary, a good procedure is to let the battery run down before connecting the Power Charger. This will maintain maximum battery capacity.

The last consideration is temperature. NiCd batteries are not designed for wide temperature extremes. With the exception of some special cells, most NiCds vent if they are allowed to exceed 45 °C (113 °F). Especially avoid leaving them in a closed car on a sunny day. Also, at low temperatures the chemical activity in the battery slows down. NiCds can be used below freezing, but the capacity is reduced. For these reasons, charging of any type should be minimized when the battery is very warm or very cold.

## A Controlled Battery Charger for Emergency Power Supplies

It's essential to use proper charging methods to maintain emergency battery power supplies in a ready-to-be-used condition. It's possible to keep a lead-acid battery continuously connected to a charger — provided the charger incorporates features to prevent the battery from overcharge! This project, presented by Dick Jansson, WD4FAB, describes the design and construction of a battery charger that may be left connected to a lead-acid battery at all times, whether in storage or at an emergency site. The battery is kept fully charged and ready for use if commercial power fails. Figs. 59 through 63 accompany this project. A number of these chargers have been built by the Orange County, FL, ARES group.

### The Circuit

Today's commonly available voltage-regulator ICs make the construction of a

Fig. 59 — The controlled battery charger can be built in several configurations. Size depends on the intended application.

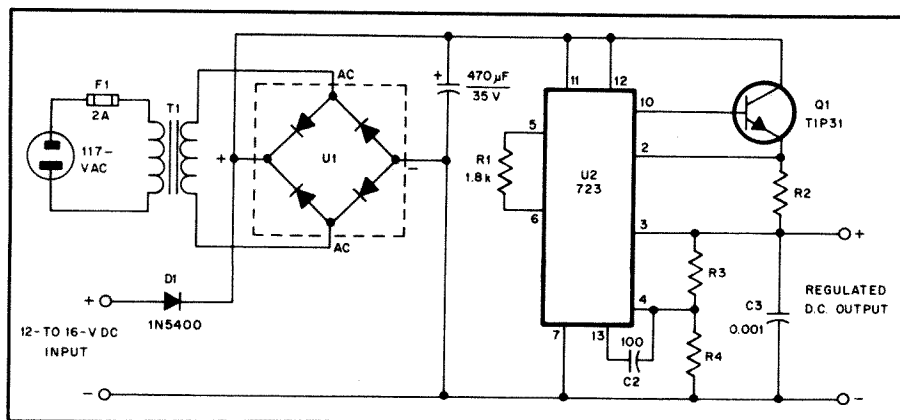

Fig. 60 — Schematic diagram of the controlled battery charger. Radio Shack part numbers are given in parentheses.

C1 — Electrolytic capacitor, 470  $\mu$ F, 35 V (272-1018).

C2 — Ceramic disc capacitor, 100 pF (272-123).

C3 — Ceramic disc capacitor, 0.001  $\mu$ F (272-126).

D1 — Silicon diode, 50 PIV, 3 A (1N5400 or equiv. 276-1141).

F1 — Fuse, 125 V, 2 A (270-1275) in a chassis-mount holder (270-307).

Q1 — Power transistor, NPN, 40 W, TO-220 case (TIP31 or equiv. 276-2017).

R1 — Resistor, 1.8 k $\Omega$ ,  $\frac{1}{4}$  W (271-1324).

R2 — Resistor,  $\frac{1}{2}$  or 1 W. See text and Table 1.

R3 — Resistor,  $\frac{1}{4}$  W, 1%. See text and Table 1.

R4 — Resistor, 7.15 k $\Omega$ ,  $\frac{1}{4}$  W, 1%. See text.

T1 — Filament transformer. Primary, 117 V; secondary 12.6 V at 300 mA or 1.2 A. See text. (273-1505 or 273-1385).

U1 — Bridge rectifier, 50 PIV, 3 A (276-1151).

U2 — Regulator IC, type 723 (276-1740).

### Limiting Resistors for Controlled Battery Charger

Current Limit (mA)	R2 Value (Ohms)
1000	0.62
280	2.2
100	6.2
26	24.0

Voltage Limit (V)	R3 Value (Ohms)
10.5	3.40 k
11.9	4.75 k
13.8	6.80 k

transformer and an appropriate pass transistor with an adequate heat sink.

### Construction

Although this simple circuit does not require a PC board, one was designed to simplify construction of a number of these chargers for the local ARES group. Fig. 61 is a parts-placement guide; a full-size etching pattern appears at the back of this book. Two versions of the finished unit are shown in Fig. 62. Both are built into small aluminum boxes purchased at Radio Shack. One unit was built with a 1.2-A transformer and is used for charging lead-acid batteries. Q1 is used here, and the tab is thermally connected to the box with insulating hardware. Q1 gets only comfortably warm, so no other heat sink is necessary.

The other charger uses two of the regulator boards to charge two different sizes of NiCd battery packs for hand-held transceivers. A 300-mA transformer is used for this application, and only one rectifier/filter (located on the lower PC board) is needed for both regulated outputs. Q1 is not used here, so a wire jumper is used to connect the PC board pads normally connected to the Q1 base and emitter. Insert the jumper between U2, pin 2 and U2, pin 10.

### Adjustment

The most critical value to be adjusted is the output limiting voltage. With no battery load connected, turn on the charger and measure the open-circuit voltage with an accurate voltmeter. If possible, use a digital voltmeter with 0.1% accuracy. If the voltage is not exactly what you need, you will have to experiment with the value of R3. Major voltage adjustments should be made by changing the value of this resistor. Minor output voltage trimming may be accomplished by shunting R3 with a high-ohmage carbon resistor to lower the voltage, or by shunting R4 to raise the voltage.

For a six-cell lead-acid battery, set the voltage to approximately 13.75 V. This value was chosen to hold electrolyte vaporization to an acceptable level. Voltage limits for NiCd battery packs are nominally set to 1.43 V per cell. Some commercially

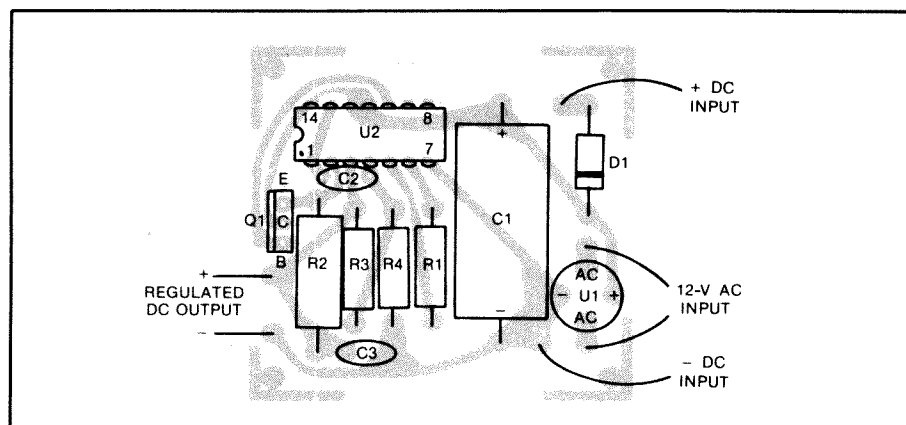

Fig. 61 — Parts-placement guide for the controlled battery charger. A full-size etching pattern appears at the back of this book.

sophisticated charger relatively easy. Fig. 60 is a schematic diagram of the charger. The unit is constructed from parts available from Radio Shack, except for the precision resistors needed to set the values for voltage limiting (R3 and R4). Several values for voltage- and current-limiting resistors are given in Table 1. The builder may customize the charger for a specific need based on the information given. For example, a builder may wish to build one charger for lead-acid batteries and another to provide controlled charging for a NiCd battery pack.

The charger has two possible inputs. For operation from 117-V ac, T1 provides 12.6-V ac to U1, a full-wave bridge rectifier, and filter C1. Filtered output is approximately 18-V dc. The charger may also

be powered from a 12- to 16-V dc source connected to the DC INPUT terminals. This feature is especially handy for charging a NiCd battery pack from a car battery. U2, a 723-type (LM723,  $\mu$ A723, MC1723CP and so on) voltage-regulator IC, regulates the dc and controls voltage and current limits. If the battery voltage falls below the voltage limit set by the ratio of R3 and R4, the charger provides a constant-current output whose value is set by R2. When the battery charges to the voltage limit, the current "folds over" to hold that voltage limit. U2 can safely provide currents up to 100 mA. For applications requiring more current, up to 1 A, pass transistor Q1 is needed. If you do not use Q1, connect pins 2 and 10 of U2. Higher-current applications can be adapted by using a properly sized

Fig. 62 — Two versions of the controlled battery charger. The unit at the left is designed to charge a lead-acid storage battery. The one at the right is designed to charge two different low-current NiCd packs. See text for a complete explanation.

made packs have built-in protective series diodes, so 0.7 V must be added to the total battery voltage to compensate for the drop across the diode.

#### About Batteries

The best type of battery for long-term emergency use is the deep-cycle lead-acid

battery. Designed to power electrical fishing boat motors and accessories in recreational vehicles, these batteries are designed to be discharged over a long period at a steady rate. Normal automotive batteries are designed to discharge partially at a very high rate (to start the car), and then be recharged promptly while the alter-

Fig. 63 — The controlled battery charger, attached to a deep-discharge lead-acid battery in a waterproof enclosure, is ready to be transported to an emergency site.

nator is also carrying the load.

Fig. 63 shows a Sears no. 9601 deep-discharge battery in its companion waterproof case. The charger is housed in the box attached to the case. In an emergency, the entire 25-pound assembly can be picked up by the handle and taken to the field complete with charger. This setup gives reliable service at a moment's notice.

## Emergency Gelled-Electrolyte Battery Pack

Since loss of commercial power is often encountered in an emergency, it's a good idea to have a fully charged prime power source on hand. The battery pack and charger described here is designed to operate a 10-W (output) transceiver for 8 hours, 80% of which is standby, 10% receiving and 10% transmitting. This project, shown in Figs. 64 through 68, was designed and built by Warren Dion, N1BBH.

Calculations indicate that a 2 ampere-hour (Ah) battery should be adequate. A battery with twice that capacity was selected, however for the following reasons:

- 1) Published ampere-hour ratings are based on a steady 20-hour drain. Occasional high-current bursts required for transmitting lower capacity.

- 2) A battery left on FLOAT (see below)

will not be charged to full capacity.

- 3) Some 12-V gear won't work well at the battery manufacturer's 10.5 end-voltage.

- 4) Aging reduces battery capacity.

Accordingly, the following project uses

Fig. 64 — Both the battery pack and companion charger are built in identical, compact enclosures.

a 4-Ah battery. While larger batteries may be substituted, smaller ones are not recommended.

Lead-acid batteries with a gelled electrolyte were selected for this project. These batteries may be left on a trickle charge for extended periods without damage, and they may be deep-discharged if necessary. The gelled electrolyte helps the user avoid leaking liquids and escaping gas normally associated with liquid-electrolyte lead-acid batteries. In addition, these cells may be operated in any position without the worry of leakage through vent holes.

#### The Battery Pack

The battery pack, shown in Fig. 65, is little more than two batteries in a case. A few notes apply, however. The batteries are

Lead-acid batteries easily produce currents of insulation-melting proportions. The 5-A fuse will limit damage caused by a dead short. The connector, an Anderson Power Products 1300 series, is one chosen

**Fig. 65 — Interior of the battery pack. Care is taken to secure the batteries to keep them from moving.**

## The Charger

1) Voltage limiting to prevent over-charging.

- 2) Current limiting to protect batteries that are heavily discharged.
- 3) A worst-case current limit of 1.5 A.
- 4) A thermal limit to protect the regulator.
- 5) FULL and FLOAT charging options.
- 6) Isolation from the power line.

A battery in any state of charge may be connected and left on charge without risk of damage to the charger or battery. With the FULL-FLOAT switch on float, the battery may be left on charge indefinitely, trading off a little capacity for this convenience. The LED turns on to indicate that the battery is fully charged.

## The Circuit

The charger schematic diagram is shown in Fig. 66. Most components are available from Radio Shack. Since the final charging voltage must be held to within 0.1 volt, and precision components are impractical, 5% tolerances are prescribed throughout. The two trimmer potentiometers, R4 and R8, provide sufficient range to set the charging voltage and indicator light precisely.

Regulator U1 is the key component, maintaining the final charging voltage, and

The *absolute maximum* charging current is ¼ the rated ampere-hours, in this case 1.0 A. The recommended charging current is 0.15 to 0.20 times the Ah rating, 0.6 to 0.8 A in this case. If a faster charging rate is desired, or a larger battery is used, the charging rate can best be adjusted by shunting R9. Refer to the following table:

<i>R9A</i>	<i>Current Limit</i>
None	0.6 A
6.2-6.8	0.7
3.0-3.3	0.8
2.0-2.2	0.9
1.0	1.2

## Full vs. Float

When a "12-V" battery is fully charged, its terminal voltage reaches 14.4, while accepting a low maintenance current from the charger. Long periods in this state will damage the battery. Therefore, if the battery is to be left on charge for extended periods, the voltage must be reduced by about 0.1 V per cell. In a "12-V" battery this figures out to 13.8 V, which is, conveniently, 0.6 V lower than full charge. A

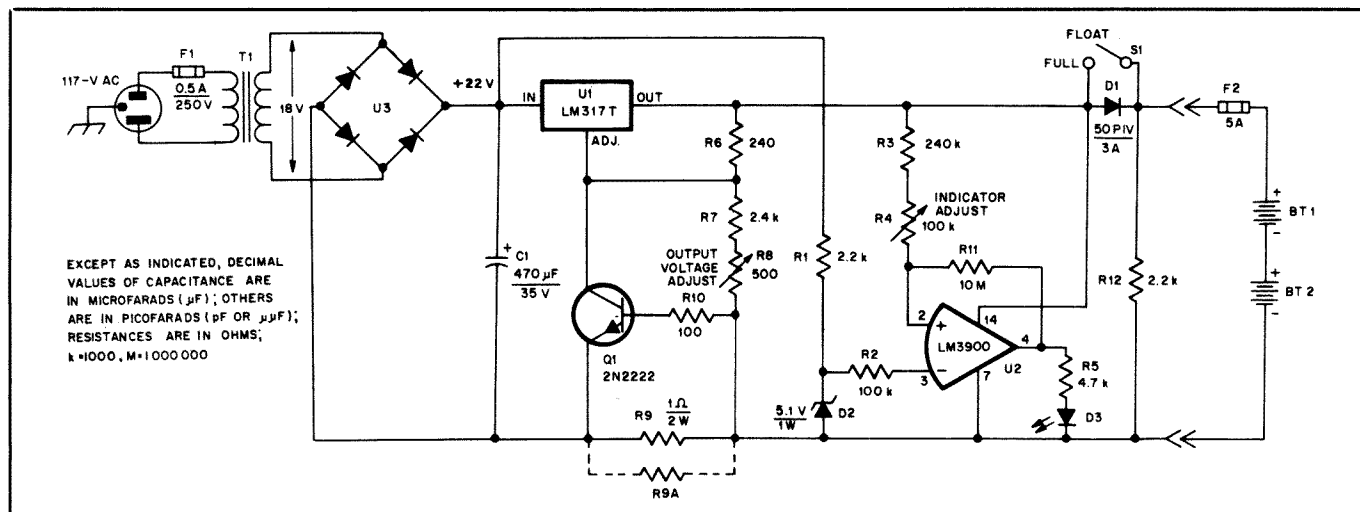

Fig. 66 — Schematic diagram of the battery pack and charger. All resistors are  $\frac{1}{4}$  W, 5% tolerance, unless noted. Parts numbers given in parentheses are Radio Shack catalog numbers.

- BT1, BT2 — Gelled-electrolyte, lead-acid battery, 6 V, 4 Ah (Yuasa NP4-6 or equiv. Available from Glynn Electronics, Box 800, Middleboro, MA 02346).
- C1 — Electrolytic capacitor, 470  $\mu$ F, 35 V (272-1030).
- D1 — Silicon rectifier, 50 PIV, 3 A (276-1141).
- D2 — Zener diode, 5.1 V, 1 W, 5% tolerance (276-565).
- D3 — Red LED (276-062).

- F1 — Fuse, 0.5 A, 250 V (270-1271).  
F2 — Fuse, 5 A, 250 V (270-1278).  
Q1 — Transistor, NPN, 2N2222 (276-1617).  
R4 — Trimmer potentiometer, 100 k $\Omega$ .  
PC-board mount (271-220).  
R8 — Trimmer potentiometer, 500  $\Omega$ .  
PC-board mount (271-226).  
R9 — Resistor, 1 ohm, 2 to 5 W.  
R9A — Optional resistor, see text.  
S1 — Slide switch, SPST (275-401).

- T1 — Transformer; primary 117 V, secondary 18 V, 1.2 A (modified Radio Shack 273-1480, see text; or Radio Shack 273-1515, with 18-V secondary).  
U1 — Adjustable three-terminal regulator, LM317T (276-1778).  
U2 — Quad op amp, LM3900 (276-1713).  
U3 — Full-wave bridge rectifier, 100 PIV, 4 A (276-1171).

Fig. 67 — Interior view of the battery charger. Although perforated board is used in this version, a PC-board layout is shown in Fig. 68.

silicon-junction rectifier in series with the output supplies the needed drop, and requires only one adjustment for both the voltage limit and indicator light settings.

### Charger Indicator

Full charge is signaled by the state of two variables, namely, terminal voltage and end-of-charge current. The current is affected by battery condition and temperature; therefore, terminal voltage is the chosen indicator. The LM3900 op amp (U2) used in this portion of the circuit is a current-sensitive device. The voltage from any forward-biased pin to common is an almost constant 0.6 V. For this application Zener D2 provides a reference voltage. The current through R2 [(5.1 - 0.6)/100,000

= 45  $\mu$ A] is fed to pin 3. When this exceeds the current into pin 2, U2 output is pulled down and D3 is not lit. When the charger output voltage reaches 14.4, trimmer R4 is adjusted so that the current into pin 2 is slightly greater than 45  $\mu$ A. At this point U2 toggles, and the light turns on. R11 provides positive feedback to sharpen the switching point.

### Construction Notes

Construction of the charger, shown in Fig. 67, is conventional, and parts location not critical. Perforated board construction obviates the need for a printed circuit, but the layout is directly transferable to a one-sided etched board. For builders wishing to use a PC board, a full-size etching pattern may be found at the back of this book. Parts placement is shown in Fig. 68. It is best to socket the LM3900. The LM317T requires a heat sink. In this design it is screwed to the cabinet using a mica washer insulator. Radio Shack 3  $\times$  5  $\times$  5-7/8-in cabinets (No. 270-253) are used for both battery pack and charger.

### Reworking T1

Transformers with 18-V secondaries are not as easy to find as the popular 12.6 and 25.2 styles. The 12.6-V types will not supply enough voltage to bias the regulator properly, and will cause the regulator to overheat. A secondary value of 16-18 V RMS is ideal. This can be obtained by pruning the secondary of the recommended 25.2-V transformer, if a suitable 18-V transformer is not available.

Place the transformer on its back and pry up the four tabs that lock the "U" frame mounting strap. Pull the legs of the frame apart and lift out the core with its windings.

The core is built up of laminations shaped as letters E and I. Run a thin-bladed

knife between one of the outside I laminations and the stack. Remove the lamination and save it. Next run the knife between the abutting E lamination and the stack, especially where it passes through the coil window. Next, place the stack on the edge of the bench with the legs of the E facing upward and the loosened lamination just clear of the edge. Place a screwdriver blade against the center leg of the E, and tap gently on the handle until the lamination slides free. Carefully pull the lamination out of the stack.

In the same manner, remove the rest of the laminations and save them. Bent laminations can be straightened by placing them on a smooth, flat surface and *tapping* gently with a hammer.

Next, unwind the plastic insulating tapes and save them. Find the outside turn of the secondary and remove it from its solder lug. Unwind 55 turns. Cut off the excess wire, clean the end and resolder it to its lug. Replace the tapes.

Reassemble the core alternating E laminations end-for-end, and interleaving the I laminations. It will be necessary to squeeze the stack a little to get the last lamination into the coil window. Place the stack on a flat surface and tap the edges of the stack with a hammer, turning so that all four sides are tapped. This will make the stack square and even.

Wrap the mounting strap back around the core and clamp the legs tightly against the sides. Bend in the four lugs, and hammer them down well. Connect the primary to 117 V, 60 Hz and measure the secondary voltage. It should be between 16 and 20 V RMS.

### Initial Tests and Adjustments

Before connecting the battery, do the following:

- 1) Check the circuit for correctness.
- 2) Connect a 1000-ohm resistor across the output.
- 3) Turn trimmer R8 until the output voltage is exactly 14.4.
- 4) Turn trimmer R4 until the light turns off and then back R4 off until the light just comes back on.
- 5) Repeat 3 and 4, above.

Most moving-pointer (D'Arsonval) meters are not accurate enough for these adjustments. Use a digital meter in good condition with at least 2½ (preferably 3½) digits.

### To Charge a Battery

Plug the battery pack into the charger and the charger into the power line. The charging light should be on. Select FULL or FLOAT, as required. If fully discharged, a recharge should take 6 to 8 hours. If partially discharged, it will take about the same number of hours that the battery has been in service since its last charge. When the light turns on, disconnect the battery. If the battery is to be left on charge, be sure it is switched to FLOAT.

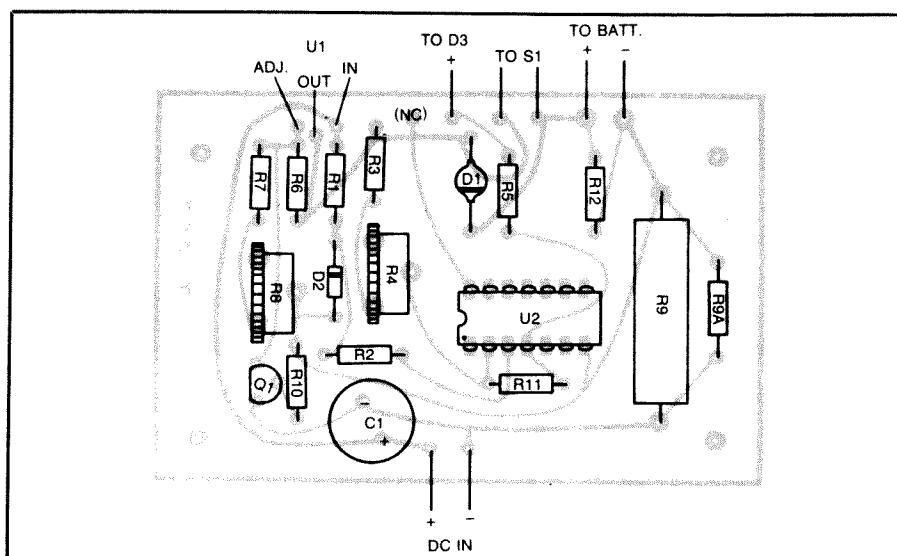

Fig. 68 — Parts-placement guide for the emergency battery pack. A full-size etching pattern is given at the back of this book.

# A 2000-Volt Power Supply

The power supply shown in Figs. 69 through 72 is capable of supplying 2000 volts at 1 ampere in conservative operation. Many ceramic tubes, such as the 8874, 3CX800A7 and 4CX250 family, require 2-kV plate supplies. This project is intended to illustrate various design techniques used in high-voltage (HV) supplies. Although all of the parts used here are readily available from commercial suppliers, sufficient information is presented for a builder to adapt the project to suit individual needs and to incorporate components on hand. This power supply was designed and built in the ARRL lab by Mark Wilson, AA2Z.

## Circuit Details

The heart of this supply, shown schematically in Fig. 70, is an Avatar Magnetics AV-415 transformer. Although the AV-415 has a dual primary, use of 234 V is essential to good regulation. The secondary has taps for 1375, 1515 and 1650 V to allow the builder to optimize the output voltage for the filter capacitor used. A full-value secondary was chosen, rather than a lower voltage secondary and voltage-doubler circuit, to aid voltage regulation. The transformer is rated for 1.2 A, continuous duty.

Fig. 69 — The completed 2000-V, 1-A power supply.

This supply is intended to be placed away from the operating position in an inconspicuous spot, perhaps under the operating table, so it may be activated remotely by J1. If J1 is jumpered, the supply may be activated by S1. When S1

and J1 are both closed, the coil of K1 is energized, closing the contacts and applying primary power. R1 and R2 in the primary feed to T1 provide inrush current protection. At turn-on, the filter capacitors are discharged and look like a dead short. The

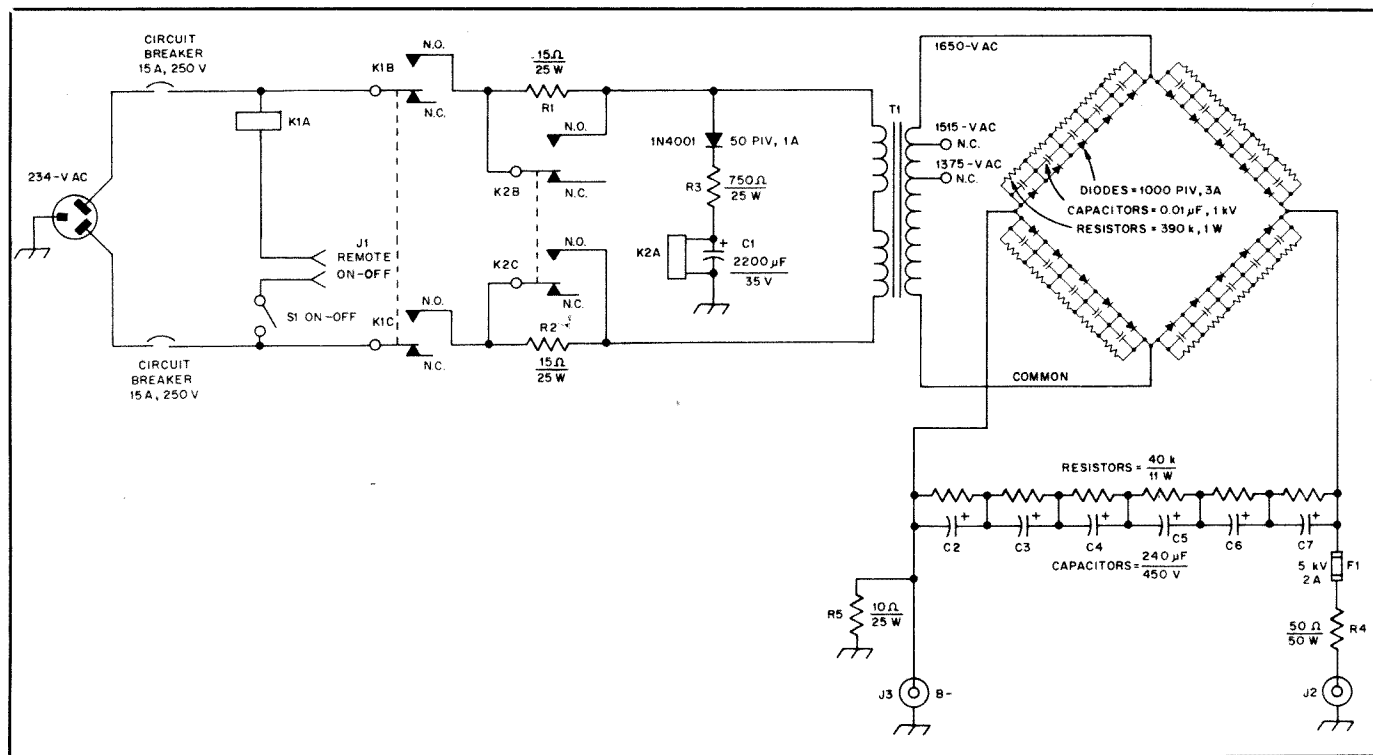

Fig. 70 — Schematic diagram of the 2-kV, 1-A supply.

C2-C7 — Electrolytic capacitor, 240  $\mu$ F, 450 V (Mallory CG241T450V4C or equiv.).  
F1 — High-voltage fuse, 5 kV, 2 A (Buss HVJ2).  
J1 — Two-conductor socket (Cinch S-402-AB or equiv.).  
J2, J3 — Chassis-mount female MHV

connector (Amphenol 27000).  
K1 — Relay, DPDT, 240-V ac coil, 240-V, 25-A contacts (Potter and Brumfield PRD11AYO-240V or equiv.).  
K2 — Relay, DPDT, 24-V dc coil, 240-V, 25-A contacts (Potter and Brumfield PRD11DYO-24V or equiv.).

S1 — Switch, SPST, 240-V.  
T1 — Power transformer; primary 117/234 V, secondary 1650-V, 1.2-A Continuous Commercial Service (CCS) (Avatar Magnetics AV-415 or equiv. Available from Avatar Magnetics, 1147 North Emerson, Indianapolis, IN 46219).

Fig. 71 — The primary components of the 2-kV supply are mounted on the rear panel.

Fig. 72 — Parts placement for the rectifier board. The full-size etching pattern appears at the back of this book.

charging current surge is high enough that the rectifier diodes may rupture, so R1 and R2 are necessary to limit the inrush current to a safe value. After a 0.6-second time delay (determined by C1 and R3), K2 closes and shorts out R1 and R2. Full primary power is now available. K1 and K2 both have high-current contacts.

A full-wave bridge rectifier follows the transformer. The bridge is made from a number of individual diodes with a 1000-PIV rating. Each diode is shunted with a 0.01-μF capacitor to suppress transient voltage spikes and a 390-kΩ equalizing resistor. Although three of the 1000-PIV diodes would allow an ample safety margin for a 2-kV supply, the limiting factor is the 500-V breakdown rating of 1-W metal film resistors. Using five diode/capacitor/resistor sets in each leg of the bridge presents 400 V to each resistor.

Filtering is accomplished with a string of six 240-μF, 450-V capacitors connected in series. The nominal rating of this string is 40 μF at 2.7 kV. This value of capacitance was chosen to keep the ripple under 3% and was calculated using the formula

$$C = \frac{1}{2\sqrt{3} f_r R_L (\text{Ripple Factor})}$$

where

C = capacitance in farads

$f_r$  = ripple frequency in hertz

$R_L$  = load resistance in ohms

In this application,  $F_r = 120$  (full-wave rectification),  $R_L = 2000$  (2000 V divided by 1 A) and the ripple factor = 0.03 (3%). Plugging these values into the equation yields 40.1 μF for the target value. The 240-μF capacitors (6 in series = 40 μF total) were the closest readily available value. The total 2.7-kV rating includes a safety margin.

A 40-kΩ, 11-W resistor shunts each filter

capacitor. The actual value of electrolytic capacitors may vary as much as  $\pm 20\%$  of the rated value, so these resistors are necessary to equalize the voltage across each capacitor in the string. The shunt resistance should be about 100 ohms per volt of supply output. In this case,  $2000 \text{ V} \times 100 \text{ } \Omega/\text{V} = 200,000 \text{ ohms total}$ . Six resistors are used, so each should be 200,000 divided by 6, or 33.3 kΩ each. The closest readily available value, 40 kΩ, was selected. The power rating of each resistor is determined from Ohm's Law ( $E^2$  divided by R). In this case,  $E = 333$  (2000 V divided by 6 resistors), and  $R = 40 \text{ k}\Omega$ , resulting in a power requirement of 2.8 W. The 11-W resistors chosen give an adequate safety margin. The equalizing resistors also form the bleeder.

Two protective devices follow the filter. F1 is a special 5-kV, 2-A fuse made by Buss. This fuse is 5 inches long and has a ceramic body. It will open if sustained excess current is drawn. R4 is a current-limiting resistor used to protect the power supply and amplifier in case of a high-voltage arc. R5 keeps the negative lead a few ohms above ground for current-metering purposes in the amplifier.

### Construction

The final weight of this supply is about 60 pounds, so construction on an ordinary lightweight aluminum chassis is less than optimum. To avoid chassis-flexing problems, a framework was constructed from aluminum angle stock. Top and side panels then bolt to the framework. The bottom panel is made from 1/8-in-thick aluminum, adding to the rigidity of the structure. The power supply measures  $9 \times 8\frac{1}{2} \times 20$  inches (HWD). The framework is easily fabricated with hand tools, and the angle stock is available from most hardware

stores. The side and top panels may be cut and filed by hand, but many sheet metal suppliers will shear panels to the correct size for little or no additional cost.

All of the primary circuitry, including K1, K2, J1, S1, R1-R3 and C1 are all mounted on the rear panel (Fig. 71). Liberal use of solder lugs adds to a neat appearance. All primary wiring was done with no. 12 wire.

The bridge rectifier diodes and associated components are mounted on a glass-epoxy circuit board. The diodes and resistors are mounted slightly above the board to allow airflow to all sides for cooling. The PC board is mounted vertically on ceramic standoff insulators. Parts placement for the rectifier board is shown in Fig. 72, and a full-size etching pattern may be found at the back of this book.

Filter capacitors and equalizing resistors are mounted on a sandwich made from acrylic sheet. In addition to securing the capacitors, the acrylic provides additional insulation between the capacitors and chassis. Copper straps interconnect the capacitors, and the 40-kΩ resistors are mounted far enough above the capacitors to allow adequate airflow for cooling.

F1 and R4 are mounted on ceramic standoffs bolted to the front panel. Amphenol MHV high-voltage receptacles, similar to BNC connectors but designed for use up to 5 kV at 5 A, are used for the output. No. 18 test lead wire with insulation rated to 5 kV is used for all secondary wiring.

Care in mounting and wiring the components in a high-voltage supply is essential for safety. Any components and connections carrying high voltage should be kept well away from the chassis to avoid accidental arcs. High-voltage supplies should be fully enclosed to prevent accidental contact. Safety and common sense are the watchwords — *HV is lethal!*

# A 3500-Volt Power Supply

The high-voltage power supply shown in Figs. 73 through 75 will loaf along during legal-power-limit operation. Capable of powering amplifiers employing such tubes as the 3-1000Z, 3CX1200A7, 4CX1000, and 8877, this supply is rated for 3500 V at 1 A output. Mark Wilson, AA2Z, built this project in the ARRL lab.

## Circuit Details

Fig. 73 is the schematic diagram of this supply. The transformer used here is manufactured by the Peter W. Dahl Co. It features a 220/240-V primary and a 2650-V secondary rated at 1.5 A Intermittent Commercial and Amateur Service (ICAS). The core material is hipersil, which represents a significant weight saving over conventional material. One of the design goals was good regulation under heavy loads, so a 117-V primary wasn't even considered. Similarly, use of a full-value secondary and bridge rectifier, rather than a voltage-doubler scheme, aids in good regulation. Of course, a center-tapped secondary (2650-0-2650 V) would work just as well.

This supply was built to power several amplifiers requiring different voltages, so a variable autotransformer is used on the primary. Supply output can be varied between 0 and approximately 4 kV.

High-voltage block-type rectifiers are used here, rather than strings of individual 1-kV devices. These rectifiers are rated at 14 kV at 1 A and have a 250-A surge-

Fig. 73 — Front view of the completed 3500-V power supply.

current rating. If a builder were to purchase new the individual diodes, resistors and capacitors necessary to make a bridge rectifier suitable for this power supply, the cost could easily exceed that of the block rectifiers. Additionally, these HV rectifiers are compact and much easier to replace should they fail.

The filter capacitor used here is a 25- $\mu$ F, 4-kV oil-filled unit made by Condensor

Products Corp. This capacitor does not contain any of the carcinogenic chemical PCB, but many oil-filled capacitors available at flea markets do, so be wary if another capacitor is substituted. Oil-filled capacitors have some advantages over HV filter capacitors made from strings of individual electrolytics. Oil-filled capacitors are sealed and will not dry out after years of service. They may be used all the way

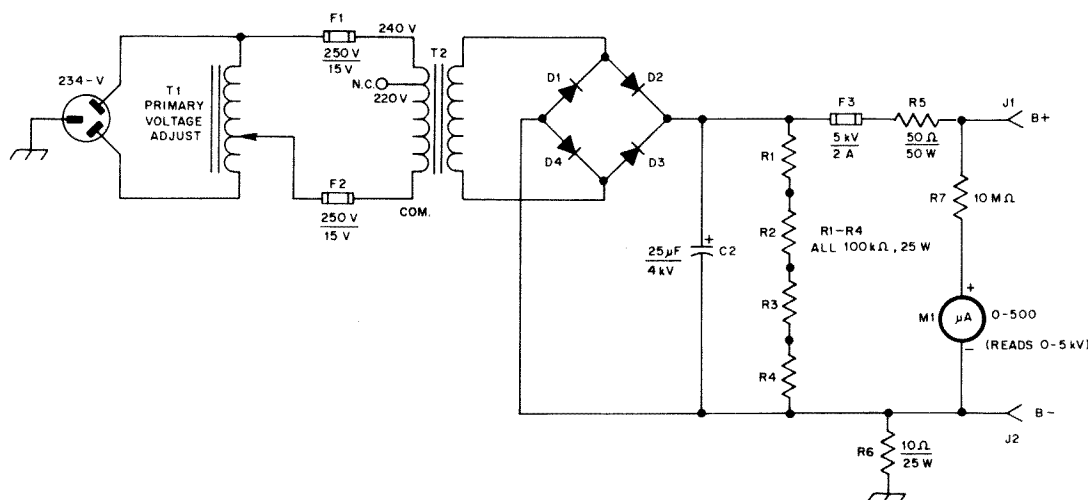

Fig. 74 — Schematic diagram of the 3500-V power supply.

C2 — Filter capacitor, 25  $\mu$ F, 4 kV (Condenser Products KMOC 4M25ES-1 or equiv. Available from Condenser Products Corp., P.O. Box 997, Brooksville, FL 33512).

D1-D4 — Rectifier diode, 14 kV, 1A (K2AW HV14-1 or equiv. Available from K2AW's Silicon Alley, 175 Friends La., Westbury,

NY 11590).

F3 — High-voltage fuse, 5 kV, 2 A (Buss HVJ2 or equiv.).

J1,J2 — High-voltage connector (Millen 37001 or equiv.).

R7 — Meter shunt made from five 2-M $\Omega$ , 2-W resistors in series.

T1 — Variable autotransformer, 0-280 V, 10 A

(Superior Electric 236B Powerstat® or equiv.).

T2 — Power transformer; primary, 220/240 V, secondary 2650 V, 1.5-A ICAS (Dahl ARRL-001 or equiv. Available from Peter W. Dahl Co., 4007 Fort Blvd., El Paso, TX 79930).

Fig. 75 — Interior view of the 3500-V power supply.

up to their maximum voltage ratings, and they often take up less space than a stack of electrolytics. Oil-filled capacitors are somewhat more expensive initially — in this case about 30% more than a comparable string of electrolytics; however, they do last a long time and are definitely worth considering.

R1-R4 act as a bleeder. Four 100-k $\Omega$ , 25-W units are used to minimize the voltage across any individual resistor. If one large resistor was used, arcing could occur between the turns of wire that make up the resistor.

Like the 2000-V supply, this circuit employs a high-voltage fuse and a series resistor in the HV output lead to protect against overcurrent and arcs. A homemade fuse can be made from a piece of no. 30 tinned wire suspended on ceramic stand-offs. The minus lead is kept a few ohms above ground for metering purposes in the companion amplifier.

A 0-5-kV meter is included. The basic movement is 0-500  $\mu$ A, so a 10-M $\Omega$  shunt resistor is necessary. Be careful to mount the resistors away from the chassis. Here,

they are mounted on a circuit board behind the meter.

### Construction

This supply is built on a homemade chassis and cabinet measuring 9  $\times$  17  $\times$  14 inches (HWD). The bottom plate, which supports most of the components, is made from 0.125-inch-thick aluminum sheet. Aluminum angle brackets bolted to the bottom plate provide additional strength, as well as allow for attachment of the panels. The front and rear panels are made from 0.062-inch-thick aluminum sheet. The top and side panels are made from two pieces of aluminum sheet, each bent 90 degrees. The two top/side halves meet in the center where they are screwed to a bracket running between the front and rear panels. The entire chassis and cabinet could be made with hand tools, but a trip to the local aluminum supplier with a list of needed panel dimensions will probably yield the nicely sheared, square panels necessary for a professional-looking project.

As shown in Fig. 75, all components mount on the front and bottom panels. Even the line cord passes through the front panel, leaving the rear panel empty so the supply may be placed on the floor against a wall in the shack. The line cord and primary wiring are no. 12 wire. The transformer is securely bolted to the bottom plate by 1/4-in bolts. The block rectifiers are mounted to the bottom panel with silicone heat-sink compound to aid in cooling.

F3 and R1-R6 all mount on a circuit board that is mounted on ceramic stand-offs above C2. Be sure that this board is mounted well-away from the chassis or other components.

All secondary wiring is done with no. 18 test lead wire with insulation rated at 5000 V. The output connectors, mounted on the front panel, are of the Millen 37001 type and are rated for 7000 V.

As with any project incorporating high voltage, lead dressing is important. High-voltage can bridge small air gaps, so care must be taken to keep component terminals and wires away from the chassis. Only wire with suitable insulation should be used, because HV will arc through insulation designed for lower voltages.

# Audio and Video Equipment

The story of radio begins with amateurs transmitting and receiving dots and dashes. Soon hams were communicating by voice. Amateurs were

transmitting pictures 20 years before commercial TV came into being. Hams still communicate by Morse code, voice and TV. The techniques they use have changed and other modes have been added. All that

communication activity has created a demand for a wide variety of electronic equipment. This chapter describes a number of projects for audio and video.

## A Simple, High-Performance CW Filter

This inductor-capacitor CW filter uses one stack of the familiar 88-mH inductors and two 44-mH inductors in a five-resonator circuit that gives high performance at low cost. The center frequency is fixed at 750 Hz because most transceivers use this sidetone frequency, but sidetones between 700 and 800 Hz can be received with less than 1 dB attenuation relative to the center frequency. Ed Wetherhold, W3NQN, designed and built the filter presented here. The author can provide parts for this project at nominal cost. Write E. E. Wetherhold, W3NQN, 1426 Caplyn Place, Annapolis, MD 21401 for more information. If you need a design for a different center frequency, the author can provide that as well. Be sure to include a self-addressed, stamped 9½- × 4-inch envelope with your request.

One feature of this filter is a 3-dB bandwidth of 236 Hz. This bandwidth is

narrow enough to give good selectivity, and yet broad enough for easy tuning with no ringing. Five high-Q resonator circuits provide good skirt selectivity that is equal to or better than most commercial active filters costing more than \$80. In comparison, this CW filter can be built for less than \$15. Simple construction, low cost and good performance make this filter an ideal first project for anyone interested in putting together a useful station accessory.

### Design

Fig 1 shows the filter schematic diagram and component values. These values were selected for a center frequency of 750 Hz and for a filter impedance level of 230 ohms. The filter sees a 230-ohm source impedance consisting of the 200-ohm source (transformed from 8 ohms), a 22-ohm transformer winding resistance and an 8-ohm inductor resistance. In a similar

way, the filter sees a load impedance of 230 ohms. This design was selected so that only one turn needs to be removed from both windings of a standard 44-mH inductor to give the required L2 and L4 values.

### Construction

Fig 2 is a pictorial diagram showing the filter wiring. Note the 44-mH lead connection, as well as the connections between the capacitor leads, the 88-mH stack terminals and the 44-mH inductor leads. Fig 3 shows the finished filter installed in an aluminum box. Before beginning construction, obtain one 88-mH five-inductor stack with a mounting clip and two 44-mH inductors, and then follow steps 1 to 5.

1) Remove one turn from each of the two windings of one 44-mH inductor to get 43.5 mH (total turns removed is two). Carefully scrape off the film insulation and connect the start lead (with sleeve) of one

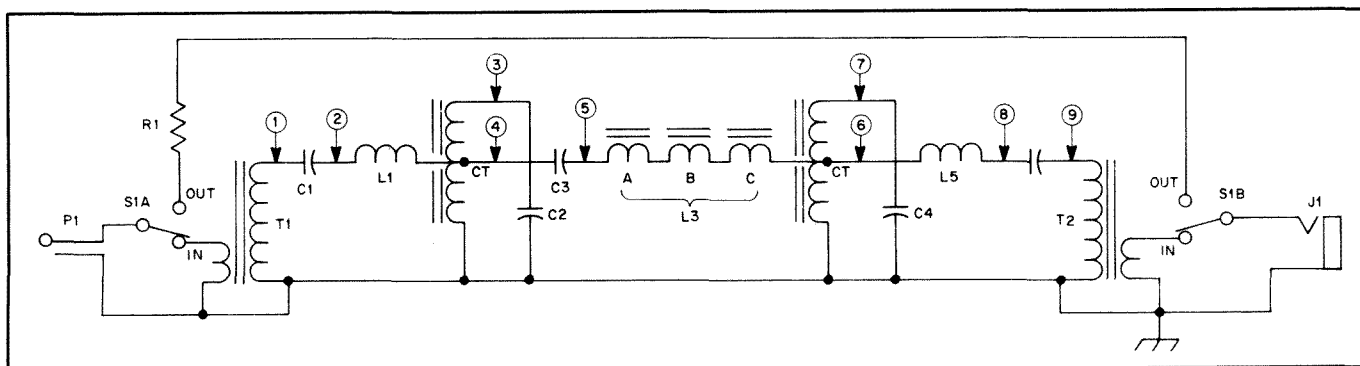

Fig 1—Schematic diagram of 750-Hz CW filter. Use 1% tolerance capacitors for best results.

C1, C5—0.512  $\mu$ F capacitor.

C2, C4—1.036  $\mu$ F capacitor.

C3—170.7 nF capacitor.

J1—Phone jack, or jack to match your headphones.

L1, L5—88-mH toroid (part of toroid stack, see text).

L2, L4—43.5 mH toroid (modified 44-mH toroid, see text).

L3—264-mH toroid (part of toroid stack, see text).

P1—Phone plug, or plug to match your receiver.

R1—Zero to 220-ohm, ½-W, 10% resistor (see text).

S1—DPDT switch.

T1, T2—8-ohm to 200-ohm impedance-matching transformer, 0.4-W.

Fig 2—Pictorial diagram showing L2 and L4 lead connection and wiring of inductor stack (L1, L3, L5).

Fig 3—The assembled filter is shown installed in a CR-800 aluminum box. The thru/bypass switch (S1) and input/output transformers (T1, T2) are at the left end of the box.

winding to the finish lead (no sleeve) of the adjacent winding to make the center tap as shown in Fig 2. Do the same for the second 44-mH inductor.

2) Fasten both of the 43.5-mH inductors to opposite ends of the 88-mH stack using clear silicone-rubber sealant, available from most hardware stores.

3) Position the 43.5-mH inductors so their leads can be easily connected to the rest of the circuit. Solder the capacitor leads to the stack terminals as shown in Fig 2.

4) Obtain a suitable box and make holes for the inductor mounting clip, the DPDT switch, and the phone jack and phone cord. First, install matching transformers T1 and T2 and the inductor stack with capacitors. Fasten the transformers (with leads pointing up) to the bottom of the box with silicone rubber sealant. Secure the stack to the bottom of the box with a 1-3/8-inch component mounting clip and two no. 6-32  $\times$  5/16-inch screws. Instead of the 8  $\times$  3  $\times$  2 3/4-inch aluminum box shown in Fig 3 (Mouser Stock No. 537-CR-800), a small cardboard box may be used to minimize cost.

5) Complete the wiring of the transformers, the DPDT switch with resistor R1, and the phone jack and phone plug. Then check the correctness of your wiring by measuring and comparing the filter node-to-node resistances with the values listed in Table 1.

#### Installation

T1 and T2 match the filter to the receiver low-impedance audio output and to an 8-ohm headset or speaker. If your headset is high impedance, T2 may be omitted. In this case, connect a 10%, 1/2 W resistor from node 9 (C5 output lead) to ground. Choose the resistor value so the parallel combination of the headset and resistor gives the correct filter termination im-

Table 1

Node-to-Node Resistances for the CW Audio Filter

Nodes From	To	Components	Resistance (ohms)
1	GND	T1 hi-Z winding	12
2	GND	L1 and 1/2 L2	10
3	GND	L2	4
4	GND	1/2 L2	2
5	GND	L3 and 1/2 L4	26
6	GND	1/2 L4	2
7	GND	L4	4
8	GND	L5 and 1/2 L4	10
9	GND	T2 hi-Z winding	12
2	4	L1	8
5	6	L3	24
6	8	L5	8
2	3	L1 and 1/2 L2	10
8	7	L5 and 1/2 L4	10

#### Notes

- 1) See Figs 1 and 2 for the filter node locations.
- 2) Check your wiring using the resistance values in Table 1. If there is a significant difference between your measured values and the table values, you have a wiring error that must be corrected.
- 3) For accurate measurements, use a digital VOM or an analog VOM (such as a Triplett Model 630) that has a scale center of about 5 ohms on the  $\times$ 1 ohmmeter range.

pedance (within 10 percent of 230 ohms).

#### Performance

The measured 30-dB and 3-dB bandwidths are about 511 and 235 Hz, respectively, and the 30-dB/3-dB shape factor is 2.17. This factor can be used to compare the performance of this filter with others. The measured insertion loss at 750 Hz is less than 3 dB and is typical of passive filters of this type. This small loss is compensated by slightly increasing the receiver audio gain. R1 helps to maintain a constant audio level when the filter is switched out of the circuit. The correct value of R1 for your audio system should be determined by experiment. Start with a short circuit for R1 and then gradually increase the resistance until the audio level

appears to be the same with the filter in or out of the circuit.

More than 700 hams have constructed this five-resonator filter (using either the 2-stack or the newer 1-stack arrangement) and many have commented on its excellent performance and lack of hiss and ringing.

# A Passive Audio Filter for SSB

While audio filters are most often used during CW reception, the SSB operator can also benefit from their use. Shown in Figs 4 and 5 is a passive band-pass filter designed by Ed Wetherhold, W3NQN, for phone operation. This filter was described in Dec. 1979 *QST*.

All of the inductors are the surplus 88-mH toroidal type with their windings wired either in series or parallel to get the required 88 or 22 mH of inductance. The series connection is shown in Fig 2. The 0.319- $\mu$ F capacitors were selected from several 0.33- $\mu$ F capacitors that were about 3 percent on the low side. The 0.638- $\mu$ F value was obtained with a single 0.68- $\mu$ F capacitor that was about 6 percent on the low side. The 1.276- $\mu$ F values were obtained by paralleling selected 1- $\mu$ F and 0.33- $\mu$ F capacitors.

Fig 5 shows the measured and calculated attenuation responses of the filter. The difference between the measured and calculated responses at the low frequency side of the passband is probably caused by the much lower Q of the inductors at these frequencies.

The necessary termination resistance of this filter is 206 ohms. While this is not a standard value, it should not be too difficult for most amateurs to accommodate. If low-impedance headphones are used, a matching transformer can be used to provide the correct termination. A suitable transformer is available from Mouser Electronics (see Chapter 35 parts-suppliers list). The part number is 42TU200, and it is a 200-ohm CT to 8-ohm CT unit.

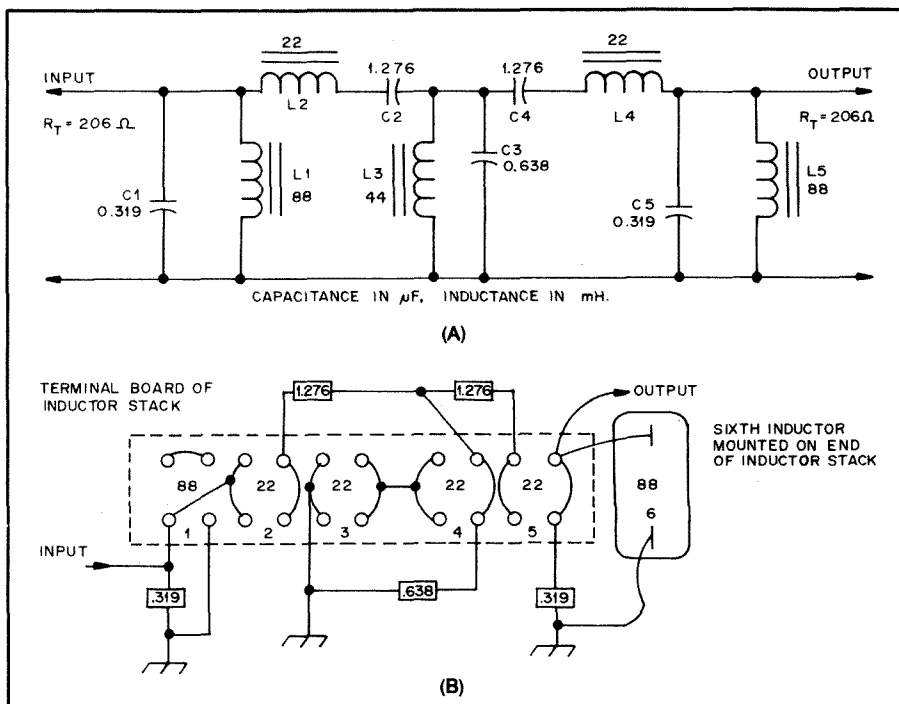

Fig 4—Schematic diagram of the SSB band-pass filter (A). Shown in B is a pictorial wiring diagram of the terminal board on the inductor stack.

Fig 5—Response curves of the SSB band-pass filter.

# RC Active Audio Filters

The active audio filter is more popular than the passive type shown in Figs 1 and 4. The primary advantages of active filters are (1) unity gain or greater (passive filters have some insertion loss), and (2) that they are more compact than LC filters. Another advantage of RC active filters is that they can be made with variable Q and variable center or cutoff frequencies. These two features can be controlled at the front panel of the receiver by means of potentiometers.

Most RC active filters are designed for a gain of 1 to 5. A recommended gain is 2 for most amateur applications. The more filter sections placed in cascade, the better the skirt selectivity. The maximum number of usable RC filter sections is typically four. The minimum acceptable number is two for CW work, but a single-section RC active filter is often suitable for SSB reception in

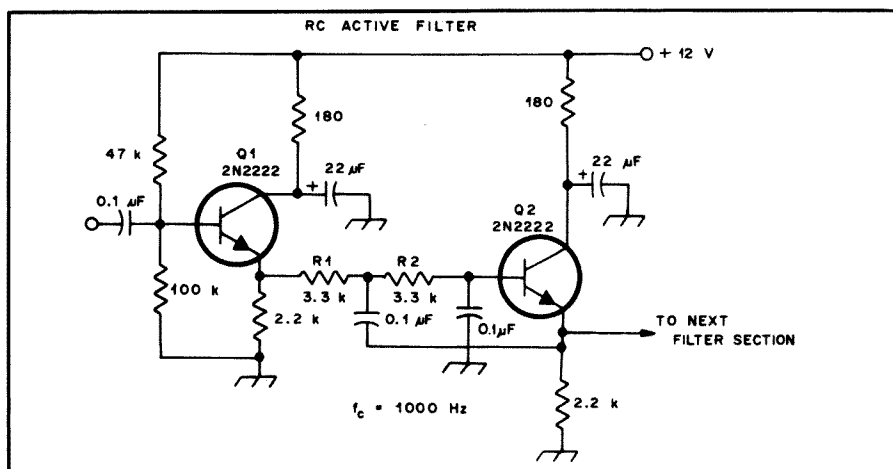

Fig 6—Circuit example of one pole section of an RC active audio filter that uses discrete active devices, Q1 and Q2.

## BAND-PASS FILTER

Pick  $H_0 Q, \omega_0 = 2\pi f_c$   
where  $f_c$  = center freq.  
Choose C

$$\text{Then } R1 = \frac{Q}{H_0 \omega_0 C}$$

$$R2 = \frac{Q}{(2Q^2 - H_0) \omega_0 C}$$

$$R3 = \frac{2Q}{\omega_0 C}$$

If  $H_0 = 2, f_c = 800 \text{ Hz}, Q = 5$  and  
 $C = 0.022 \mu\text{F}$   
 $R1 = 22.6 \text{ k}\Omega$  (use 22k)  
 $R2 = 942 \Omega$  (use 1000)  
 $R3 = 90.4 \text{ k}\Omega$  (use 91k or 100k)

Fig 7—Equations for designing a band-pass RC active audio filter are given at A. B and C show design information for low-pass and high-pass Butterworth filters.

## LOW-PASS FILTER

$$C1 \leq \frac{[a^2 + 4b(K-1)]C2}{4b}$$

$$R1 = \frac{2}{[aC2 + \sqrt{[a^2 + 4b(K-1)]C2^2 - 4bC1C2}] \omega_c}$$

$$R2 = \frac{5}{bC1C2R1\omega_c^2}$$

$$R3 = \frac{K(R1 + R2)}{K-1} \quad (K > 1)$$

$$R4 = K(R1 + R2)$$

where

$K$  = gain  
 $f_c$  = -3 dB cutoff point  
 $\omega_c = 2\pi f_c$   
 $a = 0.765367$  (see text)  
 $b = 1$   
 $C2$  = a standard value near  $10 / f_c \mu\text{F}$

Note: For unity gain, short R4 and omit R3.

Example:

$K = 2$   
 $f = 4000 \text{ Hz}$   
 $\omega_c = 25,132.74$   
 $C2 = 0.0025 \mu\text{F}$   
 $C1 \leq 0.003 \mu\text{F}$   
 $R1 = 19,254 \Omega$  (use 20 k $\Omega$ )  
 $R2 = 11,278 \Omega$  (use 11 k $\Omega$ )  
 $R3 = 61,066 \Omega$  (use 62 k $\Omega$ )  
 $R4 = 61,066 \Omega$  (use 62 k $\Omega$ )

## HIGH-PASS FILTER

$$R1 = \frac{4b}{[a + \sqrt{a^2 + 8b(K-1)}] \omega_c C}$$

$$R2 = \frac{b}{\omega_c^2 C^2 R1}$$

$$R3 = \frac{KR1}{K-1} \quad (K > 1)$$

$$R4 = KR1$$

where

$K$  = gain  
 $f_c$  = -3 dB cutoff point  
 $\omega_c = 2\pi f_c$   
 $a = 0.765367$  (see text)  
 $b = 1$   
 $C$  = a standard value near  $10 / f_c \mu\text{F}$

Note: For unity gain, short R4 and omit R3.

Example:

$K = 4$   
 $f = 250 \text{ Hz}$   
 $\omega_c = 1570.8$   
 $C = 0.04 \mu\text{F}$  (use 0.039  $\mu\text{F}$ )  
 $R1 = 11,407 \Omega$  (use 11 k $\Omega$ )  
 $R2 = 23,358 \Omega$  (use 24 k $\Omega$ )  
 $R3 = 15,210 \Omega$  (use 15 k $\Omega$ )  
 $R4 = 45,630 \Omega$  (use 47 k $\Omega$ )

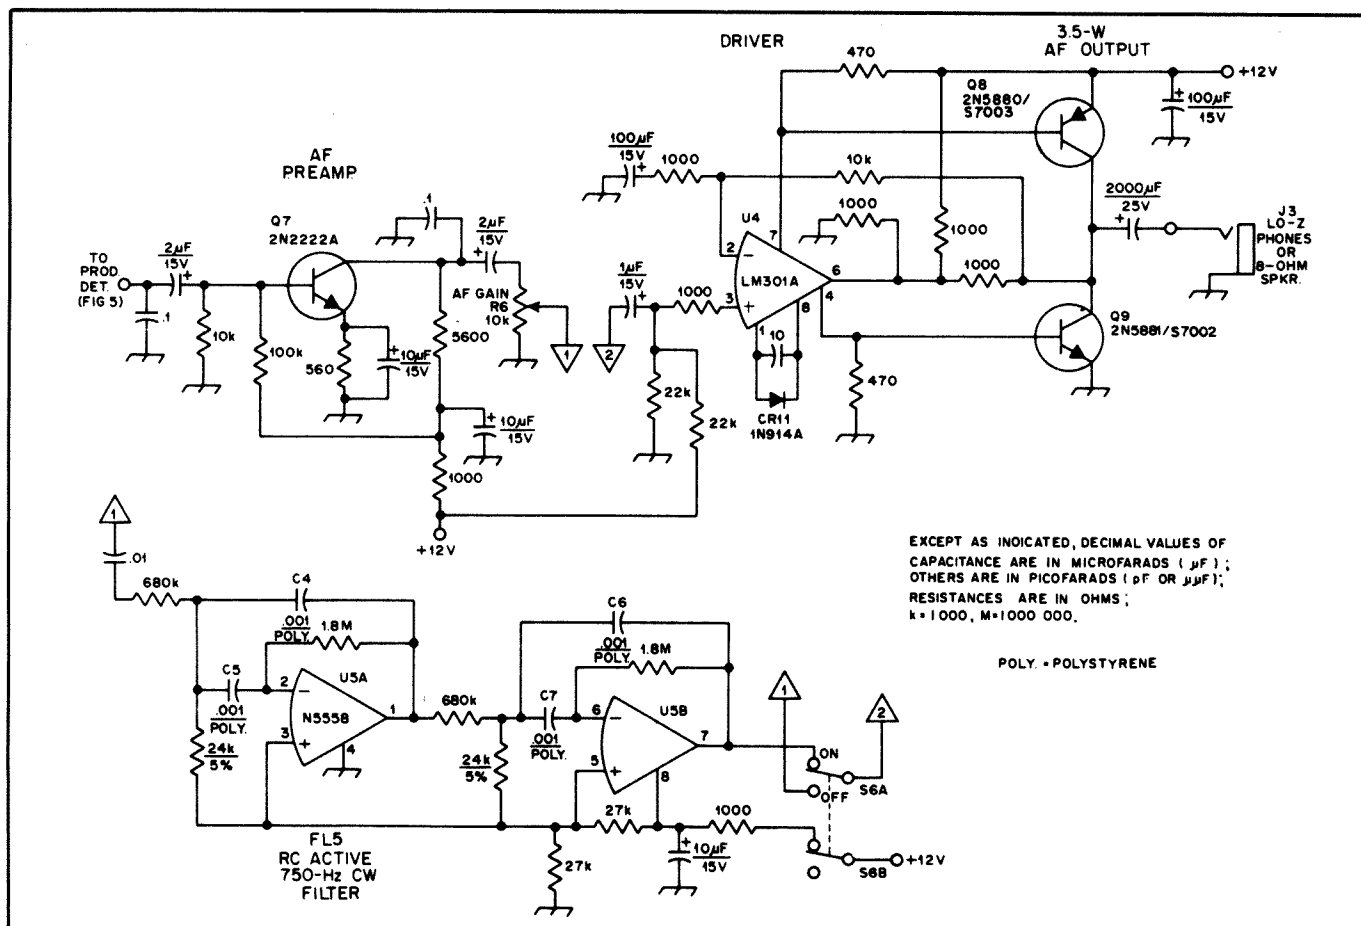

Fig 8—Practical circuit for a two-pole CW RC active filter, showing how it can be switched into and out of the audio channel of a receiver.

simple receivers. As the Q and number of filter sections increases there is a strong tendency toward "ringing." This appears in the speaker or earphones as a howling sound, which can be most unpleasant to hear. The same is true of passive audio filters that have extremely high loaded-Q values.

Op amp ICs are used as the active devices in most RC active filters. The 741, LM301 and 747 ICs are suggested for that application. However, discrete devices can be used with equal success if the builder so desires. Fig 6 shows one section of an active filter that uses transistors. Q1 serves as a source-follower at the input and Q2 is one section of the filter. Additional cascaded filter sections would consist of the circuit that is common to Q2. The values of R1 and R2 would be changed to modify the center frequency ( $f_c$ ) of the filter. The lower the resistance value the higher the  $f_c$ . A dual potentiometer could be used in place of R1 and R2 to provide variable frequency

response.

Design data for a band-pass active filter using a single op amp is shown in Fig 7A. Only one pole is shown for clarity. The term K represents the desired gain of the filter. Gains of 1 (unity) and 2 are most common. The desired filter Q can be calculated by dividing the center frequency by the bandwidth ( $\Delta f$ ) at the  $-3$  dB points.

Design data for second-order Butterworth VCVS low-pass and high-pass filters is shown in Figs 7B and 7C respectively. The desired filter gain is designated K, and the frequency at the  $-3$  dB points is designated  $f_c$ . To design one of these filters, start by selecting the gain (K) and cutoff frequency ( $f_c$ ). Then start plugging the variables into the formulas in the order given. Second-order calculations are shown, and these give approximately 40 dB per decade of attenuation outside the passband. If greater attenuation is desired, cascade another second-order section, this time substituting 1.847759 for a in the second section. This

second section attenuates unwanted frequencies an additional 40 dB per decade.

High-Q, stable capacitors are imperative to proper filter performance. Polystyrene capacitors are recommended for use at C of Figs 6 and 7. The frequency-determining resistors and capacitors should be as close to the design values as possible. Variations greater than 5 percent in resistance and capacitance in a multipole filter will widen the 3-dB bandwidth and cause dips in the nose of the response curve. In other words,  $f_c$  should be exactly the same for *all* filter sections in an ideal example.

A practical example of a two-pole RC active filter that uses a dual op-amp IC is given in Fig 8. It is switched in and out of the audio amplifier by means of S1. As shown, the filter represents the minimum acceptable design for most CW work. A three- or four-section filter of this type would be more desirable for CW work under adverse band conditions (QRM or weak signals).

# An Audio Amplifier with AGC for Simple Receivers

Many excellent articles describing simple receivers have appeared in the amateur literature. In many respects these receivers perform well. However, most of the designs lack an automatic gain control (AGC) circuit. This amplifier module was first described in April 1983 *QST* by Rick Littlefield, K1BQT.

There are several ICs on the market that satisfy amateur receiver audio requirements. The LM-386 is well suited for amateur use. This chip features low distortion, plenty of gain (up to 200), low current drain and high stability. With a 9-V supply it delivers 200 mW of audio power, more than sufficient to drive a speaker.

## Automatic Gain Control

IF-derived AGC is probably the best. However, deriving a control signal from the IF stage may not be practical in simple designs in which the IF signal levels are low and BFO leakage is common. Audio-derived AGC is usually a safer choice. But deriving AGC from a receiver that employs a single high-gain audio chip can also present a problem. The only voltage-sampling point before the volume control is at the output of the product detector, where the voltage level is very low. Thus, a functional AGC circuit would require the addition of high-gain circuitry to develop a usable control voltage.

The simplest alternative is to derive the control voltage at the audio-amplifier output, where the signal level is high. The AGC circuit then keeps the amplifier from being driven past a predetermined output level. Limiting is set somewhere below the maximum undistorted output level of the audio amplifier at a comfortable "maximum" volume level for the radio. A drawback to this approach is that AGC action does not occur at very low gain settings. This should not be a problem in quiet listening environments — the human ear can adapt easily to changes of 20 dB or more in normal conversation. In noisy environments the radio would be operated at a higher volume level, and heavy AGC action would keep the output more constant. This is a compromise compared to a 90-dB AGC system operating independently of the audio gain control; but it works and does not add much to the complexity of the receiver circuit.

## Circuit Information

The circuit shown in Fig 9 has been used successfully in several small receivers. The LM386 audio section is compact and stable. Miniature 220- $\mu$ F, 16-V capacitors (available from Radio Shack) contribute to the small size of the layout. The circuit is designed to drive an 8-ohm speaker. Operation with headphones is possible by adding a simple attenuator similar to those used in transistor radios. A 10-ohm resistor

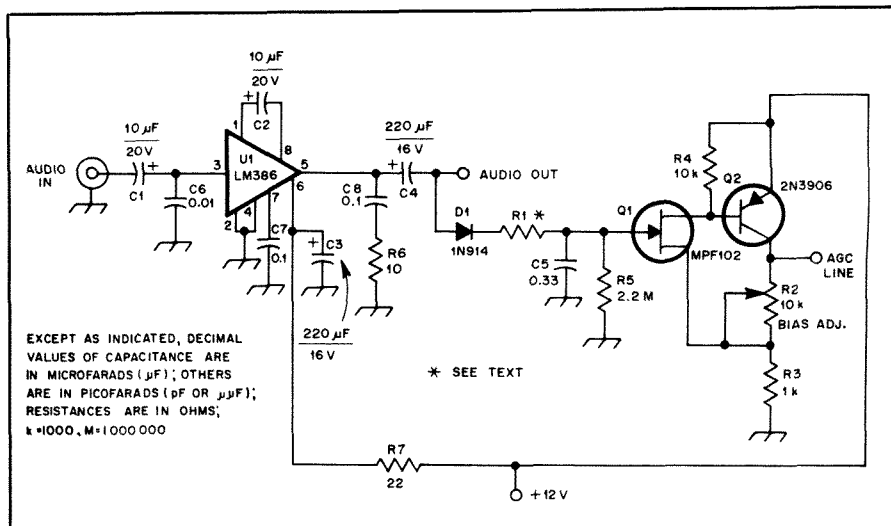

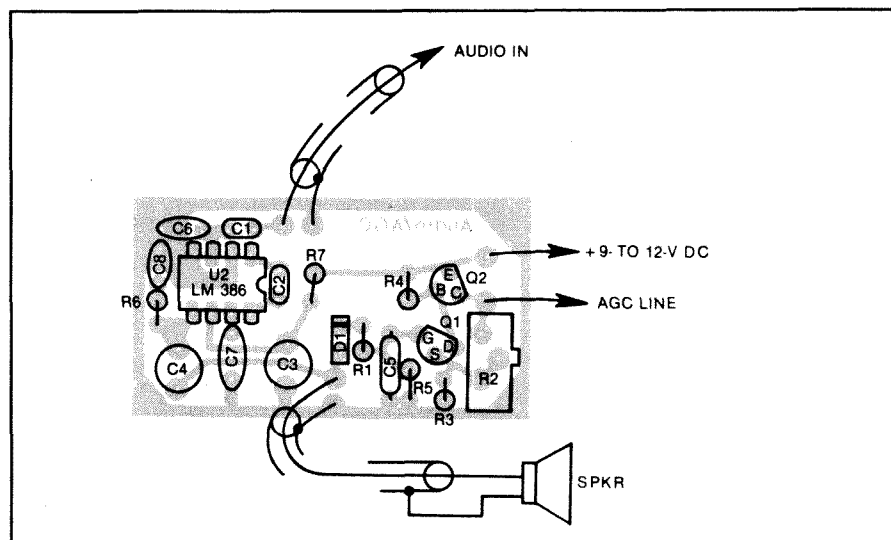

Fig 9—Circuit diagram of a simple audio amplifier and AGC module for use with homemade receivers.

# An Expandable Headphone Mixer

From time to time, active amateurs find themselves wanting to listen to two or more rigs simultaneously with one set of headphones. For example, a DXer might want to comb the bands looking for new ones while keeping an ear on the local 2-meter DX repeater. Or, a contester might want to work 20 meters in the morning while keeping another receiver tuned to 15 meters waiting for that band to open. There are a number of possible uses for a headphone mixer in the ham shack.

The mixer shown in Figs 11 through 13 will allow simultaneous monitoring of up to three rigs. Level controls for each channel allow the audio in one channel to be prominent, while the others are kept in the background. Although this project was built for operation with three different rigs, the builder may vary the number of input sections to suit particular station requirements. This mixer was built in the ARRL lab by Mark Wilson, AA2Z.

## Circuit Details

The heart of the mixer is an LM386 low-power audio amplifier IC. This 8-pin device is capable of up to 400 mW output at 8 ohms — more than enough for headphone listening. The LM386 will operate from 4- to 12-V dc, so almost any station power supply, or even a battery, will power it.

As shown in Fig 12, the input circuitry for each channel consists of an 8.2-ohm resistor (R1-R3) to provide proper termination for the audio stage of each transceiver, a 5000-ohm level control (R4-R6) and a 5600-ohm resistor (R7-R9) for isolation between channels. C1 sets the gain of the LM386 to 46 dB. With pins 1 and 8 open, the gain would be 26 dB. Feedback resistor R10 was chosen experimentally for minimum amplifier total harmonic distortion

(THD). C2 and R11 form a “snubber” to prevent high-frequency oscillation, adding to amplifier stability. None of the parts values are particularly critical, except R1-R3, which should be as close to 8 ohms as possible.

## Construction

Most of the components are arranged on a small PC board. Parts placement is shown in Fig 13, and a full-size etching pattern is shown in the back of this book. Perfboard will work fine also, but some attention to detail is necessary because of the high gain of the LM386. Liberal use of ground connections, short lead lengths and a bypass capacitor on the power-supply line

all add to amplifier stability.

The mixer was built in a small diecast box. Tantalum capacitors and ¼-W resistors were used to keep size to a minimum. The '386 IC is available from Radio Shack (cat. no. 276-1731). A 0.01-μF capacitor and a ferrite bead on the power lead help keep RF out of the circuit. In addition, shielded cable is highly recommended for all connections to the mixer. The output jack is wired to accept stereo headphones.

Output power is about 250 mW at 5% THD into an 8-ohm load. The output waveform faithfully reproduces the input waveform, and no signs of oscillation or instability are apparent.

Fig 11—The 3-channel headphone mixer is built on a small PC board. Note that the lead length was kept to a minimum to aid stability.

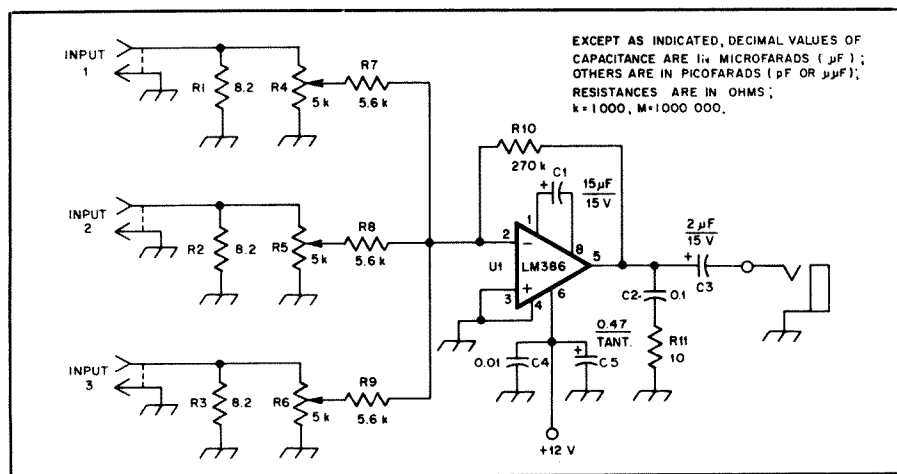

Fig 12—Schematic diagram of the LM386 headphone mixer. All resistors are ¼ W. Capacitors are disc ceramic unless noted.

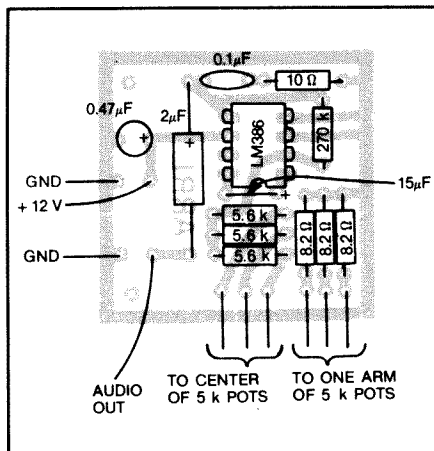

Fig 13—Parts-placement diagram for the LM386 headphone mixer. A full-size etching pattern appears in the back of this book.

# An ATV Monitoring Instrument

To maintain high-quality video images, amateur television enthusiasts must monitor their transmissions. RF sampling is often used to siphon a portion of the transmitter's RF output from the transmission line for monitoring purposes. This relatively easy-to-build video sampler, shown in Figs 14 through 21, is based on this technique, but goes several steps further. By employing a directional coupler, it not only provides low-level output to a TV monitor, but also permits percentage modulation and relative SWR measurements. Biagio Presti, of Apron Laboratories, Inc., designed and built this instrument. John Gereke of Southwest Sound also contributed to this project.

## Circuit Description

Fig 14 is a schematic diagram of the unit. The stripline directional coupler provides detection of both forward and reverse power. When SI is in the VIDEO position, modulation is detected and routed to chopper IC U1. The IC switches inside U1 are connected as shown in Fig 15.

If S3 is also placed in the VID position, then IC switch 1-2 is always closed, and IC switches 3-4 and 9-8 are always open. Detected video is then routed to the input of the video amplifier consisting of Q2, Q3 and Q4. The output from Q4 is capable of driving a TV monitor input and must be terminated in 75 ohms. For percentage modulation measurements, this output is

connected to an oscilloscope.

If S3 is placed in the CHOP position, then IC switches 3-4 and 9-8 are turned off and on at a 60-Hz rate by Q1. In this configuration, the connections of switch 9-8 form a 60-Hz inverter that drives IC switch 1-2. This produces a ground reference on the face of an oscilloscope connected to the video output terminal and set to view the signal at the horizontal TV rate.

Placing SI in the SWR position allows making SWR measurements.

## PC Board Assembly

Fig 16 shows the PC-board parts placement. The board is made from 1/16-inch, double-sided glass-epoxy stock, so the

Q1 — VN10KM FET.  
Q2, Q3 — General-purpose NPN silicon

transistor, 2N4124 or equiv.  
Q4 — Small-signal PNP amplifier transistor, 2N4126 or equiv.  
T1 — Power transformer. Primary, 117-V ac. Secondary, 12.6-V ac, 100 mA.  
U1 — Quad bilateral switch IC, CD4066.  
U2 — 12-V, 1.5-A three-terminal regulator (LM7812 or equiv.).

The case used should be at least three inches deep to allow room for the switches and meter to mount to the front panel. The power transformer can be mounted to the case bottom plate. Use sensible wiring

The 1N34 diodes should be a matched pair for best results. You can match such diodes adequately by using an ohmmeter and measuring the forward drop of a number of diodes until two are found that read the same or nearly so.

The area of construction requiring some care is the mechanical placement of the Type-N connectors to the rear panel and the metal shield parts. The reason is that

Fig 17—Component-mounting details. At A, components that mount to the circuit side of the board must be spaced away from the board so you can solder the leads to the circuit traces. Any leads that go to ground are also soldered to the foil groundplane on the component side of the board. At B, details of the components that mount to the stripline may be seen.

Fig 18—The pieces of the PC board shield are made from tin plate (or thin sheet brass or copper). The piece at A solders to the PC board circuit side to form three sides of the stripline compartment shield. The connector shield piece, shown at B, forms the fourth side of the shield. It is held in place by the connector-mounting hardware. See Fig 19C. The shield cover piece shown at C completes the stripline enclosure.

once the connectors are mounted, along with the shield piece associated with the connector mounting, the nuts holding these pieces are no longer reachable when the PC board is slipped into position. The PC mounting holes for the center conductor of the connectors must then slip perfectly into place or the PC board will not fit, and the shield associated with the connector will not butt properly to the PC board shield piece. See Figs 18 and 19.

#### How to Use the Instrument

It is a simple matter to use the instrument to monitor video. First, connect the video output to a monitor terminated in 75 ohms. Place the VID/CHOP switch in the VID position. Adjust video gain for suitable contrast. If you have a multiburst signal available, then the quality of transmitter performance can be checked as well.

#### To Check for Percentage Modulation

A properly designed TV transmitter has a clamping circuit that establishes the sync tip to a constant value. Because the RF amplitude of the signal approaches zero for "white-going" signals, any overmodulating white peaks will bring the carrier to zero, causing "sync buzz." To avoid this condition, peak white modulation is set to 87.5%.

First, connect the transmitter output to the IN Type-N connector and the antenna line to the OUT Type-N connector. Next, connect the video output to an oscilloscope with sufficient bandwidth to view video (10 MHz) and terminate the output in

(A)

(B)

(C)

Fig 19—Assembly of the shield. At A, the stripline shield is soldered to the component side of the PC board. At first, the shield is tack soldered in place. Next, the connector shield piece is attached to the rear case wall. At final assembly, all seams will be soldered to make an RF-tight enclosure. As shown at B, the PC board is spaced  $\frac{1}{4}$  inch away from the rear wall of the case. The center conductor of the connector inserts in the stripline hole just enough to make a good solder connection to the circuit trace. Dimensions for mounting the connectors are given at C.

75 ohms. You can make an adequate termination by using a  $\frac{1}{4}$ -watt, 5%, 75-ohm resistor with one lead soldered to the center pin of a BNC male connector and the opposite end of the resistor soldered to the shell. By using a BNC T connector, you can then make the connection to the scope. TV monitors general-

ly provide 75-ohm terminations, but if not, then the same scheme can be used for the monitor as well. Then, set the scope horizontal sweep rate to allow two or three TV lines to be viewed.

The ideal signal to use for modulating the transmitter is a test-generator stairstep signal since the "white" step is clearly de-

fined. If, however, you do not have a test signal, a black card with a white square in the center can be used in conjunction with your camera. The idea is to have a clear white video reference with which to set the percentage modulation.

Set the VID/CHOP switch to CHOP. Set the VID/SWR switch to VID. With every-

Fig 20—When you have set up the monitoring instrument with a test generator to check percentage modulation, the scope display should look like this.

Fig 21—Use this graph to determine SWR from the meter readings. See text.

thing turned on, the scope display should appear as in Fig 20.

Adjust the scope vertical gain and the

instrument video gain to a calibrated vertical deflection. For example, if the scope display is set to a 4-cm vertical de-

flection from the chopper reference bar to the tip of sync, then each cm of deflection represents 25%. Setting the tip of sync to video white at 3.5 cm is equivalent to 87.5% modulation.

Adjust the *transmitter* video level and sync stretch for proper sync to video ratio and percentage modulation.

#### To Monitor SWR

Set the VID/SWR switch to SWR and the FWD/REV switch to FWD. Adjust the SET control for full-scale reading on the meter (200  $\mu$ A).

Now switch the FWD/REV switch to REV and read the meter. The ratio of the reverse to forward reading is used by referring to the SWR chart in Fig 21 or calculate using

$$\frac{F + R}{F - R}$$

where

F = forward reading

R = reverse reading

For example, if the reverse reading is 40  $\mu$ A, then the ratio is 40/200 or 0.2. Referring to Fig 21, read 0.2 on the RATIO scale to the curve and then to the SWR scale and read 1.5 SWR.

The instrument will handle more than 50 watts and can be left in place without degradation to the quality of transmission or power output.

# A Weather Satellite Display System Using A Dedicated CRT

A system for display of automatic picture transmission (APT) weather satellite imagery using a dedicated CRT is described here. This method has been used by amateur and professional satellite users for many years, although commercial users have now largely abandoned it in favor of more complex (and much more costly) imaging systems. This system, shown in Figs 22-38, was designed and built by Grant Zehr, WA9TFB.

Using a dedicated CRT system, the electron beam is intensity modulated as it is swept across the CRT screen. With proper timing the satellite image is traced out on the CRT screen. Because of the long times required to draw a complete image, the screen must be photographed (in a darkened room) for the image to be seen in detail.

While there are some limitations to a dedicated CRT system, it is still popular among amateurs because it offers high-resolution, photographic-quality imagery at low cost. The only other amateur systems with similar resolution and photographic image quality are those built around photographic drum machines.<sup>1</sup> These machines produce excellent imagery but offer the complexity of drums, motors, glow lamps and traverse mechanisms.

The principles of CRT operation are discussed in Chapter 7 and are well worth reviewing before beginning this project. The CRT for this project is used in an entirely conventional manner except that the sweep rates are much slower than those typical for standard monitor use.

## System Overview

Operation of the system is relatively straightforward. During the time a satellite is within range of the receiving station, the signal from the satellite is recorded on the right channel of a stereo tape recorder (see Fig 22). At the same time, a highly accurate 2400 Hz signal of constant strength is recorded on the left channel of the tape recorder. During playback, the satellite signal (right channel) is fed into the analog processing circuit and the resulting signal used to intensity modulate the CRT using a high-voltage transistor amplifier. The synchronizing tone (left channel) is fed into the phase-locked loop/digital countdown circuit. These countdown circuits generate properly timed digital pulses to reset the analog sweep circuits and blank the screen during retrace of the CRT beam.

## Circuit Description

The 2400 Hz local oscillator shown in Fig 23 is a TTL circuit similar to that used by many amateurs in crystal calibrators. The 2.4 MHz TTL signal is divided by ten in a 7490 decade counter then divided by

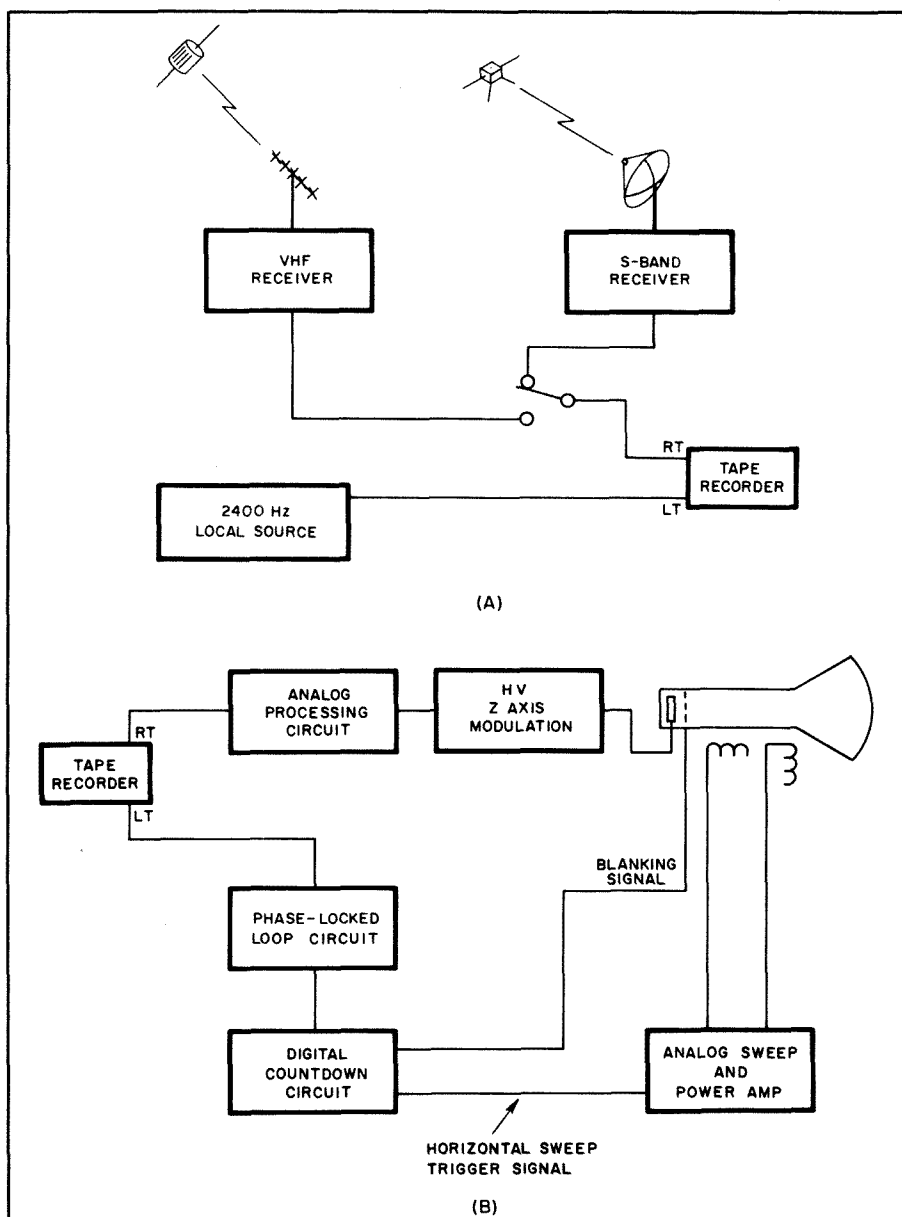

Fig 22—Block diagram of a satellite imaging system. Part A shows the recording mode, and part B shows the playback and display mode.

ten again in a CMOS 4017 decade counter. The last divide by ten is done with a CMOS 4018 in a digital sine-wave generator configuration. The secondary winding of a small audio transformer serves as a choke to further smooth the output of the local oscillator to provide a signal that can be recorded without excessive distortion. Because the harmonics have been greatly reduced by the sine-wave generation step, the playback signal is easier to use later for synchronization of the horizontal sweep.

After the satellite pass is complete, the signal can be played back and an image produced. During playback the satellite signal from the right channel is routed to the analog processing circuit and applied to the input of a 600 Hz high pass active

filter (U5 of Fig 24) to reduce 60 Hz interference. The output from this filter is detected by a precision rectifier (U6A, B). The 10 kΩ potentiometer allows adjustment for symmetrical detection. The output from the detector is then filtered to remove the 2400 Hz subcarrier (U7, 8). The resulting dc level follows the video subcarrier envelope. An offset amplifier (U9) allows for adjustment of the amplitude and dc offset before the signal is applied to the high voltage driver amplifier.

In some situations, a stage of logarithmic amplification will produce a more satisfactory image. With logarithmic amplification the black level remains black, the grey level is somewhat brighter than with linear amplification and the whites will

be compressed somewhat. In some situations this will allow for better resolution of ground detail in the APT image. In this display unit, an Intech A-730 hybrid circuit module is used to achieve logarithmic shaping of the video signal. See Fig 25. Other integrated circuits or discrete circuits could be used for this purpose. Even greater flexibility is possible using digital image enhancement at this point.<sup>2</sup>

The video signal, either linear or logarithmic, is applied to the contrast potentiometer shown in Fig 26. Adjusting the brightness control allows for a fairly wide range of voltages on the cathode of the CRT while still maintaining forward bias on the emitter-base junction of Q1 and class-A operation of the amplifier stage.

The CRT is used in a conventional cathode drive configuration. Electro-magnetic deflection is used with a matching yoke, and electrostatic focus is used. All voltages supplying the CRT are regulated (except the 9 kV anode supply). If unregulated voltages are used, the circuits will operate satisfactorily but the images will show objectionable ac "ripple" that degrades the image. Grid 2 of the CRT

normally operates at 100 V dc; grid 3 is at ground potential. Grid 1 rests at ground potential until blanking is desired. At that point -15 V is applied to grid 1 to produce good blanking of the CRT trace. The TTL pulse signaling the timing for the blanking is amplified at U11 and further amplified with care taken to preserve the correct polarity of the final blanking pulse. This circuitry could probably be simplified, again taking care to preserve the option to blank three out of four sweeps of the CRT beam (see discussion below).

During playback of the satellite signal the 2400 Hz sine wave recorded on the left channel is fed into the phase-locked loop circuitry shown in Fig 27. First the 2400 Hz signal is amplified in two stages (U12 A, B). The signal is next filtered in a 2400 Hz bandpass filter to reduce harmonic content and noise (U13). The signal is then fed into a comparator to achieve a square wave (U14A) and reduced in amplitude with an amplifier having less than unity gain (U14B). After rectification, a 5 V square wave is available for the phase-locked loop to lock onto. This allows the monitor to track the satellite on the right channel even though the level of the satellite signal drops to zero. Systems locking on the satellite subcarrier will "unlock" if the signal level

drops below threshold resulting in loss of horizontal synchronization of the CRT trace. A 4049 CMOS buffer is used to obtain a satisfactory level to drive the TTL ICs used in the "countdown" circuitry.

The countdown circuitry is shown in Fig 28. This circuit divides the 2400 Hz reference down to either 8, 4 or 2 Hz. (U18, 19, 20). One half of a 74123 (U21A) is used to generate a short pulse at these slower frequencies. This pulse is used to reset the horizontal sweep on the CRT sweep drive (see sweep circuit discussion below). This pulse is also applied to the line blanking circuit to blank the CRT while the retrace occurs. The other half of the 74123 (U21B) is used to trigger on the output from the first half, pause until the sweep is complete, and finally blank the CRT so that damage to the phosphor does not occur. This feature is needed only when the sweep rate is increased (for example, to expand a small feature by expanding the portion of the image of interest). Two 7476 flip flops (U22, 23) are used to provide the option of blanking either alternate lines or three lines out of four. The alternate line blanking is used for "normal" processing of the Tiros image so that either the visible or IR image portion of the image can be shown alone. Using this option, the vertical and horizontal sweep rates must be increased so the image fills the entire screen and the proper aspect ratio is maintained. By blanking three lines out of four the typical Tiros image can be "enlarged" on the CRT so that small details on the image can be seen. The sweep rates must again be increased when this option is used.

The 74LS368 (U17) tri-state buffer allows the option of phasing the picture either to the right or left during operation of the monitor. This is a very convenient feature during operation of the monitor. Pressing the horizontal phase (right) button causes the 2400 Hz input to be interrupted for a short pulse (determined by U21) each sweep cycle. This results in fewer than 2400 cycles being counted and allows the picture to slew to the right on the screen. Pressing the left phase button allows 2400 Hz to be applied briefly to U18 at pin one instead of 1200 Hz (from pin 12). This results in more than 2400 Hz being counted and allows the picture to slew to the left. In an effort to reduce the amount of digital noise around the monitor, TTL gates (U24-27) were used so that panel switching simply involves grounding one pin of the appropriate gate. Direct switching of the TTL lines can be employed but will result in more "noise" in the linear video circuits described above because of the longer lead lengths required. The various blanking inputs are combined and switched at Q4. The horizontal reset pulse from U21A is routed to the sweep circuits described below.

The video sweep circuits for the CRT are shown in Fig 29. An op amp connected as an integrator is used to generate the voltage ramp to drive the sweep circuit (U28A, 29A). The vertical sweep is reset manually

<sup>2</sup>Grant Zehr, "The VIP: a VIC Image Processor," QST, Aug 1985, pp 25-31.

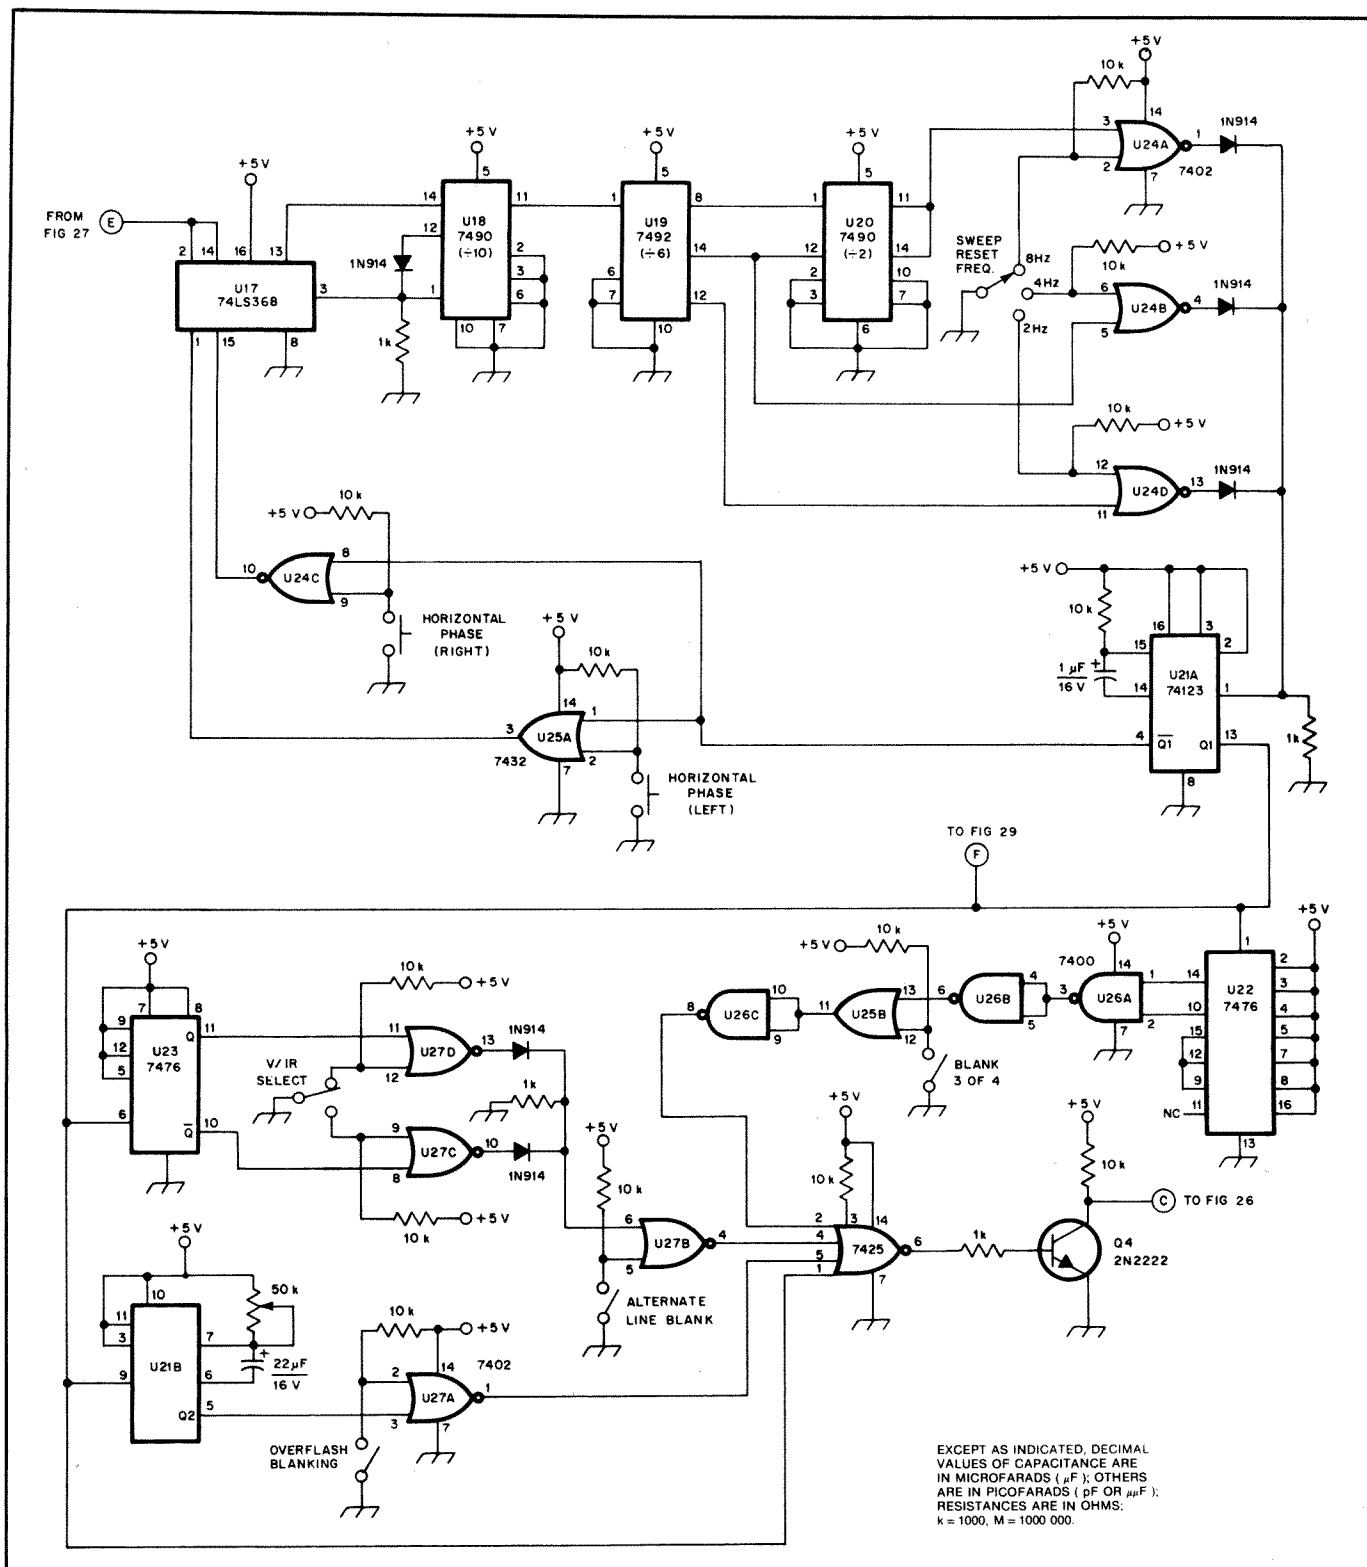

Fig 28—Schematic diagram of the "countdown" circuit schematic. All resistors are 1/4 W types unless noted. Capacitors are disc-ceramic types unless noted. Capacitors marked with polarity are electrolytic.

is important so the images will have straight edges. The initial adjustment of the oscillator can be checked with a frequency counter. If a highly accurate frequency counter is available, this may be adequate. Depending on the exact crystal used, the values of C1 and C2 may have to be

changed slightly to achieve centering at exactly 2.4 MHz. An inexpensive way to achieve accurate adjustment is to calibrate the local oscillator against the satellite generated 2400 Hz subcarrier. For this an oscilloscope with external trigger capability is needed. First the vertical input is con-

nected to the receiver audio connection and the sweep rate of the oscilloscope is adjusted so the 2400 Hz sine wave can be seen while the satellite passes overhead. Next the external trigger input of the oscilloscope is connected to the output of the local oscillator. By adjusting C3 while one of the

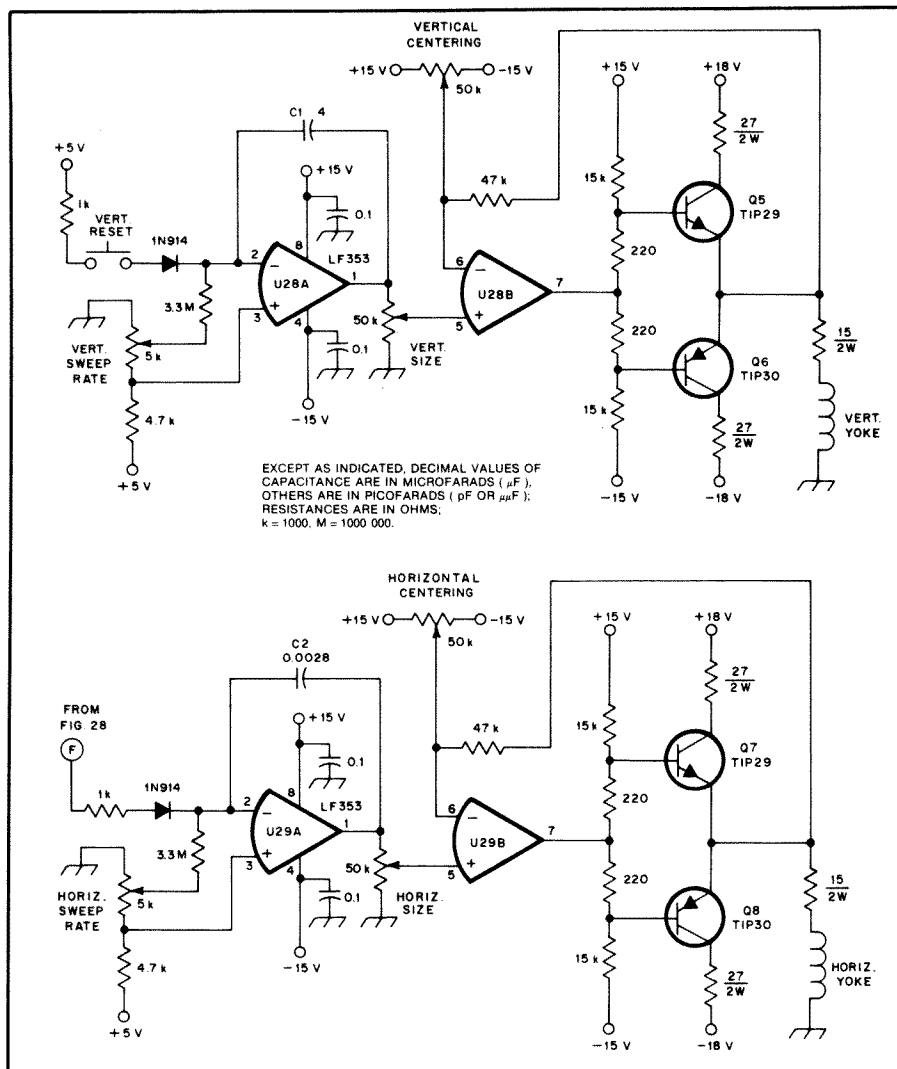

Fig 29—Schematic diagram of the sweep circuits. All resistors are  $\frac{1}{4}$  W types unless noted. Capacitors are disc-ceramic types unless noted. Capacitors marked with polarity are electrolytic.

NOAA satellites passes overhead, the satellite-generated sine wave can be made to march off the oscilloscope screen either toward the right or left. By carefully adjusting the capacitor, the sine wave will remain very nearly stationary on the screen, indicating that the local oscillator and the satellite signal are at the same frequency.

Construction of the audio processing circuitry is straightforward. An audio signal generator is useful to check the operation of this section (although playing back a tape recording of the local oscillator works well as a substitute). With a 2400 Hz signal input, the rectifier balance can be adjusted for symmetrical detection at the output of U6B. Output offset should be adjusted so that low-amplitude input (black) gives an output of about zero volts. Maximum signal level (white) should be around +5 V initially, but may need to be adjusted depending on the other circuit adjustments.

The video amplifier (Fig 26) uses a Radio Shack 276-2061 high-voltage transistor. If this transistor cannot be located the commercial equivalent is the SE7056. Other

small-signal NPN high-voltage transistors might be substituted. During normal operation the voltage at the emitter of Q1 should be between about -1 and -2 V. With the Sylvania CRT used in the prototype, +54 V at the collector of Q1 results in black on the CRT screen, and +40 V results in white. Initial adjustments should be made on the high side so the trace will be too dark rather than too white (which can burn the phosphor coating on the CRT screen). The brightness and contrast controls should be panel mounted since they will require frequent adjustment during operation of the display unit.

In the phase-locked loop circuit (Fig 27) the 5 k $\Omega$  potentiometer should be adjusted so the phase-locked loop runs free at about 2400 Hz. There is no need to offset the free-running frequency, and the only adjustment is to approach 2400 Hz as closely as possible.

The CRT used here was a Sylvania 9ST4716AP39. Other small (9 or 12 inch) green phosphor (P31 or P39 phosphor) CRTs could be used for this project. A 9-inch tube is easier to work with from a mechanical standpoint and requires somewhat less power-supply current. Select a tube using electromagnetic deflection and electrostatic focusing, and be sure to obtain a matching yoke with the CRT. A high-impedance yoke (50-75 ohms) is easier to use in this application if available. If a different CRT is used a manufacturer's data sheet should be obtained to be sure the "pin-outs" are the same and the operating voltages described here are appropriate for the CRT selected. With the widespread use of computer terminals, new surplus CRTs

Fig 30—The completed CRT and high-voltage supply are mounted on a small homemade chassis.

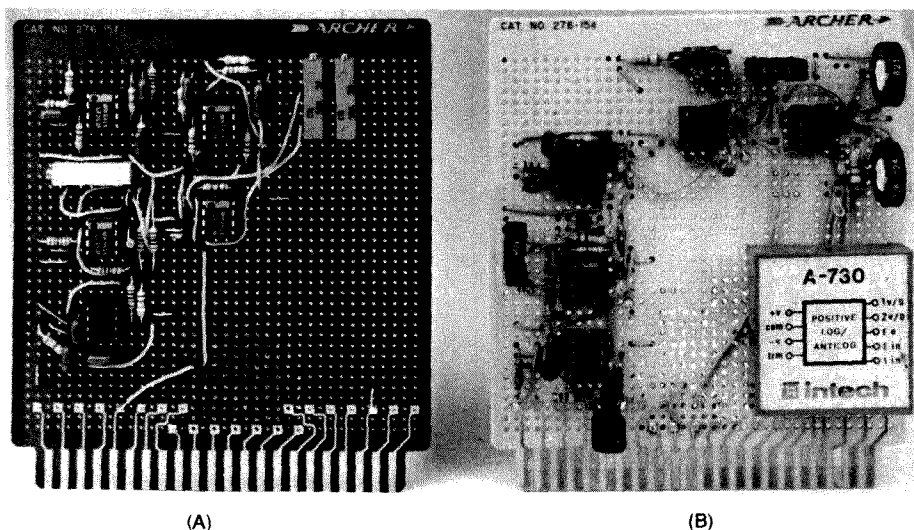

Fig 31—The linear video processing circuit of Fig 24 is shown at A, while the board at B also contains the logarithmic video amplifier of Fig 25.

are often available at low cost at hamfests and computer gatherings. The experimenter is encouraged to purchase two tubes initially if an inexpensive source is located. During the testing stages some phosphor burns are almost inevitable. Later when the unit is working properly, the "fresh" CRT can be used to provide images free of phosphor defects.

In the sweep circuits the timing capacitors used to generate the ramps (C1 and C2 of Fig 29) should be the highest quality Mylar or polyester type that can be obtained. Values slightly different from those listed could be used since the sweep rate can be adjusted by changing the setting of the sweep rate controls. These controls should be panel mounted. The drive transistors should be mounted using heat sinks. In a high-current application such as this, it may be wise to substitute a Darlington-type power transistor. One

possibility is to substitute a TIP 122 NPN Darlington transistor for the TIP 29 shown and to substitute a TIP 127 PNP Darlington transistor for the TIP 30 shown. These devices have approximately twice the current rating of the sweep transistors used here.

The yoke was modified by separating the windings at the yoke feed and connecting all the horizontal coils in series rather than parallel. The vertical windings were also reconnected in series. This raised the resistance of the yoke from about 1  $\Omega$  to 6-8  $\Omega$ . A 2 W resistor was connected in series with the yoke to provide some current limiting. These modifications are not needed if a yoke in the 50-75  $\Omega$  impedance range is available. Raising the resistance of the yoke reduces the power requirement in the drive circuit.

The power supply for this project is conventional, with regulated voltages

supplied throughout. See Figs 33 to 39. Simple 1 A regulators (with heat sinks) are suitable for the 5 V, 6 V (filament supply), +15 V and -15 V supplies. The 6 V regulator operates near its maximum rating and should have a generous heat sink or be chassis mounted. Because of the large power requirements in the sweep circuits, separate regulated 18 V, 2.25 A power supplies are used. Although multiple-secondary transformers could be used, separate transformers for each supply are an effective way to keep noise and "ripple" generated in the digital circuits from appearing in the sensitive linear video processing and sweep circuits.

The CRT high-voltage supply was built using an NE 555 (U33) oscillator to drive a power transistor (see Fig 36) which drives a television-type flyback transformer. The NE 555 oscillator is adjusted to run at about 15 kHz. Be sure to use a high grade polyester capacitor for C1. The value of C2 may need to be adjusted depending on the flyback transformer used. Values from 0.1 to 0.47  $\mu$ f will usually be appropriate. It is important that this supply be built within a separate shielded chassis to avoid electrical shock. The 2N3055 power transistor should be mounted using a heat sink. Depending on the construction used, the wall of the shielding chassis may serve as a mounting point and heat sink. The 500 M $\Omega$ , 20 kV resistor and 500 pF, 20 kV capacitor provide some degree of regulation of the high voltage. By inserting a 470 k $\Omega$ , 1/2 W carbon resistor at the ground end of the 500 M $\Omega$  resistor, a test point is created. About 20 V here corresponds to an output voltage of about 10 kV. If a separate HV module can be obtained, it may be preferable to use a commercially available 8-11 kV supply. A Venus brand LU 15 high-voltage module, located at a hamfest, has been substituted for the unit shown here.<sup>3</sup>

Another alternative is to obtain a CRT complete with HV supply and use the original HV supply circuitry. A separate front panel switch was included to shut off the high voltage supply independently.

The 300 V supply was built using high-voltage capacitors from surplus flash equipment. Zener diodes can be combined back to back to obtain the required values.

The importance of regulating these power supplies cannot be overemphasized, if annoying ripple is to be avoided. It is also important to build the power supply and sweep circuitry on a chassis which can be moved an inch or two away from the CRT if needed to control residual ripple.

### Operation

The image is obtained by darkening the room and photographing the CRT screen using long exposure times and a closeup lens. A "macro" lens is ideal, but less expensive screw-on lenses have been used at this location with satisfactory results. A 35mm SLR camera is mounted on a tripod in front of the monitor and the shutter is opened with a cable release, holding the shutter open until the entire image has been drawn on the screen. The shutter is then released and the film processed and printed. The results may be seen in Figs 37 and 38.

During photography sessions the contrast can be reduced somewhat from what appears ideal to the eye. The camera film will respond better, in most cases, to a CRT image that appears only moderately bright and almost too low in contrast to the eye. Care must be taken to focus on the CRT trace itself rather than the glass screen of the CRT or the film will show an image which is slightly out of focus. Experimentation is required to find the best camera settings. Good results have been obtained with Kodak Plus-X film (ASA 125) developed in Kodak D-76 and exposed at about f4. Remember that exposure times may change if a different developer is used.

While construction of this monitor is a major project, some experimenters will find it easier to manage than the mechanical drum type construction. The major disadvantage of the CRT method is the inconvenience of processing film before viewing the image. In addition, because of the geometry of the CRT, there will almost always be some slight "bowing" of the image margins. Advantages of the CRT method include simple adjustment of the aspect ratio, adaptability to new sweep rates, and the option of rapid sweeping of the CRT to "blow up" a small part of the image for an enlarged view. If immediate results are needed, Polaroid films can be used. If 35mm film is used, the final image can be printed many times from a single favorite negative. With careful voltage regulation to eliminate ac "ripple" in the images this unit can serve as a versatile, reliable, and inexpensive imaging instrument for the amateur APT station.

Fig 37—This photograph, made from the dedicated CRT screen, shows Hurricane Alicia on Aug. 17, 1983. This a full frame from NOAA 7.

Fig 38—Using the dedicated CRT in the expanded mode (by sweeping the beam faster), it is possible to "blow up" an image. This is part of the image shown in Fig 43, but much more detail is available.

# Digital Equipment

Digital techniques are finding more and more application in Amateur Radio with each passing year. In addition to enhancing projects for the "standard" modes, such as CW and

Baudot RTTY, digital technology is leading amateurs into new areas such as AMTOR and packet radio. As time passes, amateurs are thinking of new ways to interface their radio equipment with computers for even

more enjoyment, creating the need for modems specifically designed for radio applications. Chapters 8 and 19 contain related information that may be helpful in understanding the projects in this chapter.

## A Simple CMOS Iambic Keyer

The keyer shown in Figs 1 through 3 features iambic operation, dot and dash memories and internal sidetone generation. The keyer was designed and built by Paul Newland, AD7I, and originally appeared in June 1988 *QST*.

### Circuit Details

Fig 2 shows the schematic of the CMOS keyer. The clock circuit was designed by Roy Lewallen, W7EL, and was used in his keyer project that first appeared in an issue of *SPRAT*—a QRP journal—several years ago. This clock has the advantage of good asynchronous starting without elongating the first clock period. Exclusive-OR gates U1B and U1C are used for the dot and dash memories. A Schmitt-trigger gate (U2D) configured as an AF oscillator serves as a handy, low-cost, minimum parts-count sidetone generator.

The keyer circuit is composed of five major sub-circuits. They are:

- Dot timer
- Dash timer
- Dot memory
- Dash memory
- Asynchronous clock

First, let's focus on the dot and dash timers. The heart of each timer is a CMOS 4017 decade counter. This chip's count advances on the rising edge of the clock input when both the reset and inhibit inputs are low. If the inhibit line is high, clock signals are ignored. When the reset line is high, the counter immediately goes to the zero state. The outputs of this counter are decoded; when the counter output is in the zero state, the zero output is high and all other outputs are low. When the counter is in the two state, the two output is high and all other outputs are low, and so on.

The dot and dash timers operate in a similar way. For clarity, we'll cover just the dash timer. When no dashes are desired,

the timer is in the four state and is held there because the inhibit input is tied to the four output. If both the dot and dash timers are inhibited, both inputs of U2A are high and the clock is disabled. When in the idle state, the outputs of both the dot memory (U1B) and dash memory (U1C) are high. Note that when the dot memory is idle, D5 is reverse biased, and when the dash timer is idle, D6 is reverse biased.

The only thing keeping the dash timer from being reset is that D4 is forward biased, holding the dash timer's reset input low (inactive). When the dash paddle is closed, the output of the dash memory formed by U1C, R6 and R7 goes low (C4 bypasses stray RF). This signal is inverted by U1D, and D4 is then reverse biased. Because all diodes at the reset input of the

dash timer are reverse biased, the reset signal goes high, forcing the counter to go from four to zero.

When the dash timer is in the zero state, the keying transistor, Q1, is biased on by the current flowing through R9. Because of the low base-emitter voltage drop of Q1, most of R9's current goes into the base-emitter junction of Q1. When the state-four output of the dash timer goes low (when the timer leaves the four state), the clock signal from U2B goes from high to low and quickly back to high. (The speed of this process is determined by how fast C7 discharges through D7.) The time constant provided by R8 and C6 ensures that the dash timer remains reset long enough to ignore the first rising edge of the clock. (If this time constant is too short, the first dash

Fig 1—This simple CMOS keyer uses four common ICs, seven diodes, four transistors, 21 resistors, 13 capacitors and two potentiometers.

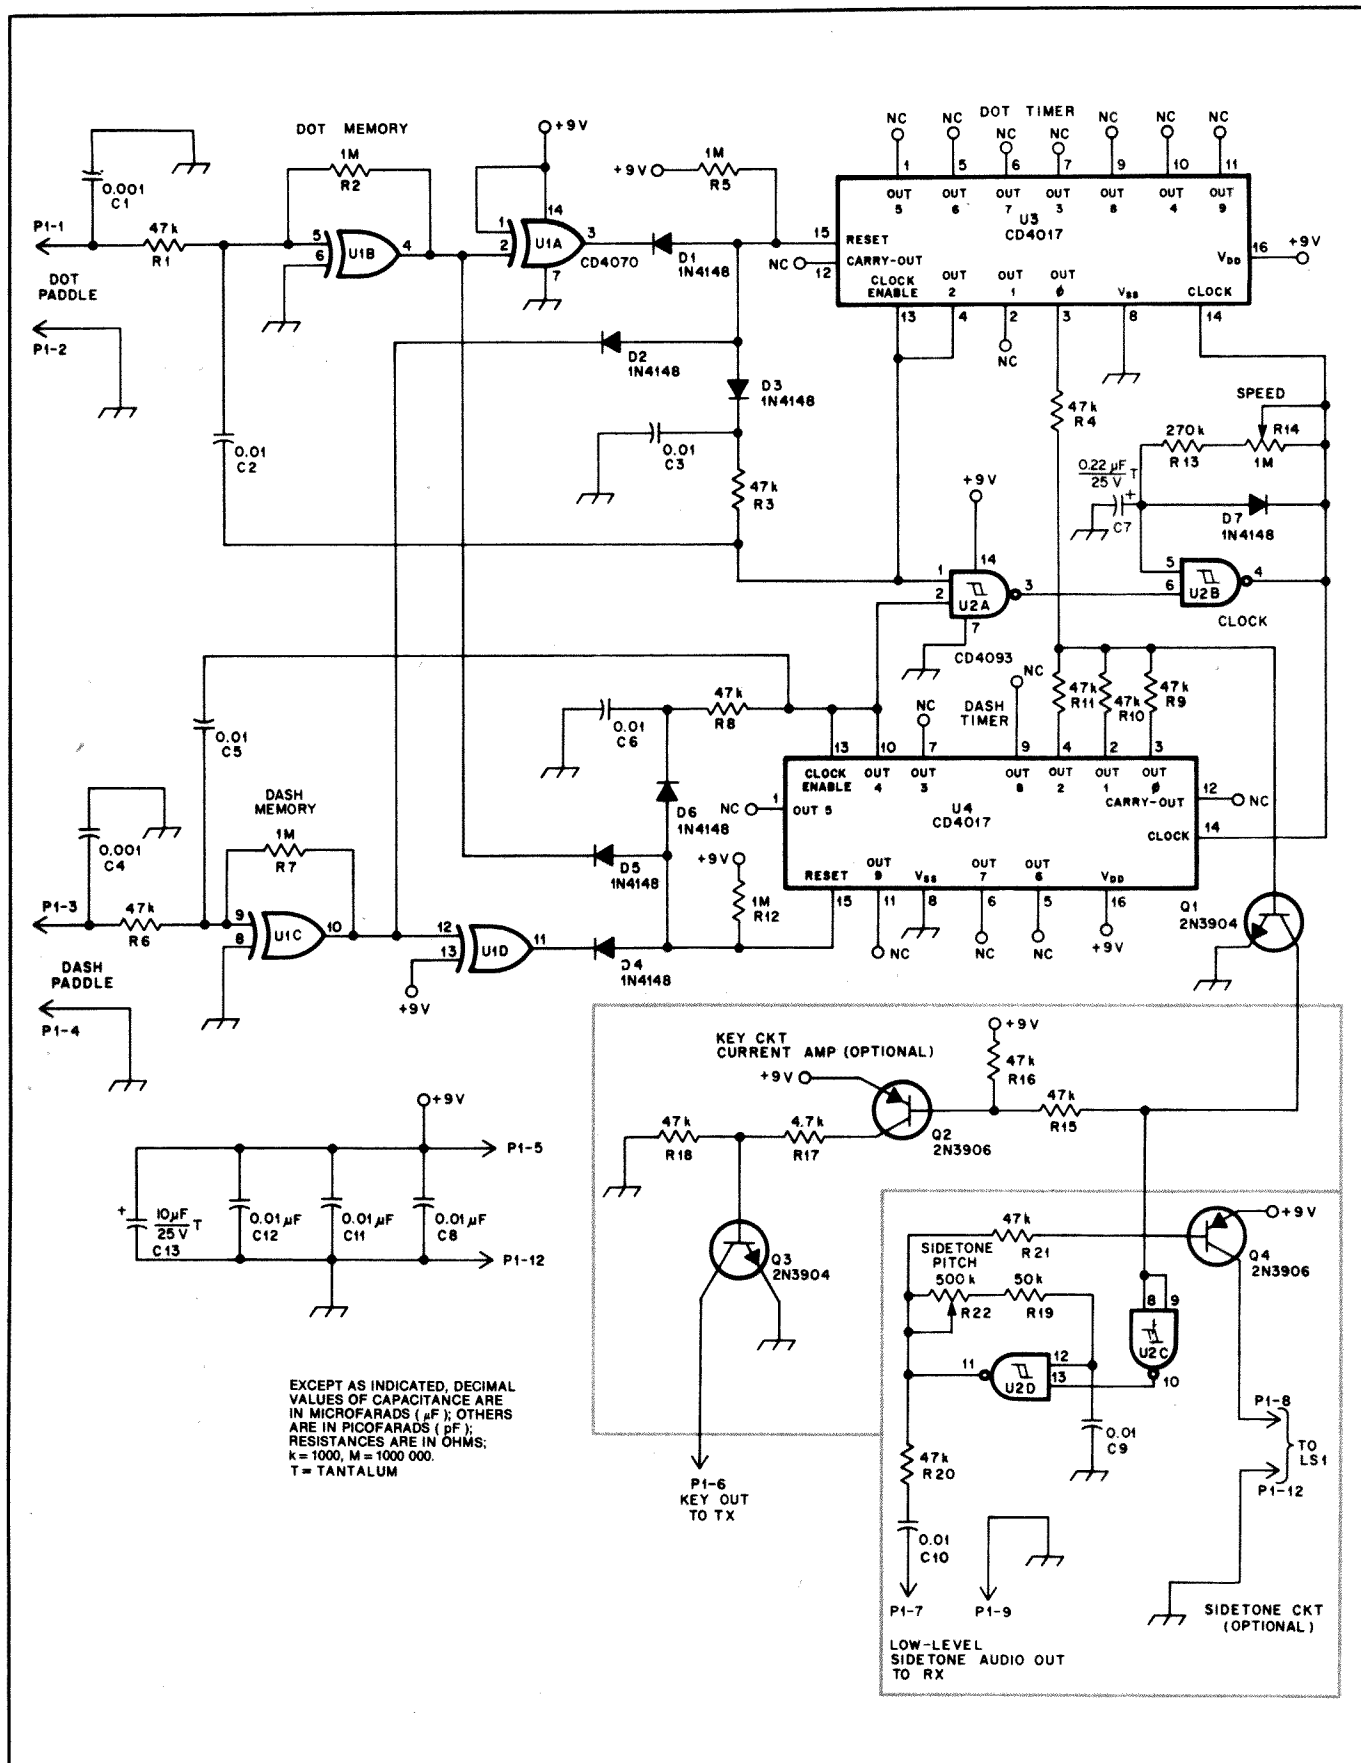

Fig 2—Schematic of the simple CMOS keyer. The portion of the circuit enclosed by the shaded line is optional. If you choose not to include the sidetone circuit, be sure to ground the unused inputs of U2 (pins 8, 9, 12 and 13).

C7—0.22  $\mu$ F tantalum or ceramic. Q1, Q3—2N3904, 2N2222 or equiv. U1—CD4070.  
 J1— $\frac{1}{4}$ -in. three-conductor jack. Q2, Q4—2N3906, 2N2907 or equiv. U2—CD4093.  
 LS1—8- $\Omega$  or 100- $\Omega$  speaker. R14—1 M $\Omega$  potentiometer. U3, U4—CD4017.

would only be two Morse elements in length instead of the requisite three.) On the second rising edge of the clock, the dash timer moves from state zero to state one. Now the bias current for Q1 is provided by R10 instead of R9. Similarly, R11 provides bias current for state two. State three provides the space for the inter-element timing period.

The next rising edge of the clock moves the dash timer into the idle state (state four) and disables the clock. A reset pulse from the dash timer's state-four output also tries to reset the dash memory (U1C) via C5. If the paddle is open, this pulse clears the memory to a high state. If the paddle is still closed, the pulse momentarily clears the dash memory, but because of the remaining key closure, the memory is set again as soon as the charge on C5 is dissipated through R6.

If the dot paddle is closed while a dash is being sent, the dot memory is set before the dash timer reaches state four. During the period when C5 is trying to reset the dash memory, the dot timer is reset (D4, D5 and D6 all reverse biased). This makes the keyer send a dot followed by a space immediately after the dash/space combination is finished. Voila—iambic operation! During the time when the dot timer is active, the dash timer is held idle by forward-biased D5, until the dot-timer cycle finishes.

### Construction

The prototype keyer was built on a piece of perf board. A PC board has since been developed; Fig 3 shows the parts-placement diagram. The PC board and a kit of parts are available from A&A Engineering<sup>1</sup>. Nothing about the layout is particularly critical, so the layout shown in Fig 3 can be modified to suit your needs. Just about any construction method is fine; dead bug, wire wrap, point-to-point and etched PC-board wiring are all fine. One caution you need to observe is the sensitivity of CMOS ICs to static electricity. Always use a grounding wrist strap or its equivalent to protect the ICs during handling. Also, if you elect not to use the PC-board layout shown in Fig 3, be sure to place the bypass capacitors as close as possible to their respective IC pins. The signal levels in the keyer are very small, and poor RF bypassing can make the keyer do some mighty strange things.

A word of caution about C7, the clock capacitor: the keyer uses CMOS ICs to provide keying at minimal current drain.

<sup>1</sup>PC boards and kits of parts are available from A & A Engineering, 2521 W La Palma Ave, Unit K, Anaheim, CA 92801, tel 714-952-2114.

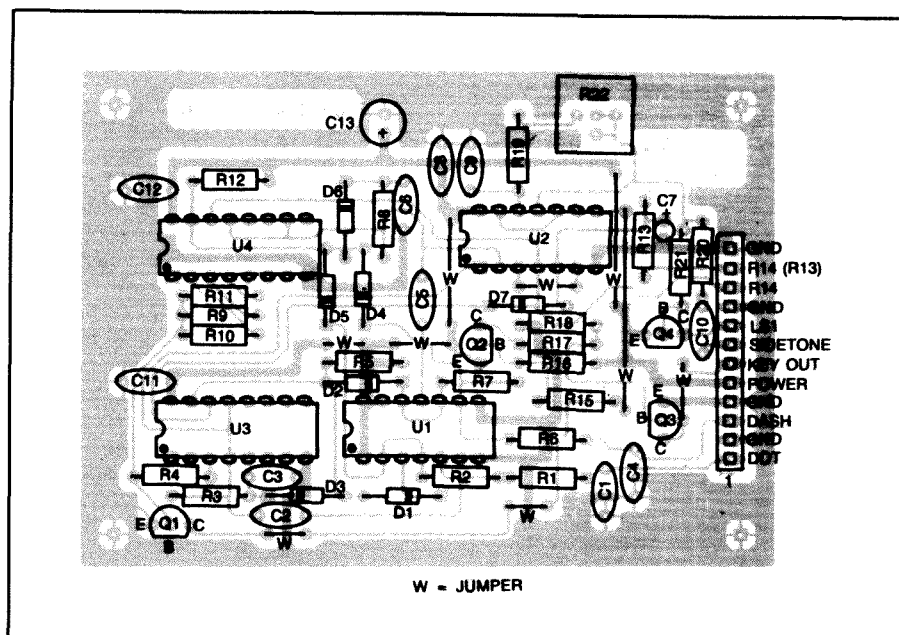

Fig 3—Parts-placement diagram for the keyer. Parts are mounted on the non-foil side of the board; the shaded area represents an X-ray view of the copper pattern. A full-size etching pattern appears at the back of the book.

Because of this, no on/off switch is included. Be sure to use a low-leakage capacitor for C7 (either ceramic or tantalum). Don't use a garden-variety electrolytic here if the keyer will be battery powered; these are often very leaky. The keyer will work fine if you use a leaky cap for C7, but battery life will be markedly reduced.

### Optional Circuitry

The optional circuitry enclosed by the shaded line in Fig 2, including the keying amplifier and the sidetone circuit, is not essential. CMOS gates were used because of their flexibility, as well as the low current drain already mentioned. These devices can be powered from anything between 3 and 15 V (74HC-series parts could also be used, but over a narrower supply-voltage range). The problem is that these devices can only supply a few hundred microamps of current from their outputs for a guaranteed logic level. If these gates are used to drive a transistor with a gain of 50 or so, only a small amount of keying current will be available to drive a transmitter. Often this is too little current for anything but QRP rigs. Q2 and Q3 (with associated resistors) form the keying amplifier, and increase available current to levels suitable for keying almost any transmitter. The value of drive current can be controlled by changing the values of R17 and R18. In general, decreasing the value of R17 will increase the available keying current.

The second optional item is the sidetone generator formed by a Schmitt-trigger gate

(U2D) with an RC circuit for feedback. The sidetone frequency can be changed by varying R22. As the resistance of R22 is increased the frequency of the sidetone decreases. Low-level audio output is available to drive an audio amplifier (such as the one in a transceiver), and the high-level output is suitable for driving a small speaker. Try to avoid using the high-level output to drive a speaker if you are running the keyer from a 9-V battery. The sidetone circuit itself doesn't draw much current, but a speaker sure does! Whenever possible, let the rig provide the sidetone, or you'll be feeding the keyer an awful lot of batteries.

### Operation

The keyer operates just like any other electronic keyer. The circuit has one anomaly that you should be aware of, however. When power is first applied (when you connect a battery, or turn on your rig if the keyer is built into it), a reset pulse is not always sent to the dot or dash counter chips. The lack of a reset signal can cause more than one of the counters to be in active states at the same time, and the keyer will stick in the key-down mode. All it takes to "un-stick" the keyer is to squeeze the paddle after power is applied. This anomaly generally isn't a problem because battery life is long, and the power is only cycled when changing cells. If you build the keyer into a rig, however, this key-down bug can be more objectionable. In this case, try a different set of 4017 counters at U3 and U4.

# CW on a Chip

Fig 4 shows a single-chip electronic keyer that can easily be built in a weekend, thanks to the Curtis keyer-on-a-chip. This IC has made it possible to construct a quality, flexible keying system with a minimum of additional discrete components. This project first appeared in an article by Paul Pagel, N1FB, and Bob Shriner, WA0UZO, in December 1983 *QST*.

Fig 4—View of the single-IC iambic keyer. The unit shown here was built around the Curtis 8044M integrated circuit, and features an analog speed readout.

## The Curtis Chip

There are four versions of the Curtis 8044 CMOS IC. Two of these (8044/8044B) are contained in a 16-pin package and the others (8044M/8044BM) in an 18-pin package.<sup>1</sup> The additional pins are connected to internal circuitry that provides a keyer sending speed monitoring function by means of a meter and a few other external components. The whole family of ICs features contact debouncing, RF immunity and self-completing character generation. A weight control, sidetone output and dot memory are also included. The memory function helps to prevent dot loss if the operator "leads" the keyer. With a quiescent current drain of about 50  $\mu$ A, an on/off switch is not really required.

The "plain vanilla" (no suffix) and B-suffix ICs offer two slightly different iambic (squeeze) keying methods in addition to single-lever (non-squeeze) keying.<sup>2,3</sup> With the no-suffix IC, a dot or dash being sent when the paddles are released is completed and nothing else is sent. The B-suffix IC completes the dot or

dash being sent upon paddle release, and then sends an opposite element; that is, a dot after a dash or a dash after a dot. Many squeeze-key operators prefer the latter method of iambic operation. If only single-lever paddle operation is desired, either IC should suffice.

## Board Design

To make the keyer as universal in application as possible, the board is patterned so that any of the ICs mentioned earlier can be used with or without some of their inherent capabilities.<sup>4,5</sup> The board is single sided, and is small enough to fit inside almost any transmitter or transceiver.

Any or all of the variable controls may be mounted on the board or brought out for external adjustment. Two on-board output keying options are provided: reed relay output (with or without arc suppression components across the contacts) or a transistor-keyed output that can be con-

<sup>1</sup>Curtis Electro Devices, Inc. generously supplied the ICs used in this project.

<sup>2</sup>L. Fay, "The Iambic Gambit," July 1981 *QST*.

<sup>4</sup>An etched circuit board and a complete kit of parts is available from Circuit Board Specialists, P.O. Box 969, Pueblo, CO 81002.

<sup>5</sup>The keyer ICs are available from Curtis Electro Devices, Inc., Box 4090, Mountain View, CA 94040. Be sure to specify IC type when ordering.

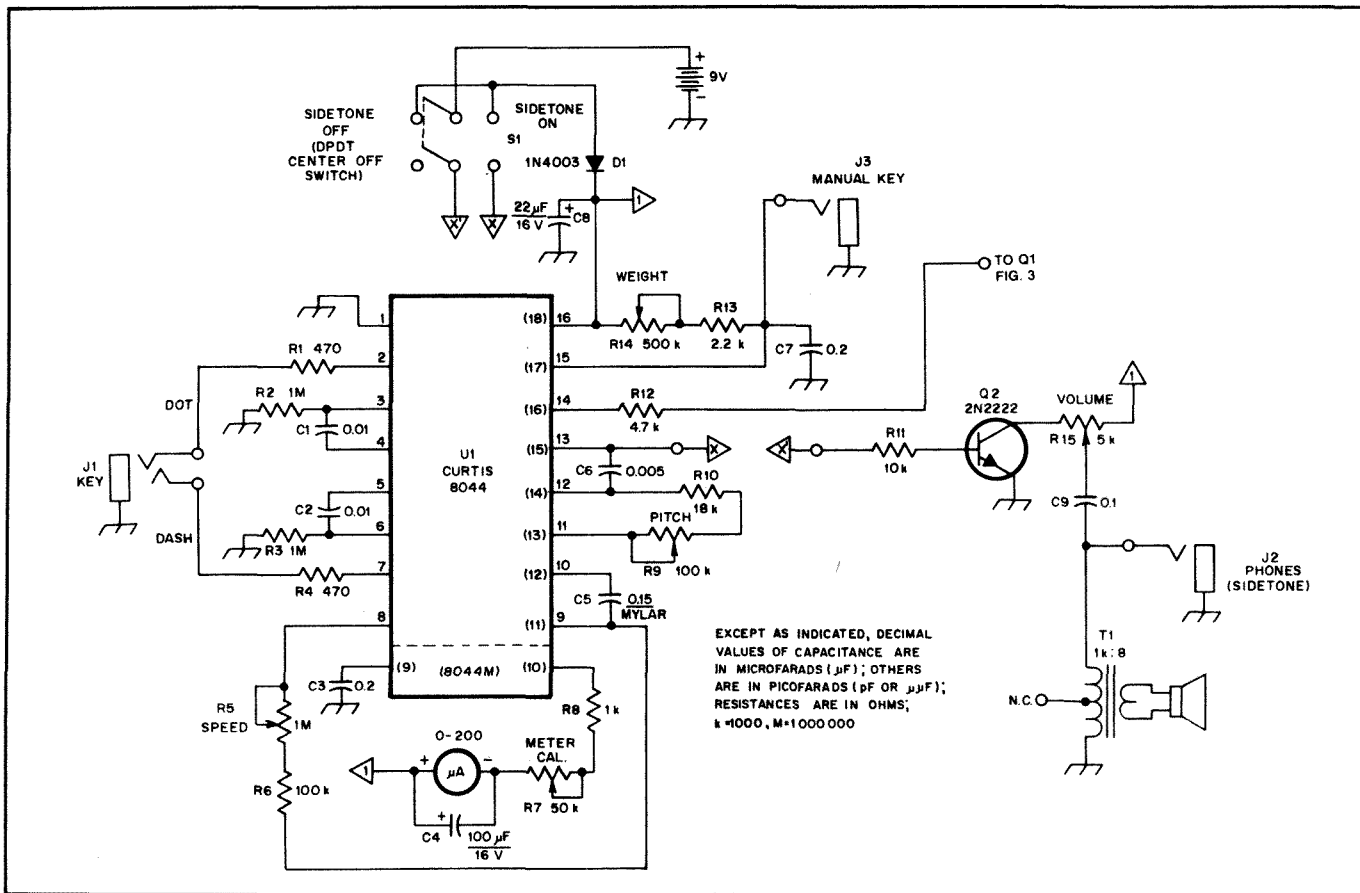

Fig 5—Schematic diagram of the keyer. All resistors shown are 1/4-W, 5% types.

figured to fit station keying requirements.

### Assembly

Construction details are given in Figs 5 and 6. A parts-placement guide appears in Fig 7.<sup>6</sup> All components except the IC should be soldered to the PC board. The integrated circuit should be installed last. A socket is recommended to avoid overheating the chip. Use an 18-pin socket, so either the 16- or 18-pin version may be used. If the 16-pin chip is used, the two extra positions on the socket are left empty; just be sure to install the IC correctly.

The keyer should be built to suit the user's requirements. Any components associated with unwanted features may be eliminated. These may include: sidetone output, level and pitch control, and the speed-meter function. If transistor-output keying is desired, the relay arc-suppression network may be deleted. A 5.6-k $\Omega$  resistor between pins 15 and 16 of U1 will eliminate the WEIGHT control, if a variable unit is not needed. If the weighting appears to be too heavy, reduce the value of C6 or eliminate it altogether. The MANUAL KEY input can be used as a TUNE function; an SPST switch that brings the line to ground will create a key-down condition.

If an IC with the speed-meter function is chosen, any meter with a full-scale deflection range of 50 to 500  $\mu$ A (with a linear scale) can be used. In the unit shown, a modified VU meter was used. A new meter scale was made with two-words-per minute increments between 0 and 100. With the 100-k $\Omega$  resistor shown in series with the SPEED potentiometer in Fig 2, the maximum speed of the keyer is about 50 WPM. Alter the value of the fixed resistor to modify the speed range. The top-end speed for this unit is about 80 WPM.

A switch is included to turn the keyer and/or the transistor audio amplifier (Q2) on and off. To increase battery life, the audio amplifier can be left off. The sidetone oscillator will probably not be required, since most modern transmitters and transceivers have built-in sidetone monitoring circuits. The keyer monitor does serve as a good indicator of battery condition: as the battery becomes depleted, the note will become quite chirpy.

### Relay-Contact Arc Suppression

Some transmitter keying lines may require the inclusion of an arc-suppression network across the keying relay contacts. Most modern transmitters and transceivers should not need this network (C10, R19), as they are usually operated at low voltage levels. But keying some transmitters and transceivers using tubes in the final amplifier may require the relay contact

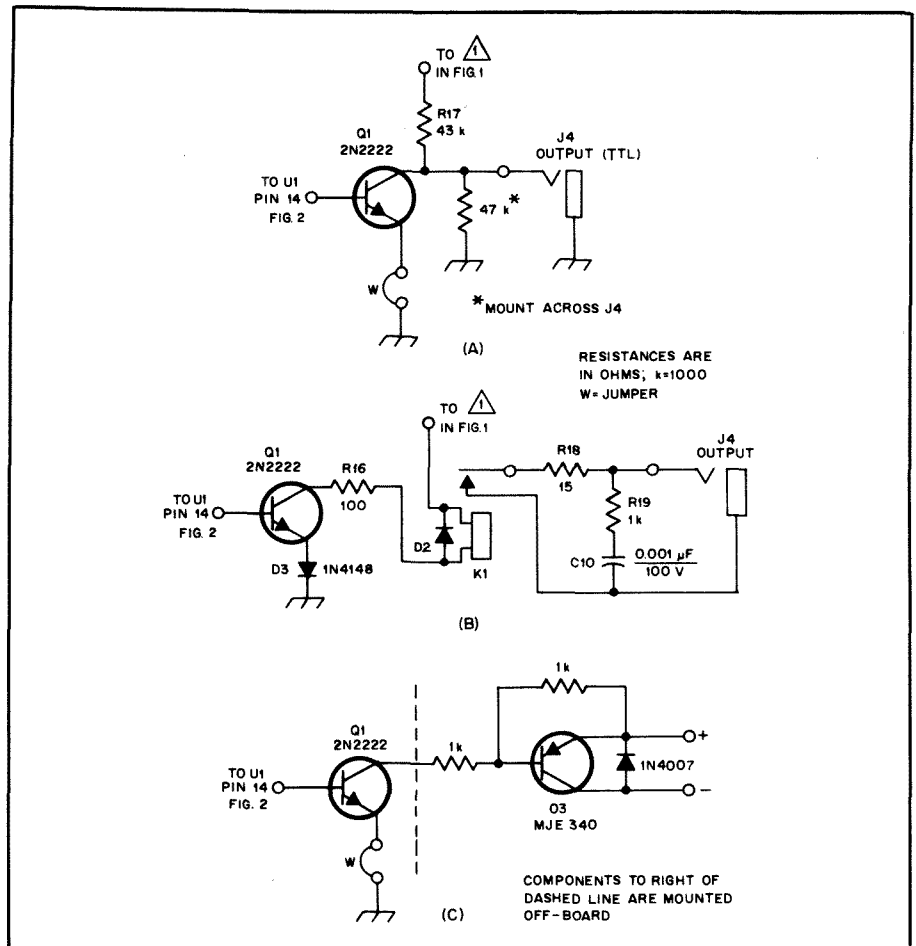

Fig 6—Some possible output circuit arrangements. The jumper (W) shown at (A) and (C) is inserted in place of D3. D3 is included to ensure rapid energization of K1; it may not be needed. Q3 and the components to the right of the dashed line in (C) are not mounted on the keyer circuit board.

Fig 7—Parts-placement guide for the Curtis-IC keyer. Parts are placed on the nonfoil side of the board; the shaded area represents an X-ray view of the copper pattern. A full-size etching pattern appears at the back of this book.

<sup>6</sup>Templates for the sloping-panel keyer cabinet are available from ARRL HQ for a business-size envelope and \$2 to cover template and postage costs.

**Table 1**  
**Series Resistor Values**

Voltage	Value (ohms)
70	100
100	200
150	450
200	800

protection. The prototype keyer has been successfully used with a Kenwood TS-820S transceiver without the arc-suppression network; no problems resulted. The key line voltage in that rig is -65-V dc. The information presented in Table 1 should assist prospective users to determine the required network values.

#### Calibrating the Speed Control

Sending speed can be determined by counting the number of dashes (dahs) sent in a five-second period. This number is the code speed in words per minute. A more refined measurement method uses an oscilloscope or a frequency counter connected to pin 12 of U1.

The formula is

$$\text{speed} = \frac{f}{1.2}$$

where speed is in WPM and f is the dot

frequency measured at pin 12 of U1. Thus, for speeds of 10, 25 and 50 WPM, the frequency counter should display dot frequencies of 8.33, 20.8 and 41.6 Hz, respectively.

#### Keyer Case Construction

Two enclosure styles have been tried. The first—the rectangular configuration—is easy to assemble. The control labels may be difficult to read at some angles, however. The sloping-panel version is more attractive, but a bit more difficult to put together. Either case style is available from Circuit Board Specialists; case style desired should be mentioned when ordering.

Double-sided PC board material is used for the enclosure. Once the box parts have been cut to size, they should be burnished with fine steel wool. The edges must be beveled for a good fit. Use caution to avoid removing too much material from the parts.

The speaker should be laid on a flat surface and the grill pressed into position. Quick-drying epoxy cement secures the grill.

After the box parts are prepared, they should be tack soldered together and checked for alignment and correct fit. If all is well, lay a bead of solder around each seam. A 25- to 45-W soldering iron should be sufficient.

A light coat of clear polyurethane varnish over most of the box will help maintain a pleasant sheen. The prototype cabinet was accented with light-blue epoxy spray paint.

Install the panel mounted controls, jacks, meter and speaker. The keyer board should be mounted with the meter-calibration potentiometer on the bottom.

#### Appendix

Most modern Amateur Radio transmitters, particularly solid-state designs, do not require additional relay-contact protection. When using this keyer with such a low-voltage transmitter, R18 can be removed or jumpered.

Some grid-block-keyed transmitters will require additional relay-contact protection in the form of an added series-connected resistor if the key-line voltage exceeds 70 and a large-value bypass capacitor is tied between the key line and ground. The appropriate resistor value can be determined from Table 1. Resistor power rating can be calculated by multiplying the resistor value by the square of the key-down circuit current in amperes. This resistor can often be placed within the body of the key-line plug. A silicon diode should be connected across the contacts of K1 (in place of C10, R19) to absorb the "kick" when keying inductive loads (such as another relay).

## The Mike & Keyer—A Microprocessor-Based Memory Keyer

Microprocessors are everywhere in electronics today. Most modern commercial radio equipment contains at least one microprocessor, so it is only natural to find home-built projects following this

electronic evolution. Figs 8 through 11 show the Mike and Keyer, an electronic memory keyer designed around the Zilog Z80® microprocessor. The keyer was designed and built by Michael Dinkelman,

WA7UVJ. In addition to eight 2-kbit memories it includes such standard features as iambic operation, dot/dash memories and paddle-controlled message abort. In addition, optional enhancements include a

(A)

(B)

real-time clock, liquid-crystal display and loop options allowing several message positions to perform repetitive tasks automatically. Those dismayed by the finicky storage operations of some memory keyers will find the Mike and Keyer a breeze to load. All these features are available in a package requiring only 10 integrated circuits. The key to all this versatility is that the Mike and Keyer is, in reality, a small computer. Source code for the operating

software is available, and modification of the software should be easy for anyone with a knowledge of Z80 assembly language and access to an EPROM programmer.

The Mike and Keyer can be built in two versions. The simplest is a basic memory keyer. This version contains the standard features listed above, with load/send message indicators displayed by discrete LEDs. The addition of one IC (an Intersil 7170 real-time clock), an LCD module and

several discrete parts allows you to bring all the bells and whistles on board.

Why call it the "Mike and Keyer?" Just a small way of saying thanks to all the members of the Mike and Key ARC in Seattle who provided immeasurable support. Special thanks to Ray Leslie, WA7EKH, who designed the PC board.

### Circuit Description

Fig 9 shows the schematic diagram of the Mike and Keyer. Most apparent are the VLSI (Very Large Scale Integration) chips that are the heart of the Mike and Keyer. The keyer is controlled by U2, the Z80 CPU. The CPU receives its instructions from the 2764 ROM, U4. The ROM contains approximately 3 kbytes of instructions and the LCD message formats.

The 6116L, U5, is the system RAM. A small portion of this chip is reserved for the Z80's internal needs, but the majority is message storage for the keyer. Message memory is organized into eight sections, each one bit wide. The 6116L can store 2 kbytes, so there are approximately

(C)

(D)

Fig 8—The Mike and Keyer, a Z80-based memory keyer, can be built in two versions. The "full dress" version shown at A and B, has an LCD and a real-time clock, along with options in the software that allow repetitive looping of memories. The LCD version is built in a Ten Tec SW-8 enclosure. The "no frills" version (shown at C and D) uses LEDs as indicators and has no real-time clock or looping options. The LED version is built in a Ten Tec FG-7 enclosure. Notice in the interior view at D that the backup batteries and real-time clock have been omitted. Batteries N3 and N4 are not required in the LED version, and N1 and N2 (backup power for the memory) are optional in either version.

(Next page) Fig 9—Schematic of the Mike and Keyer. The circuitry inside the dotted lines is used for the LED version, and the ICM7170 is not required. Unless otherwise noted, all resistors are 1/4 W 5% units and all capacitors are disc ceramic. Printed-circuit boards are available from Leslie PCB<sup>1</sup>.

Y1—32.7680 kHz clock crystal.

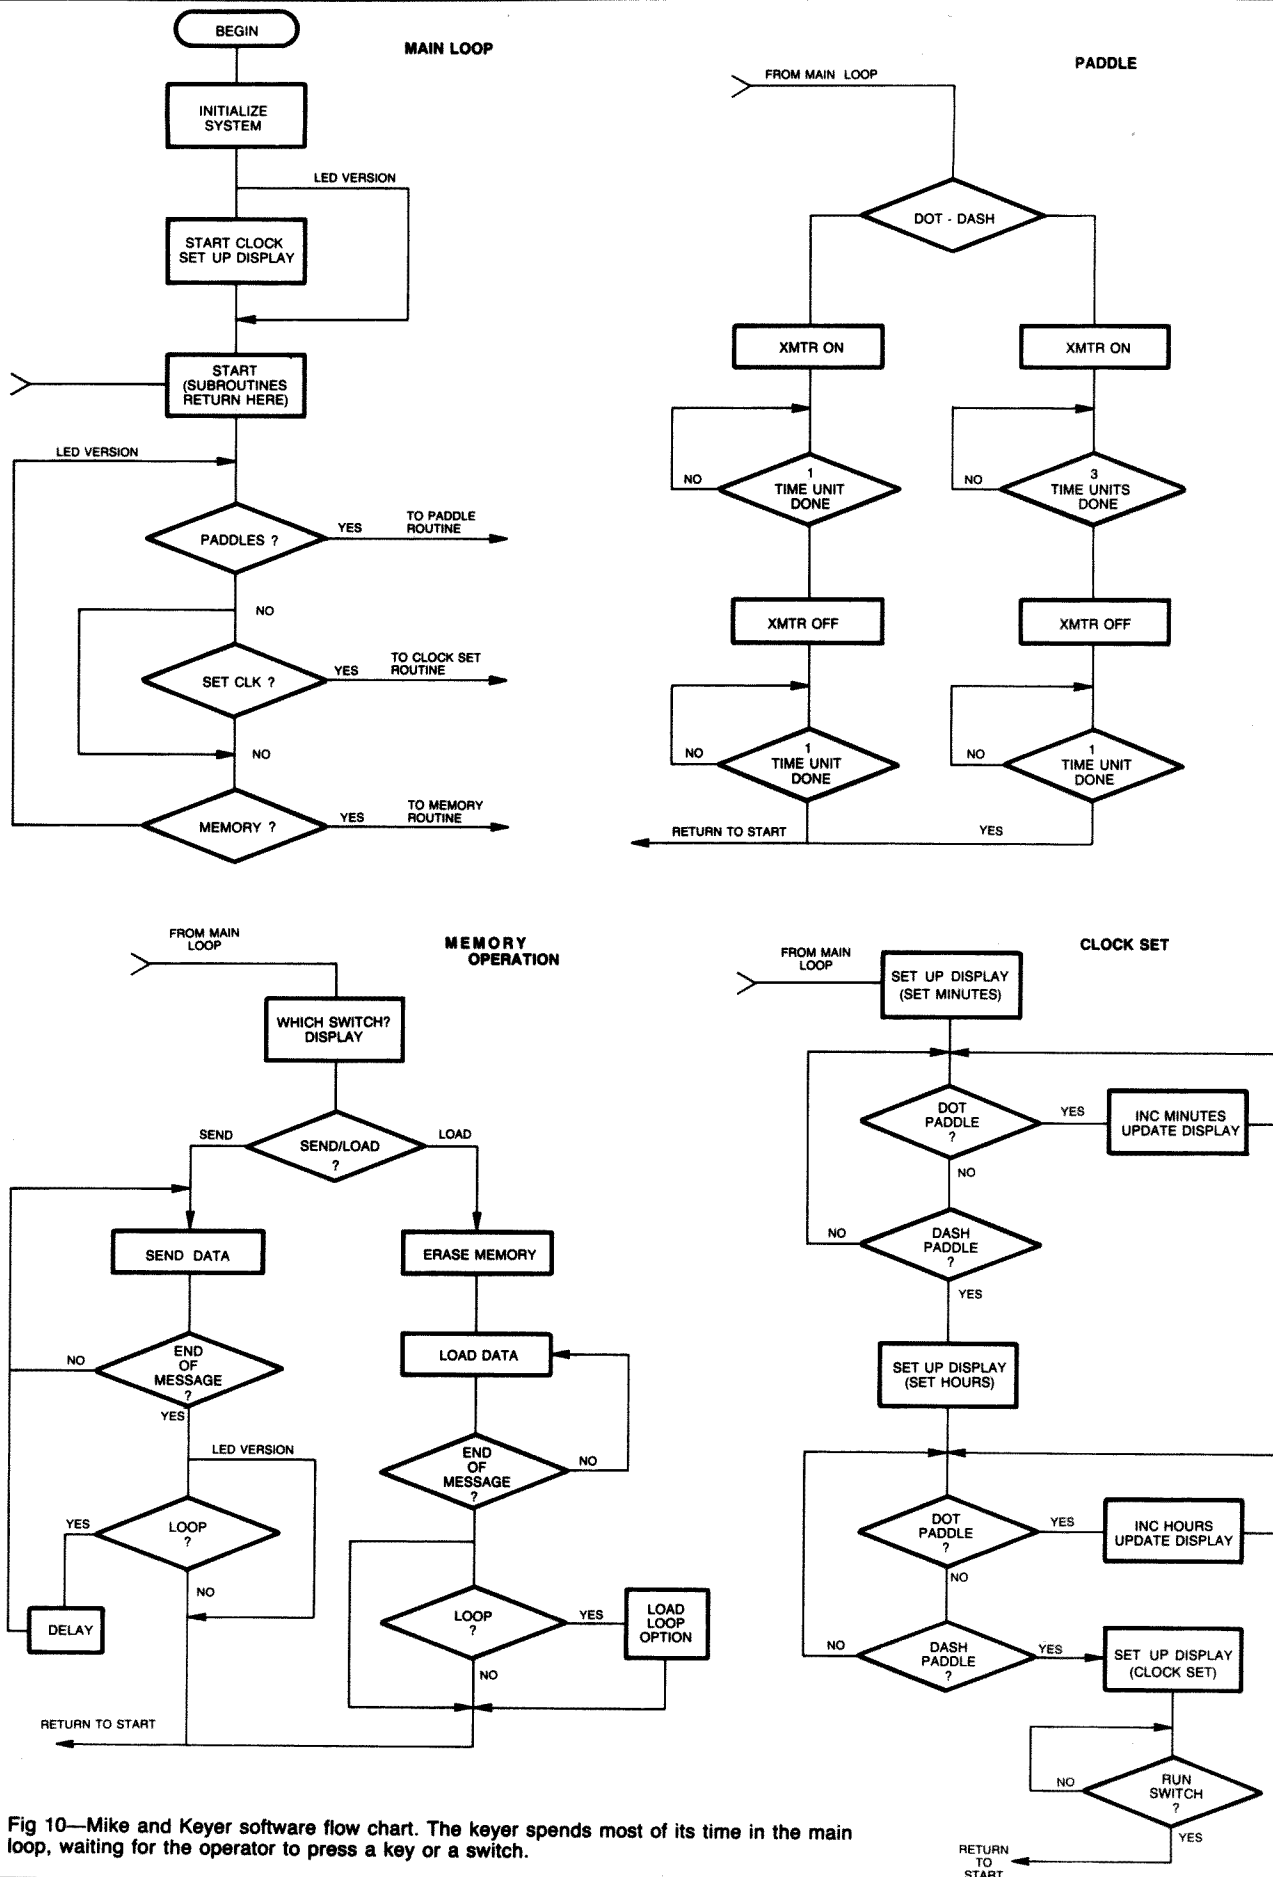

Fig 10—Mike and Keyer software flow chart. The keyer spends most of its time in the main loop, waiting for the operator to press a key or a switch.

2000 bits for each of the eight memory storage areas. Since the typical character takes 10 bits, up to 200 characters can be stored in each memory position. Batteries N1 and N2 enable the memory to retain information while the keyer is off.

U6, an Intersil 7170, is a special device. It is a real-time clock (RTC) designed for easy interfacing with microprocessors. Most important, it has the ability to generate interrupts for the Z80. These periodic "taps on the shoulder" allow the keyer to display a continuous clock on the LCD and to create special repetitive loops with several of the messages. The RTC has its own battery back-up circuit, so it will continue to operate even while the power is off.

The remaining ICs make up the "support circuitry." U1 is the master clock for the CPU. U3 and U7 help select sections of memory or I/O. For inputs, U10 buffers the message select switches, while U12 provides access to the dot/dash paddles and function switches. For output, the LCD or LEDs are controlled by U8 and U9, while U13 and U14 provide interfacing to the radio. Finally, U11 provides the basic timing for the dots and dashes.

### Functional/Operational Description

It would be redundant to describe how microprocessor systems function. Several good books cover the subject as does Chapter 8 of this *Handbook*. The flow chart in Fig 10 shows the Mike and Keyer program logic. After power is applied to the circuit, the unit scans for input from the message or function switches and the paddles. This is how the keyer spends most of its time, waiting for you to press the key or a switch.

Touching a paddle starts a simple but basic sequence of events. To understand these events it is necessary to review the structure of Morse code. A character in Morse code can be broken up into simple time units. A dot is one unit long, a dash is three units long. The space between dots and dashes within a character equals one unit and the spaces between words are seven units long. U11 creates "units" for the Mike and Keyer. Every time U11 is triggered, it turns on for a specified time period determined by its RC network (R13, R15 and C20). This time is monitored by the CPU.

The number of times U11 is triggered is determined by the Morse element to be generated. For a dot, the CPU turns on the transmitter, then triggers U11. When U11 is finished, the CPU recognizes the event, turns off the transmitter, and triggers U11 a second time. This second trigger creates the necessary space required between marks, exactly the same unit length as the dot. A dash works similarly, but once the transmitter is turned on U11 is triggered three times before the radio is unkeyed. After the transmitter is off, U11 is triggered once more to create the mandatory space

		MESSAGE POSITIONS

Fig 11—Mike and Keyer memory organization chart. A one in a memory location means "transmitter on," a zero means "transmitter off." See text for details.

unit. Adjusting the length of U11's timing period with the external speed control (R15) changes the speed of the Morse code generated by the keyer.

Loading code sequences into memory is a little more complicated. Fig 11 shows how the data is stored in the RAM. A byte consists of eight bits, and each byte has a unique address. The starting address for RAM in the Mike and Keyer is 2000 (hex) and the last address reserved for message memory is 2700 (hex). Each individual bit can be defined by a data line (D0 - D7) and its address. Each memory position uses one of the bits in each memory byte. If the transmitter should be keyed when the memory is played back, a "1" is placed in the appropriate bit of the current memory location. If a space between words or characters is required, the keyer stores a "0." Dots and dashes are predefined as discussed above (a dot is a one followed by a zero, a dash is three ones followed by a zero).

Spaces, between dots and dashes or between letters and words, are a bit more difficult; the CPU cannot differentiate between character and word spaces. A free-running clock would load the proper spaces into memory, but this technique is wasteful if the operator pauses while loading a memory. The Mike and Keyer uses a limited run count for spaces in memory. When a memory load is started, spaces are placed in memory until a maximum of ten spaces are loaded. The memory load will then stop until a paddle is touched or the LOAD/RUN switch is set to RUN. Touching a dot or dash paddle will load the appropriate data into memory, reset the spaces counter, and start the memory loading again. Having the memory counter run a maximum of ten spaces between characters allows for a little "swing" in the operator's sending style. Switching the

LOAD/RUN switch to RUN during a pause in loading will complete the loading process. In the unlikely event that the memory is overrun, a warning message will occur and the memory must be reloaded.

"Playing" the memory is a much simpler operation. Starting at address 2000 (hex) the CPU simply examines the bit corresponding to the message requested and turns the transmitter on if it finds a one, or off if it finds a zero. The keyer then triggers U11 and waits for it to time out. Again, the speed of the generated Morse code is controlled by varying the period of U11 with the speed control. Each address is examined in turn until the end of message is reached.

The end of message memory is determined by counting the number of adjacent spaces in the memory. When the message was first loaded, the CPU quickly erased each bit corresponding to the selected memory in all the RAM locations by placing a zero in each bit location. In addition, the keyer will only load 10 spaces (zeroes) before pausing for input and checking the LOAD/RUN switch. All this means that there should never be more than 10 spaces in a row before the end of a message. If the keyer finds more than 10 spaces in a row, we have reached the end of stored memory.

If the RTC and LCD are installed, interrupts every second will update the clock and display. These interrupts occur in the background to the main program and are not noticed by the user.

### Options

Including the real-time clock and liquid crystal display enables certain features of the Mike and Keyer. Some of the memories may be repeated at predetermined intervals. The original Mike and Keyer design provided for four looping options in memory locations six through eight, as well as normal single runs. These loops are set for 15, 30, 120 and 150 seconds. UHF/VHF aficionados will notice that these times correspond to the standard time intervals used in meteor-scatter and moonbounce activities.

A second version of the software provides an option of looping messages six through eight continuously with short pauses, with the pauses adjustable from two to eight seconds in two-second increments. This version may be more useful for HF operations such as calling CQ for DX or during contests. In both these versions any 16-character message can be placed on the first line of the LCD when the function/instructional messages are not needed. This message is permanently installed in ROM, locations 1000-100F (hex). If you like, you can personalize your keyer by having your call sign directly on the display.

The third software version is for the basic keyer without the RTC/LCD installed. It provides for limited function display with

LEDs; no looping or clocks are supported.

### Construction

The Mike and Keyer lends itself to easy home-brew construction. A double-sided PC board is available<sup>1</sup> and is probably the easiest method to avoid wiring errors. If you prefer, wire-wrapping is an option and easily accomplished with a couple evenings work. A wire-wrapped prototype was built by the *Handbook* editor, and the unit worked perfectly from first power-up. As always with IC projects, sockets are a good idea to facilitate troubleshooting and repairs.

U1 is a TTL-compatible clock oscillator. The clock frequency is not critical; clock frequencies from 1 MHz to 2.5 MHz were used successfully during testing. The keyer spends most of its time waiting for the operator, so a fast clock is not required.

The keyer can key a voltage to ground (through Q1) or a 5-V keyed output can be supplied if required (through Q2). The keying transistors should be selected for your transmitter's keying voltage, current and polarity requirements. The keying transistors shown will work with most rigs.

The layout of parts is not critical, but do not skimp on the bypass capacitors that help eliminate transients on the power bus. Digital devices are sensitive to power fluctuations, so a well-regulated and spike-suppressed power supply is mandatory. A metal enclosure should be used to prevent RFI both to and from the keyer—microprocessor systems make good transmitters.

Several CMOS devices are used in the Mike and Keyer. These devices are very sensitive to static charges. Observe good handling procedures when installing these and the other integrated circuits.

A printed listing of the software (in Z80 assembly language) is available from the ARRL Technical Department Secretary for an SASE and \$3. Programmed PROMs or floppy disk listings are also available from WA7UVJ<sup>2</sup>.

Suitable liquid-crystal display modules are manufactured by a number of companies. Versions of the Mike and Keyer have

been built with LCDs from Seiko, Stanley and Phillips; all worked well. Other companies that make suitable displays include Sharp and AND. These modules all use the same basic chip and commands for controlling the LCD matrix, but be aware that the pinouts usually vary from company to company. The schematic covers the Seiko M1632 LCD module—if you purchase another device, get a data sheet with it! Probably the easiest source for the module is from Digi-Key (model AMX216-ND; see Chapter 35 for the address), but almost any large regional electronics supply house stocks a version of this display. The LCD module should consist of two lines of 16 characters in a 5 × 7 format, operate from +5 V dc, and contain its own character set. It must be serially controlled and have eight-bit capability. Normally, the control chips in the module are made by Hitachi.

### Testing

Nothing is more frustrating than a circuit that doesn't work the first time. Most of the problems with prototype Mike and Keyer units were caused by careless assembly processes. Check for cold solder joints, solder bridges or incorrect wiring connections. Be careful when you insert the ICs into their sockets; it takes only a fraction of a second to kill a chip installed backwards. It is most helpful to have a friend check your work for you; many times a different pair of eyes will see mistakes you have missed.

### Adjustment

The LED version of the keyer requires no adjustments. With the LCD/RTC

version, the real-time clock oscillator frequency should be adjusted for most accurate timing. Do not try to measure the crystal directly as loading will give erroneous results. Place a frequency counter or oscilloscope on the Z80 interrupt line (INT) and adjust the trimmer capacitors (C17 and C18) for a 1-Hz reading. Setting the clock time is easy and straightforward. After you place the CLOCK SET/RUN switch to SET, the dot paddle is used to insert the correct values for minutes and hours the dash paddle places the values into memory. The software will prompt you on the LCD. After you set the hours and minutes, setting the clock switch to RUN will start the clock running at zero seconds.

### Operation

The Mike and Keyer is simple to operate. After power is applied, the keyer functions as a straight iambic keyer. To load a memory, switch the LOAD/PLAY switch to LOAD and press the appropriate memory pushbutton. Start sending the code; remember that the keyer automatically stops loading the memory after ten spaces, so this is the longest pause that can be stored in memory. When you are done loading the memory, switch the LOAD/PLAY switch back to PLAY. Playing a memory is accomplished by pressing the appropriate memory pushbutton with the LOAD/PLAY switch in the PLAY position. To abort memory playback, simply press either side of the paddle. Pressing the memory pushbutton again after an abort restarts the memory playback *at the beginning of the memory*.

### Conclusion

As mentioned above, the beauty of the microprocessor approach is its flexibility. The designer of this project hopes that others who like to dabble in software will program new enhancements for the Mike and Keyer. New programs could be written for more effective contesting, DXing, or other CW activities. Please write to WA7UVJ about any projects you undertake (enclose an SASE if you'd like a reply).

<sup>2</sup>Programmed EPROMs and disk listings only (IBM® PC or Commodore 128™ CP/M®) are available from Michael Dinkelman, 637 2nd Ave South, Kent, WA 98032. Send SASE for information.

# A Deluxe Memory Keyer

Here it is—a memory keyer with “all the features” that doesn’t cost a fortune. The memory keyer described here and shown in Figs 12 through 15 is designed around a Curtis 8044-series keyer chip and features the following:

- Optional remote-mounting of the memory pushbuttons
- Ultra-low power consumption—less than 5 mA average
- MOSFET keying outputs to accommodate virtually any rig
- Single, low-profile circuit board
- Uses commonly available, inexpensive ICs
- Can use a nonvolatile memory
- Powered by four AA-size NiCd batteries

One of the major design goals of this keyer was to include as many features as possible while keeping power consumption low and price moderate. This goal was accomplished through the use of 4000 series CMOS logic, a Curtis 8044 series keyer IC and a low-power memory IC. The Curtis keyer IC helps reduce circuit complexity; it is used for dot and dash generation (iambic operation is optional) and weighting (positive or negative). The optional M-series ICs contain a speed meter interface for indication of keyer speed. This keyer was designed and built in the ARRL Lab by Thomas Miller, NK1P.

## Circuit Details

To better understand the circuit, let’s break it down into some basic sections. Fig 13 shows the keyer schematic diagram. The first section is the clock and its control circuitry. The master clock, generated by U19, operates at 16 times the actual speed of the dots. It runs at about 130 to 1100 Hz to achieve a speed range of 7 to 80 WPM (calculated by the Paris method). This master clock is divided to the dot speed by U10 and is synchronized to the rest of the circuit by U5A, U13 and U8A. Upon closing either the dot or dash paddle, U10 is reset to zero and starts counting, supplying U3 with a pulse train. The resulting dot or dash from U3 is fed back via U4A and, upon completion, resets U10. The circuit returns to idle until another paddle closure. The master clock is also used synchronously for read and write cycles of the memory circuitry.

The second section is that of the memory and control, which includes most of the remaining circuitry. One of the most significant features of the read/write control is that of the “mouse” (the push buttons and circuitry that select the memory), which is basically a 1-of-8 encoder. This encoder is used to select and start one of the eight memory strings. It can be used remotely (next to the paddle), or it can be built inside the enclosure.

The mouse schematic is shown in Fig 14.

Fig 12—The deluxe memory keyer can be built with the memory pushbuttons inside the box or mounted in an external “mouse” that can be placed next to the paddle.

Note that only six wires are required to connect the mouse to the main circuit board. This is made possible by U1 and U2, which are used to generate and latch a three-bit word according to the pushbutton pressed. The three-bit word ultimately selects the memory to be used. U3 and its associated components are used as visual feedback. This circuit can be disabled by shorting pins 1 and 2 of P6 when low-power operation is required. Of course, this can also be done using a SPDT switch.

The remainder of the read/write control circuitry is made up of U11, U12 and associated parts. The control circuit allows for the inclusion of switches for starting a read or write function and for automatic repeat of stored messages after a user-defined delay.

An inexpensive, commonly available 2-k  $\times$  8 memory IC (U6) is used for storage. Since the memory is 8 bits wide, it is necessary to write to one of the bits while retaining the others for other messages. This is accomplished by using a feedback loop on the data I/O pins consisting of U1, U2 and feedback resistors R1-R8. Data to be written to the memory is routed through U2 (pins 9 and 10) to the appropriate data line on U1 by the mouse. All other outputs of U2 remain in the high-impedance state, allowing data at the selected address in memory to be fed back (by the feedback resistors) and rewritten to the same location.

The remaining block of the keyer is the interface to the outside world. The sidetone oscillator/amplifier was designed in its simplest form and adds less than 15 mA to the total current consumption at full output. The other part of the interface circuitry is that of the keying outputs. Both grid-block and positive outputs are provided, so this keyer will key almost any transmitter. The keying interface is extremely efficient in operation because of the use of MOSFETs. The manufacturer speci-

fies 8 ohms of on-state resistance, resulting in reliable performance over the long haul.

## Construction

The keyer can be constructed in a variety of ways, such as wire wrap and point to point. Fig 15 shows two printed-circuit board versions that were built by the author. One was built with the mouse contained inside the cabinet. This option can be incorporated in a variety of ways. It is not necessary to include all eight of the memory selection buttons and LEDs, just as many as you need. Connection points for unused pushbuttons can be left open.

PC boards and parts kits for this project are available from A&A Engineering.<sup>1</sup> Use of one of these PC boards is highly recommended. The board measures 5  $\times$  7 inches and is double sided with plated-through holes. All connections to the board are made through connectors to facilitate easy servicing and modification. Table 1 lists the connections to each connector strip.

A template package for this keyer, including PC board parts overlay and drilling information for the front and rear panels, is available from the ARRL Technical Department secretary for an SASE and \$2.00.

A number of features were added to the PC board to aid in operation/construction flexibility of the keyer. For example, the board is designed to accommodate any of the 8044 series ICs. The 8044ABM is recommended if you don’t already have a keyer chip. Strapping options for the 8044ABM allow you to disable or enable iambic paddle operation (Fig 13, connection X1) and to select positive or negative weight control (Fig 13, connection X4). Also available as an option is a meter for relative indication of speed (“M” series ICs only). See Fig 13. The usable range of the meter needs to be 0-50 microamps, so just about any 0-50 or 0-100 microamp meter will suffice.

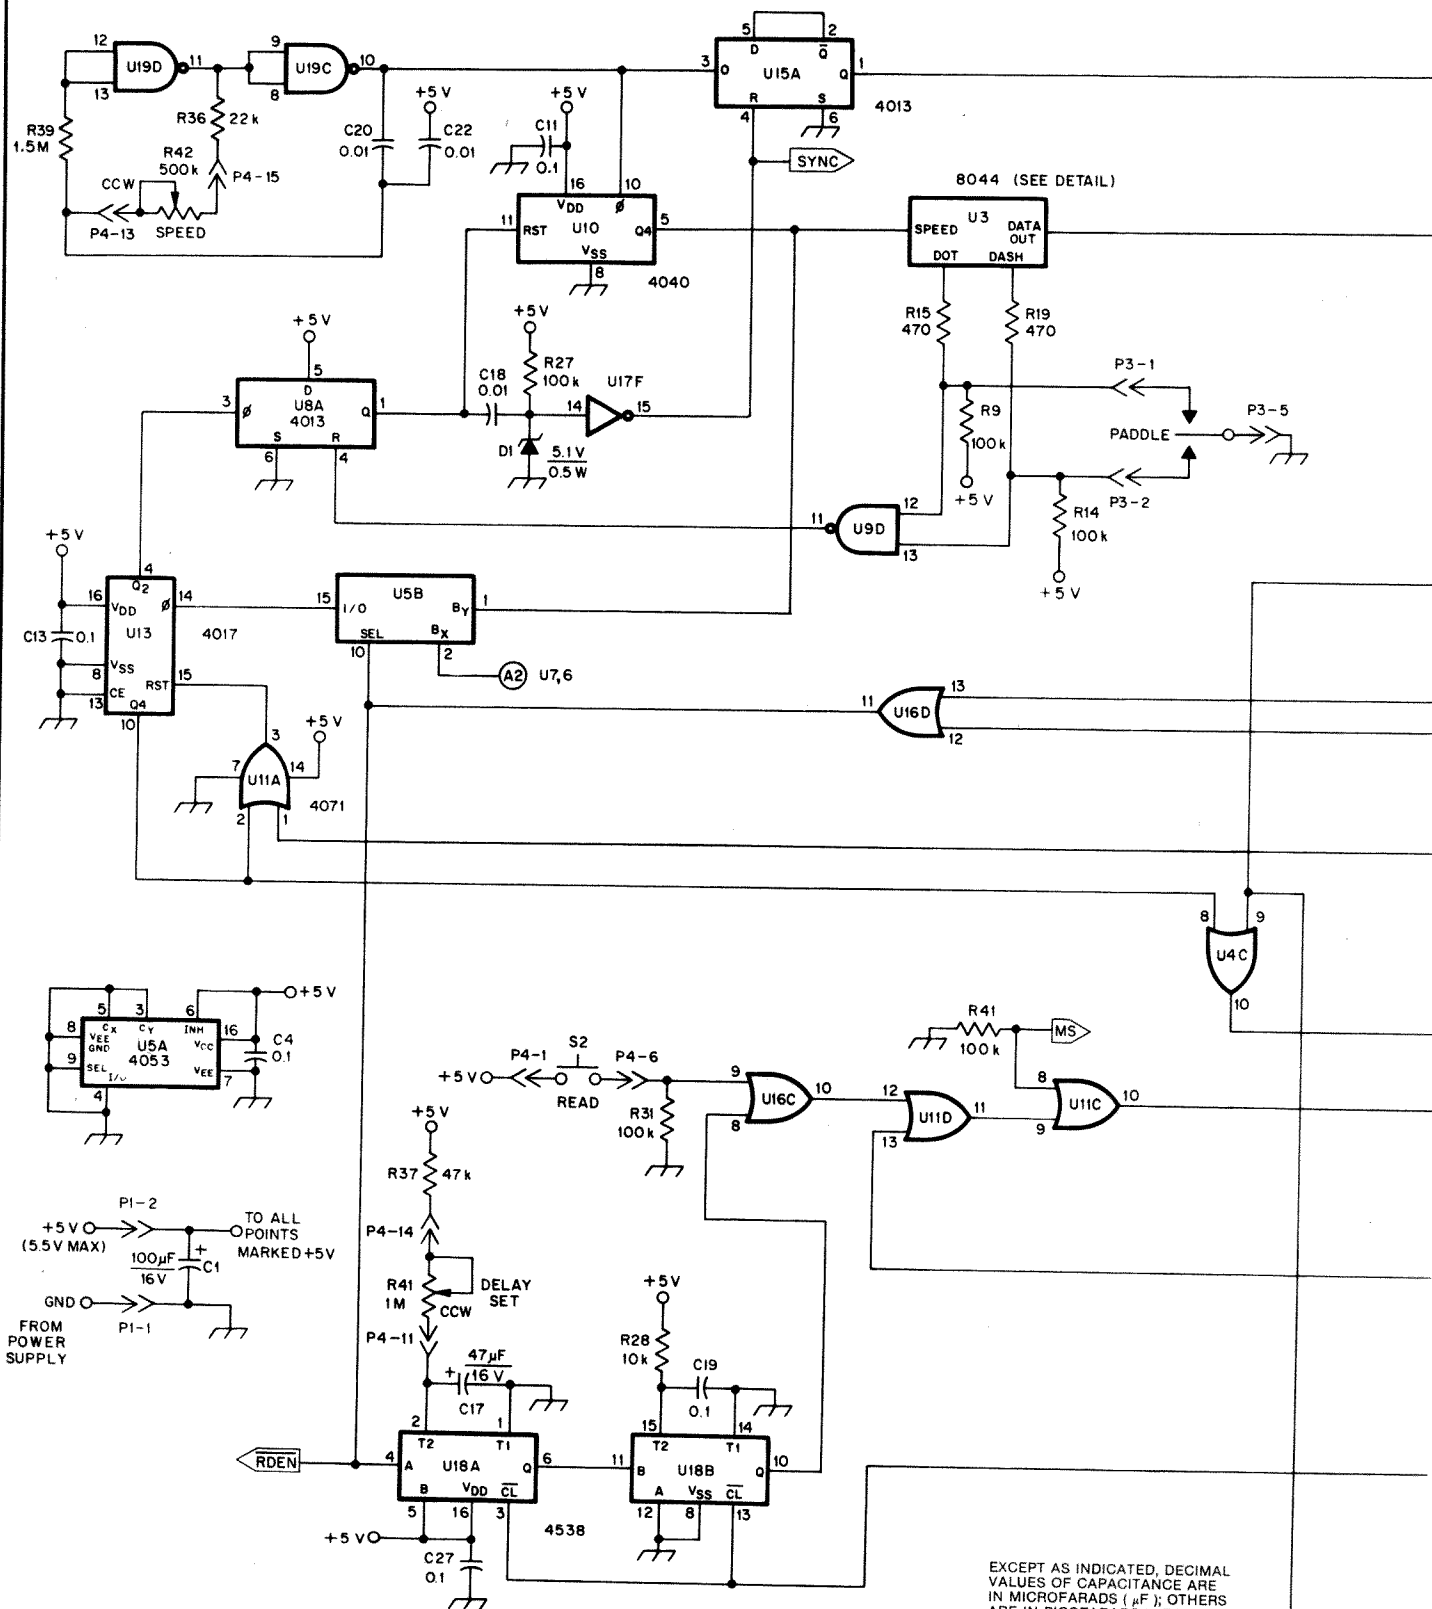

Fig 13 (Page 1 of 3)

EXCEPT AS INDICATED, DECIMAL VALUES OF CAPACITANCE ARE IN MICROFARADS (µF); OTHERS ARE IN PICO FARADS (pF); RESISTANCES ARE IN OHMS; k = 1000, M = 1000 000.

-14	DELAY control
-15	SPEED control

Another feature of the PC board is a provision to enable the keyer to read from an EPROM (Fig 13, connections X2/X3). With J2 installed, a 2716 (or equivalent) can be installed to play back a "canned" message. EPROMs can be read, but not programmed, by the keyer, so those applications will require at least an EPROM programmer. Data is stored in memory as a string of variable length, one bit wide. This enables the keyer to store as many as eight messages, each 2 k long. If you wanted to store a series of messages in EPROM, it would be necessary to first make a listing of each message in ones and zeros (3:1 dash-to-dot ratio). Then you could combine all of the messages into eight-bit words to be stored in the EPROM.

Connection X3 is used to enable the keyer to read and write to RAM. A Hitachi HM6116P-3 is recommended, but just about any 2-k × 8 RAM will work as long as the pin-out is the same. Some memory ICs that have been tried include TMM2016P-1 and TC5517APL (Toshiba) and the XLS2816AC-350 EEPROM (Exel). It is desirable to use RAM ICs with "P" or "LP" suffixes, as they require substantially lower standby currents. When using these ICs, total current draw of the keyer in standby is less than one milliamp!

The circuit will support EEPROM (Electrically Erasable Programmable Read Only Memory) which is the only true nonvolatile RAM. Since EEPROM does not require power to retain memory, it is perfectly suitable for use where battery operation is required, reducing cost by eliminating the need for batteries to back up the RAM. See Chapters 6 and 27 for more information on building an ac-operated 5-V supply.

Keep in mind that all of the integrated circuits used are CMOS and are sensitive to static discharge. Use standard CMOS handling precautions. A metal enclosure will help prevent RF from getting into the unit.

All of the parts are quite common (with the exception of the 8044) and can be obtained from most surplus houses. Many suitable suppliers are listed in Chapter 35.<sup>2</sup> Capacitors can be inexpensive ceramics or electrolytics with the exceptions of C17 (tantalum) and C20, C21 and C22 (polystyrene) for stability. The audio output transformer is a general-purpose device, with a 1-k $\Omega$  center-tapped (or 500-ohm) primary, and an 8- $\Omega$  secondary.

The circuit runs from 5-V dc and can be powered for considerable lengths of time by a NiCd battery pack. Please note that you should *never apply more than 5.5 V* to the circuit; greater voltage will damage the RAM and other ICs. Fig 13 shows two

possible power-supply configurations. One uses a 7805 three-terminal regulator to provide the necessary voltage. The other incorporates a constant-current charger and battery backup. If you choose to use the NiCd battery pack, check the voltage before connecting the batteries to the keyer. If the battery pack has been charged to more than 5.6 V, let the pack discharge through the Zener for 24 hours or until the voltage drops below 5.6 V.

### Testing and Operation

Once the unit has been built, the fun can begin! Start by double checking all connections. This may seem a little tedious, but it is well worth it in the long run. Once you are sure that the unit is wired correctly, apply power. Rotate the volume control to maximum, and upon closing the paddles, you should hear a repetition of dots and dashes. If not, try rotating the volume control in the opposite direction (it might have been wired backwards). Once you hear dots and dashes, rotate the tone and speed controls to the desired positions. Send a few words to get used to the "feel." If you have included the speed meter option, R25 on the PC board is used to set the relative position.

When all of the basic keyer functions are working, test the memory. If you are using an external mouse, connect it at this time. Press the pushbutton for the memory that you want to program (1 to 8). Press WRITE

<sup>1</sup>Contact A&A Engineering, 2521 W. LaPalma Ave., Unit K, Anaheim, CA 92801, tel. 714-952-2114, for the latest information.

<sup>2</sup>In addition to the suppliers listed in Chapter 35, the following may be of help:

Curtis Electro Devices, Box 4090, Mountain View, CA 94040, tel. 415-964-3846.  
Jameco Electronics, 1355 Shoreway Rd., Belmont, CA 94002, tel. 415-592-8097.  
JDR Microdevices, 1224 S. Bascom Ave., San Jose, CA 95128, tel. 408-995-5430.

once and then key in a short CQ or your call. Remember that data is not written to the memory until the first paddle closure. Do not leave too much space between words; the memory will interpret this as the end of the message. If you make a mistake, simply press WRITE again and start over. It is not necessary to press a mouse pushbutton again unless you intend to write to a different memory. Once you have completed the message to be stored, wait the equivalent of five dashes or more and press ABORT.

To play back the stored message, simply press the mouse pushbutton that corresponds to the memory you just programmed, and the message should be played back exactly as sent. If the mouse is not connected, you can play back the memory by pressing READ. If your

message stops in the middle, chances are that the keyer interpreted a long space as the end of the message; this is how it achieves variable message length.

To use the auto-repeat feature, rotate the DELAY pot counter clockwise and press AUTO. The message currently selected by the mouse will be played, then there will be a pause (set by the DELAY pot), and the message will be played again. This will continue until ABORT is pressed or one of the paddles is closed.

Next, test the keying outputs by connecting the appropriate output to a radio. Be sure to check your owner's manual for the specification of the voltage and current present on the key terminals, as the maximum drain-to-source rating of the keying MOSFETs (Q3 and Q5) is 60 V at 400 mA.

If you are not sure which type of keying output is required, again check the owner's manual. This completes the testing. CQ DX CQ DX CQ DX DE...

If you have used the unit for a few QSOs and feel that the paddles just don't feel quite right in either iambic or non-iambic modes, a slight capacitor value change might be in order. There are two one-shots on the 8044 (one for the dot, one for the dash) that are used to briefly inhibit their respective paddles. This feature, sometimes called "anti echo," prevents insertion of extra dots or dashes. To adjust the feel, alter the value of C5 (for the dash paddle) or C6 (for the dot paddle) by an order of magnitude. This is strictly trial and error, and be sure to take your time if you decide to try this.

## The W2IHY Audio Memory Keyer

A digital voice recorder (called a DVR, or audio keyer) is the audio equivalent of a CW memory keyer. A CW memory keyer stores Morse code messages for retransmitting. A DVR stores digitized audio messages for retransmission. Digital voice recorders are gaining popularity with SSB/FM contesters. With a DVR, memory segments can be loaded with short, frequently used messages (such as CQs and contest exchanges). These messages can then be easily retransmitted. Other uses for the audio keyer include record and playback of received audio during a QSO and voice identification for a repeater. In a few years audio keyers will be as common a station accessory as CW memory keyers are today.

The audio keyer shown in Figs 16 through 18 was designed and built by Julius Jones, W2IHY.

W2IHY thanks Herb and Barbara Sweet, (K2GBH and WA2KCL) for their assistance with the project writeup. The audio keyer has the following features:

- 1) Four message memories each capable of storing up to 10 seconds of digitized audio
- 2) A message write/read (record/send) indicator
- 3) A microphone gain indicator
- 4) A built-in audio monitor
- 5) The ability to repeatedly read (send) a selected memory
- 6) Adjustable delays between repeats
- 7) Electronic control of transmitter push to talk (PTT)
- 8) Adjustable PTT sensitivity and delay controls
- 9) Voice-activated reset (VAR)
- 10) Adjustable VAR sensitivity control
- 11) Battery back-up capability

The audio keyer is designed using commonly available components, including 74HC series high-speed CMOS, 256k × 1-bit dynamic random-access memory

Fig 16—The W2IHY Audio Memory Keyer can store four messages, each containing up to 10 seconds of audio.

(DRAM) chips, LM1458N operational amplifiers, linear voltage regulators and an Analog Devices eight-bit analog-to-digital / digital-to-analog converter (ADC7569JN) containing an on-chip track and hold circuit.

The audio keyer can be constructed, using all new parts, for about \$185. A single-message version can be built for about \$130 by replacing the 256k DRAM ICs with 64k ICs (150 ns or 120 ns). The single-message keyer may be later upgraded to full capacity simply by installing 256k ICs. All the parts are available from Jameco Electronics<sup>1</sup> and Mouser Electronics<sup>2</sup> except the A-to-D converter which is available from Analog Devices<sup>3</sup>.

The keyer has been used in high RF

environments without any problems. It has also been used in a multi-band SSB contest. On-the-air tests indicate that other stations find it difficult to distinguish between live signals and keyer-generated signals.

### Circuit Description

The schematic of the DVR is shown in Fig 17, and a block diagram of the keyer is shown in Fig 18. Audio from the microphone is amplified through two cascaded operational amplifiers. The audio microphone level control (R49) sets the gain of the second stage of amplification.

The output of the microphone amplifier is sent to a six-pole unity-gain low-pass filter and to an analog audio switch. (The audio switch will be discussed later.) The low-pass filter removes high frequencies present in the amplified microphone signal. The 3-dB cut-off frequency of the filter is 1.8 kHz.

The output of the microphone low-pass filter is sent to the analog-to-digital converter (ADC), microphone-level indica-

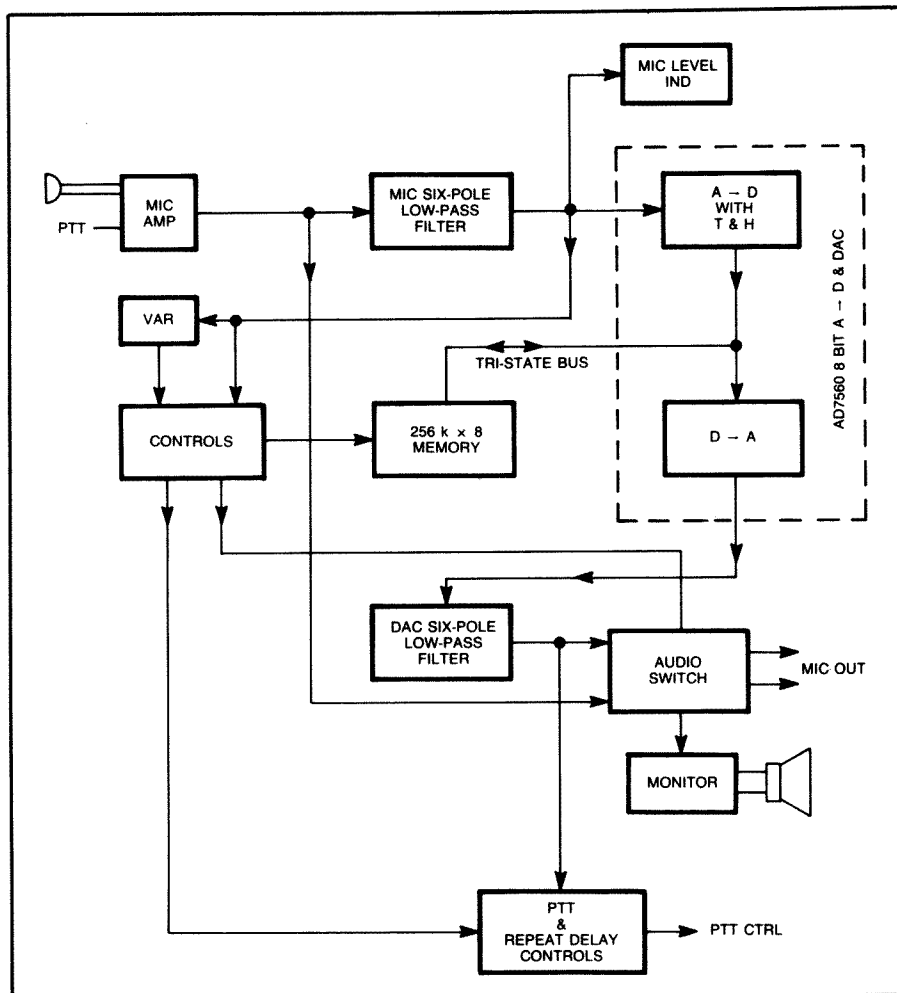

Fig 18—Block diagram of the audio keyer. See text for a discussion of this diagram.

tion circuitry and VAR circuitry. The ADC samples the low-pass filter output and converts it into an 8-bit data word.

Signals sampled by the ADC exceeding  $\pm 1.25$  volts will be clipped to  $\pm 1.25$  volts. The microphone level LED (DS1) provides visual indication when the input level to the ADC is near  $+1.25$  V. The microphone-level indicator is turned on when the ADC is sent a signal from the microphone low-pass filter exceeding 0.9 V. The microphone low-pass filter output is also sent to the voice-activated reset (VAR) circuitry. When activated, VAR allows the audio keyer to be reset when you speak into the microphone. This is analogous to resetting a CW memory keyer by tapping the paddle. VAR sensitivity potentiometer R47 establishes the microphone low-pass filter level that will reset the keyer.

The output of the ADC is sent to eight  $256k \times 1$  DRAM chips. The control circuits allow the digitized microphone input to be stored in the memory.

To send (play back) data stored in memory, an eight-bit word is read from memory and sent to the DAC, where the data is restored to analog form.

The output of the DAC is sent to a six-pole low-pass filter. (The DAC low-pass

filter is identical to the microphone low-pass filter.) This filter removes high-frequency components from the DAC-generated analog signal.

The output of the DAC low-pass filter is sent to the analog audio switch and to the push-to-talk controls. During playback, audio in analog form is gated from the DAC low-pass filter through the analog switch (transistor Q2). When the keyer is not sending or writing, the analog switch selects audio from the microphone amplifier (transistor Q1). During a write operation neither the microphone amplifier nor the DAC low-pass filter are gated through the analog audio switch.

Audio gated through the analog switch is sent to output level control R44 and to the speaker monitor amplifier. T1 provides isolation between the keyer audio output and the microphone input of the transceiver. R44 is adjusted to drive the attached transceiver to the appropriate audio level. The output of the analog switch is also sent to the speaker monitor. Control R48 adjusts the monitor volume.

The PTT controls detect audio sent from the DAC low-pass filter. When audio is detected, transistor Q3 grounds the transceiver's PTT. Adjustment of the PTT sen-

sitivity control (R45) determines the DAC low-pass filter level that will ground the transceiver's PTT. The delay (PTT) control (R46) determines the length of time Q3 is grounded after the absence of detected audio from the DAC low-pass filter.

The control circuits provide the following functions:

- 1) crystal control timebase
- 2) refresh control for the dynamic RAMS
- 3) interfaces to various front-panel controls including memory select push-buttons (S1-S4), reset pushbutton (S5), repeat switch (S7), repeat delay (R59) and send/write switch (S6).

When a memory button is pressed, the position of the send/write switch (S6) determines whether the selected memory is loaded with microphone audio or played to the transceiver. During a write operation, the VAR and repeat functions are disabled and the audio being recorded is not gated through the audio switch.

Sending recorded data with repeat on causes the selected memory to be continuously read. Sending (with or without repeat on) may be stopped by pushing the reset button, pushing (enabling) the microphone PTT or using the voice activated reset (VAR). The repeat delay function allows the user to select the amount of time between delays. The repeat delay time-out begins when the microphone PTT is disabled (transceiver PTT unkeyed). Enabling the microphone PTT prior to completion of the repeat time-out resets the timer.

The following example is meant to clarify the operation of repeat delay. Each memory may contain up to 10 seconds of audio. Suppose that memory number one contains six seconds of audio followed by four seconds of no audio. Memory number two contains four seconds of audio followed by two seconds of no audio, followed by three seconds of audio and one second of no audio. Repeat is on and repeat delay is set to six seconds. If memory number one is read, the message will be repeated every 12 seconds. If memory number two is read, the message will be repeated every 15 seconds. The minimum delay in a repeat time-out is a few milliseconds. The maximum delay in a repeat time-out is about 20 seconds.

The Memory In Use LED (DS2) is turned on during a send/write operation. At the completion of reading from or writing to memory, the LED is turned off. During a repeat operation that takes more than 10 seconds, the Memory In Use LED stays on for only the first 10 seconds of the operation (only when the memory is being read). Referring to the previous example, if memory number one is read with repeat on, the Memory In Use LED will remain on for 10 seconds and will be turned off for two seconds. If memory number two was read, the Memory In Use LED would remain on for 10 seconds and would be turned off for five seconds.

## Construction

Point-to-point or wire-wrap methods can be used to construct the keyer. A glass-epoxy double-sided board with plated-through holes, solder mask, and a silk-screened parts-placement pattern is available from W2IHY<sup>4</sup>. With this board it is recommended that sockets be used for all of the ICs. Also, all components should be soldered to the board with a low-wattage soldering iron (25 to 40 watts). The board measures 5.5 by 9.375 inches.

Wiring most switches and potentiometers to the PC board is accomplished through 16-pin IC sockets J4 and J5. Two single-ended 24-inch 16-pin DIP jumpers are connected between the various panel LEDs, potentiometers and switches and the sockets on the PC board. The schematic diagram and Table 1 provide details of the connections.

The memory select and reset pushbuttons SI through S5 can be connected to the board through either IC socket (J4 or J5). If one socket is used to connect front-panel switches to the board, the other socket may be connected to an external source (through a connector) to provide remote control of the keyer. It is important to use shielded cables as shown on the schematic. Decoupling capacitors must be used at the power connectors (0.1  $\mu$ F) and at the microphone input connections (0.01  $\mu$ F) to the keyer. Spurious signals will be heard if the capacitors are omitted. Power (ac or dc) entering the keyer must first be grounded on the PC board to prevent ground loops. In the prototype, this was accomplished by using a three-conductor miniature stereo plug and jack for the power connectors.

## Power Supply

The audio keyer may be powered by either a 9 to 12 V ac supply or a 10 to 20 V dc supply. Battery backup may also be used for short periods. If only 12 V dc or battery back up operation is desired, diode D14 may be removed. If only ac operation (without battery backup) is desired, components D11, D12, D15, U36, R41, R42, C8, C13 and C14 are not necessary. The battery backup voltage should never exceed the voltage on capacitor C47.

## Crystal Frequency Selection

The crystal frequency should be selected to optimize audio bandwidth and message size while considering the minimum refresh rate. All memory cells must be refreshed within 4 milliseconds. The minimum crystal frequency that will do this is 2.048 MHz. The following equation defines (for a given crystal frequency) the message length in seconds.

Table 1

### J4 and J5 Pin-outs

J4 Pin	Signal	J5 Pin	Signal
1	VAR sensitivity R47	1	Repeat delay potentiometer R59
2	VAR reset to switch S10	2	Memory pushbutton S2
3	PTT sensitivity potentiometer R45	3	Memory pushbutton S4
4	PTT delay potentiometer R46	4	Memory In Use LED DS2
5	PTT from microphone	5	Send/write switch S6
6	Memory pushbutton S1	6	Ground
7	Memory pushbutton S3	7	Repeat switch S7
8	Keyer pushbutton S5	8	Keyer Reset pushbutton S5
9	Audio out to speaker	9	Repeat switch S7
10	Memory pushbutton S4	10	Power on LED DS3
11	Memory pushbutton S2	11	Microphone Level LED DS1
12	PTT out to transceiver (to S11)	12	SEND/WRITE switch S6
13	Ground	13	Not used
14	PTT sensitivity potentiometer R45	14	Memory pushbutton S3
15	VAR reset (from switch S16)	15	Memory pushbutton S1
16	+5 V VAR sensitivity potentiometer R47	16	+5 V to repeat delay potentiometer R59

Message Time (in seconds) =

$$\frac{\text{Memory Size} \times 1024}{2 \times \text{Crystal Frequency (in hertz)}}$$

Using a 3.2768 MHz crystal, it will take 10.24 seconds to load one 65,536 8-bit word memory segment. It is recommended that a crystal between the frequencies of 3.0 MHz and 3.6 MHz be used. Using a crystal with a frequency below 3 MHz will require modifying the response of the low-pass filters.

## Wiring Options

**Microphone Impedance**—The microphone amplifier shown in the schematic is designed to work with a low-impedance microphone. A high-impedance microphone may be used if the following component values are used: R31 = 47k, R35 = 470k, R32 = 47k.

**Microphone Level**—Control of the microphone amplifier gain is provided by potentiometer R49. Increasing the value of R49 increases the microphone amplifier gain.

**PTT Sensitivity**—Potentiometer R45 controls the sensitivity of the PTT circuitry. Increasing the resistance of R45 increases the PTT sensitivity.

**PTT Delay**—Potentiometer R46 controls the hold time of the push to talk circuit. Decreasing the voltage on the wiper of R46 increases the PTT hold time.

**Audio Output Level**—Potentiometer R44 controls the audio keyer output level. Increasing the resistance of R44 increases the keyer analog output level.

**Monitor Volume**—Potentiometer R48 controls the monitor audio output volume. Increasing the resistance of R48 will increase the monitor volume.

**Voice Activated Reset Sensitivity**—VAR sensitivity controls the microphone audio level that resets the audio keyer. As the voltage on the wiper of R47 is increased, higher microphone audio levels are required to reset the keyer.

**Repeat Delay**—Potentiometer R59 controls the delay between reading and reread-

ing the memory. Increasing the resistance of R59 increases the delay between repeats.

## Operating the Audio Keyer

When power is first applied to the keyer it may be sending or writing. Press the reset button or microphone PTT to cancel these operations. This will return the keyer to a known state.

## Message Writing

While you talk into the microphone, adjust the microphone level control (R49) until the microphone level indicator (DS1) begins to light. Next set the send/write switch (S6) to the write position. Push one of 4 memory pushbuttons to load (write) a memory. *Do not press your PTT button at this point*; this will reset the keyer. The Memory In Use indicator (DS2) will stay on until the selected memory is full. It takes about 10 seconds to load a particular memory. During write operations the repeat, monitor output and VAR functions are automatically disabled.

## Message Sending

Set the send/write switch (S6) to the send position. Turn off the repeat and VAR switches. Press one of the four memory pushbuttons to begin the send operation. The Memory In Use indicator (DS2) will stay on until the memory read operation is completed. Again, do not press the PTT switch at this point; this will reset the keyer.

## PTT Sensitivity and PTT Delay

Follow the message sending procedure. Adjust the PTT delay to mid scale. Adjust the PTT sensitivity (R45) until the transceiver's push to talk is enabled. Adjust the PTT delay potentiometer (R46) for the desired hold time, and readjust the PTT sensitivity control if necessary.

## Repeat and Repeat Delay

PTT sensitivity and PTT delay *must* be adjusted for desired operation. Turn on the repeat switch (S7). Follow the message sending procedure. Adjust R59 to obtain

<sup>4</sup>PC boards and information available from: Julius D. Jones (W2IHY), 15 Vanessa Lane, Staatsburg, NY 12580, tel 914-889-4933.

the desired spacing between messages.

#### VAR and VAR Sensitivity

Turn on the Voice Activated Reset (VAR) switch (S10). Follow the message sending procedure. Talk into the microphone. Adjust the VAR sensitivity control (R47) until the keyer is reset.

#### Transceiver PTT Operation

Transceiver PTT operations may be activated by turning on switch S11 and

either sending a message from the keyer or by pushing the microphone PTT. When the microphone PTT is depressed, the keyer is reset. Audio from the microphone is amplified and sent to the transceiver and the transceiver PTT is grounded (activated). Switch S11 should be turned off if VOX operation is desired.

#### Keyer Bypass

A four-pole double-throw switch (S9) is

used to switch either the audio keyer or the microphone to the audio output jack. If S9 has switched the microphone directly to the transceiver, the keyer need not be powered on for the microphone and its PTT to be used with the transceiver.

#### Audio Output

The audio output control (R44) should be adjusted to drive the transceiver to the same audio level that is obtained from a directly connected microphone.

## BOB—An RS-232-C Break-Out Box

The EIA RS-232-C interface standard greatly simplifies the interconnection of digital devices. When something goes wrong at an RS-232-C interface, however, the 25 signal lines and two equipment configurations—data terminal equipment (DTE) and data-circuit terminating equipment (DCE)—can easily confuse the troubleshooter. The RS-232-C break-out box (BOB) is a piece of test equipment used to simplify RS-232-C troubleshooting. Jeff Ward, K8KA, designed and built the break-out box described here in the ARRL lab.

Break-out boxes can be simple or very complex. In its simplest form, a break-out box displays the polarity of the voltage on an RS-232-C line. Deluxe break-out boxes monitor and change the voltages on several RS-232-C lines and alter the wiring at the interface between two RS-232-C devices. The deluxe break-out box is powerful, but expensive. Fortunately, many of the problems that amateurs will encounter can be diagnosed with a relatively simple break-out box.

#### BOB

This project (Figs 19-23) describes the construction and use of BOB, an average break-out box. BOB is inexpensive, yet useful in many situations. It has the following features: a male and a female DB-25 connector at each end; a patch bay that allows any of the 7 most important lines at one end to be patched to any of the lines at the other end; the ability to set any line to +12 V or -12 V; and bi-color LEDs to indicate the polarity of the voltage on each line.

The circuit (Fig 20) is simple. Each of the signal lines (2, 3, 4, 5, 6, 8 and 20) is brought from the DB-25 connectors to the DIP socket in the center of the BOB. The DIP socket acts as a patch bay. Any line from one pair of connectors can be patched to any line on the other pair. Each line is attached to a DPDT center-off toggle switch. One position of the switch sets the line to +12 V; the other position sets the line to -12 V. The OFF position lets the line "float" at the voltage applied to it by devices attached to BOB. Bi-color, polarity-

Fig 19—The final version of the RS-232-C break-out box uses PC-board construction. The prototype, built on a perforated board using wire-wrap techniques, performed just as well.

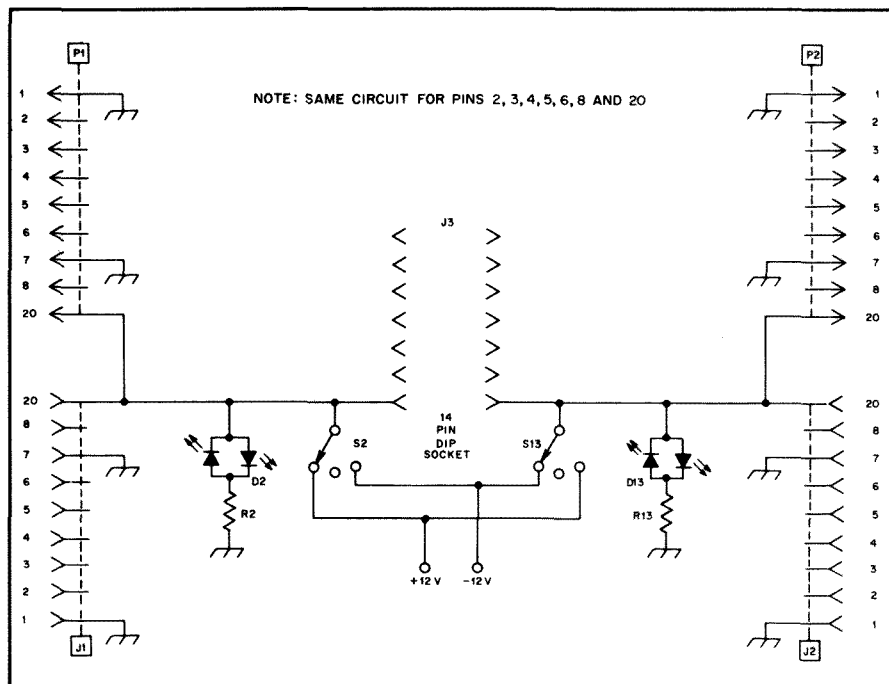

Fig 20—Schematic diagram for the RS-232-C break-out box. The same circuit is used for pins 2, 3, 4, 5, 6, 8 and 20.

D1-D14—Bi-color LEDs (Jameco #XC5491 or equiv.).  
J1, J2—DB-25-F (AMP 206584-2 or equiv.).

J3—14-pin DIP socket (3M 214-3339 or equiv.).  
P1, P2—DB-25-M (AMP 206604-1 or equiv.).  
R1-R14—1.2 kΩ, 1/4 W.

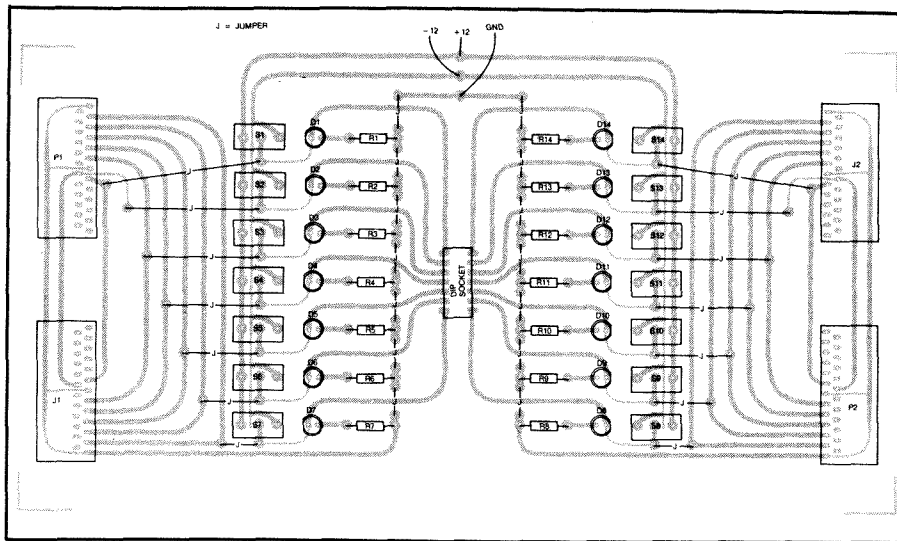

Fig 21—Parts-placement guide for the RS-232-C break-out box, shown from the component side of the board. A full-size etching pattern appears at the back of this book.

indicating LEDs with current limiting resistors display the polarity of each line.

If BOB is to be used to set voltage levels on RS-232-C lines, an external  $\pm 12$ -V power supply is needed. In this case, the ground from BOB should be connected to the power supply ground. Otherwise, BOB should be grounded to the unit(s) under test.

### Construction

The prototype for BOB was built on a perforated-board chassis using wire-wrap techniques. The LEDs were mounted on the top of the board, while the switches were mounted through the board using standard mounting hardware. Although not as refined as later PC-board models, the prototype performed well in the ARRL lab.

To avoid the complicated, time-consuming wire-wrap process, a printed circuit board was designed for BOB. All components, including the switches, LEDs and DB-25 connectors, are mounted directly on top of the board. Because the board is single sided, some jumpers are necessary. Parts placement is shown in Fig 21. Be careful to insert all of the LEDs in the same direction, with their longer leads toward the center of the board. A full-size etching pattern for this board can be found at the back of this book.

### Partial Construction

If you do not want to invest in a complete set of parts for BOB, you can construct part of the circuit. If you populate one-half of the board, you will be able to use your BOB for everything but in-line monitoring. Installing only the LEDs results in a fine RS-232-C monitoring device. Of course, you can leave one of the DB-25 connectors off of each end and

simply have a less versatile BOB. If you initially construct a partial BOB, you can add the remaining components at any time.

### The Patch Bay

The prototype had a female DB-25 connector in the center of the board for use as a patch bay. The PC-board version uses a 14-pin zero-insertion-force (ZIF) DIP socket (Fig 22). The DIP socket, although smaller and more delicate than the DB-25, is the better choice. A 7-circuit DIP switch can be inserted into the socket and used to switch through or interrupt any of the 7 RS-232-C lines. DIP component headers can also be used to wire various patch bay configurations. Although any 14-pin DIP socket will work, one with zero- or low-insertion force makes changing patches or switches much easier.

Fig 22—The zero-insertion-force DIP socket in the center of the break-out box can hold DIP headers with various jumper configurations.

### Potential Problems

Before you use BOB, you should understand two circuit shortcomings. First, BOB draws current from the unit under test. Second, unless you are careful, you can use BOB to create short circuits.

BOB draws current from the circuit under test to light the polarity-indicating LEDs. Using current from the circuit being monitored eliminates the need for active buffers, transistor switches, and a power supply. However, it means that BOB loads the RS-232-C device hooked to it. In extreme cases, this loading may interfere with circuit testing. If you suspect this is the case, use an oscilloscope or VOM to check circuit voltages. If positive voltages are much below 12 V or negative voltages are much above  $-12$  V, the circuit is overloaded.

It is possible to switch a line to  $+12$  V on one side of the patch bay, patch it across to the other side, and then switch it to  $-12$  V. This will short-circuit your power supply. You will also cause a short circuit if you attempt to reverse the polarity of an RS-232-C line which is being driven by the equipment under test. Be sure that you do not attempt to set one line to two levels, and be sure that the equipment under test is not setting a line that you are trying to set with BOB. If you are careful, you will not be bothered by the economies in BOB's design.

### Using The Break-out Box

You should become familiar with the material in Chapter 19 concerning the RS-232-C interface. While only the numbers for the various lines will be referred to here, the full names of the lines can often give insight into their functions. It is also valuable to know which type of device, DCE or DTE, generates each signal.

When you are familiar with the RS-232-C interface, and familiar enough with BOB to understand its limitations, you will be able to begin using it. It is impossible to anticipate every configuration of BOB that will be useful. However, descriptions of a few common problems and how BOB is used to solve them can help you learn how to use it.

### Activating DCE

It is often necessary to test a modem or other piece of data-circuit terminating equipment (DCE) without having it attached to a computer. To activate a DCE, lines 20 and 4 must be set to  $+12$  V. To do this, use BOB with no jumpers in the patch bay and a power supply attached. Put all of BOB's switches in the OFF position. Connect the DCE to one of BOB's DB-25 connectors, and set the switches for pins 4 and 20 to the  $+12$  position (Fig 23A). Be sure to use the switches on the same side of the patch bay as the DB-25 that you are using. Now, assuming that the DCE is a modem, you should see a carrier at its analog output.

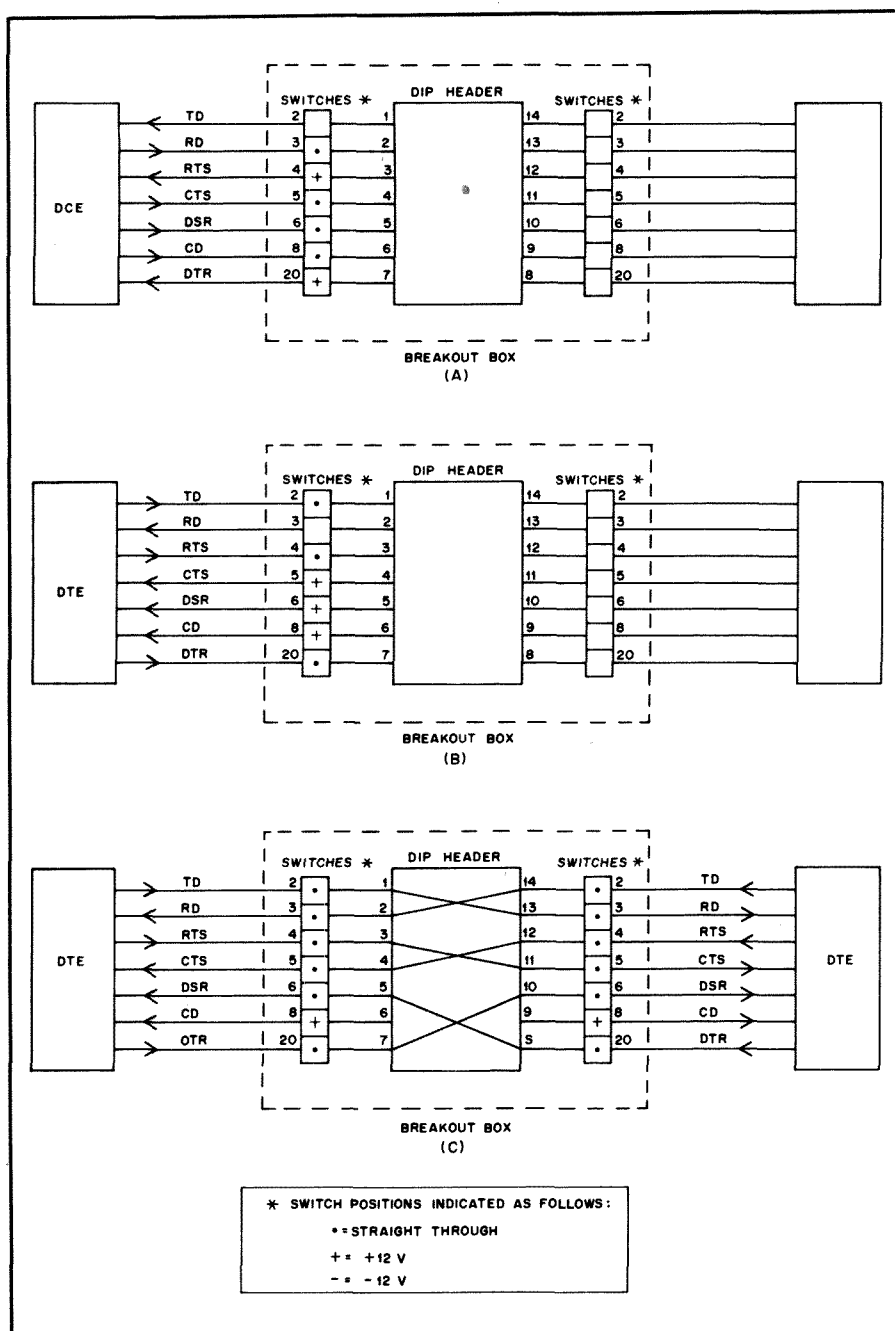

Fig 23—A shows how to use the break-out box to activate a DCE device. To activate a DTE device, use the switch settings shown at B. The jumpers and switch settings shown at C configure the break-out box for connecting two DTE devices.

By setting the switch for line 2 (transmitted data) to +12 V you should be able to change the tone coming from the modem.

LEDs should indicate that the modem is

setting pins 5 and 6 to +12 V. These lines are used to activate equipment attached to the modem. If they are inactive, or remain at -12 V, then a device attached to the

modem might never send any data.

If the modem does not respond correctly, then you have learned that it is not operating as a standard DCE device. Further troubleshooting is in order. If the modem does respond as predicted, you know that any problems you have are caused by some other piece of equipment.

### Activating DTE

BOB can also be used to activate a data terminal equipment (DTE) device, such as a terminal, to see if it is operating correctly. When BOB is configured as shown in Fig 23B, data sent by the DTE should appear as flickering of the LED on line 2.

If the data does appear, there are still some things you should use BOB to determine: Does the DTE set line 20 to +12 V? Many DCE devices must have this line set to +12 V. Does the DTE under test set line 4 to +12 V before sending data? How does the DTE react to changes on lines 5, 6 and 8? You can answer these questions quickly by changing switches and observing LEDs. The answers will come in handy when you wish to interface the DTE to other equipment.

### Connecting Like Devices

It is sometimes necessary to connect two RS-232-C devices with the same configuration (DCE or DTE). If two terminals (DTE devices) are simply wired together, they would both attempt to transmit on line 2 and to receive on line 3. The transmitted signals would collide and no received signals would be heard. Also, both units would be setting line 4 to +12 V, but lines 5, 6 and 8 would be set by neither. This would not work.

With the aid of BOB, and a DIP header wired as shown in Fig 23C, two DTE devices can be connected with no problems. In this configuration BOB is called a "null modem," since it replaces the modems that would usually connect two terminals. Two DCE devices can be connected in a similar manner.

### Conclusion

These are only a few of the things you can do with BOB. BOB is a powerful device for monitoring and changing signals at an RS-232-C interface. If you are careful to avoid short circuits, BOB can teach you about RS-232-C interfaces and help solve confusing problems.

## An LSI Modem for Amateur Radio

Whether you are trying to get on the air with a complex packet-radio terminal node controller or simply hooking up your home computer to copy RTTY, you will need an interface to change the analog output of your radio to digital input for your computer, and to change the digital output from your computer to analog input for

your radio. This interface MODulates input to the radio and DEModulates output from the radio, so it is called a *modem*. This project, shown in Figs 24 through 27, presents a modem designed around an Advanced Micro Devices Am7910 IC.<sup>1</sup> Use of this large scale integrated (LSI) circuit device greatly simplifies construction of an

inexpensive and simple, yet versatile and noise-immune, modem. Jeff Ward, K8KA designed and built this project in the ARRL lab.

<sup>1</sup>Devices, application notes and information are available from Advanced Micro Devices, 901 Thompson Pl, PO Box 3453, Sunnyvale, CA 94088.

## The Am7910

The Am7910 is a complete modem in a 28-pin DIP package. The chip requires no external filters or control circuits. Fig 24 shows that all of the control and data lines for a full-duplex FSK modem are available right on the chip. Five "mode-control" pins allow the selection of various FSK tone pairs and filter parameters. External circuitry is needed only to buffer the input and output signals and to provide operating voltage to the Am7910.

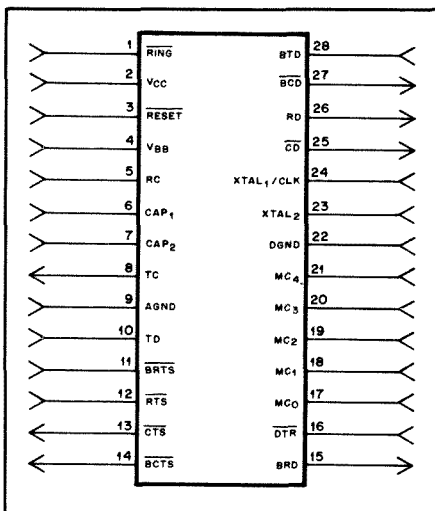

Fig 24—The Am7910 is a complete, full-duplex modem in a 28-pin DIP package.

The modulator and demodulator in the chip employ both analog and digital signal-processing circuits. The incoming signal first passes through an analog prefilter, then is converted by an analog-to-digital (A/D) converter, then passes through digital band-pass filters, and finally is digitally demodulated. The modulator is a digital sine synthesizer, followed by digital band-pass filters, a digital-to-analog converter (DAC), and an analog post filter. As a result of this mixture of analog and digital circuitry, the Am7910 has a clean, stable modulator and a selective demodulator.

### Modes and Mode Control

The mode-control pins (pins 17-21) on the Am7910 deserve some explanation. These pins should be thought of as five binary bits. Changing the voltages on the pins changes the binary word which they represent. Different "control words" cause the modem to enter different modes.

Four of the available modes are used in radio communication. Table 1 shows the switch settings and binary codes for these modes. Bell 202 is a 1200-baud FSK protocol found on most packet-radio networks. The only difference between the two Bell 202 implementations is in demodulator filter response.

Bell 103 is a 200-Hz shift FSK protocol. It is used for packet radio on the HF bands, and is also very close to the 170-Hz shift

Table 1

### Am7910 Modes Used in Amateur Radio

Switch Setting†					Mode
S5	S4	S3	S2	S1	
MC4	MC3	MC2	MC1	MC0	
1	0	0	0	0	Bell 103 originate loop-back.
1	0	0	0	1	Bell 103 answer loop-back.
1	0	0	1	0	Bell 202 main loop-back.
1	0	0	1	1	Bell 202 with equalizer loop-back.

†1 indicates an open switch; 0 a closed switch.

used by standard amateur RTTY stations. Bell 103 is a full-duplex protocol—the modem receives on one pair of tones while simultaneously transmitting on another pair. Unfortunately, for Amateur Radio use, we need to have the modem receive and transmit on the same tone pair. On most modems, this means changing a switch setting every time the station is switched from transmit to receive or vice versa. However, the "loopback" modes on the Am7910 solve this problem. These modes are usually used for testing the modem. For that purpose, the modem transmitter and receiver are put on the same tone pair. Since this is what is desired in the half-duplex radio environment, the loop-back modes are used for normal Amateur Radio operation.

### Circuit Description

Using discrete components to build a modem as versatile as the Am7910 would be a costly and delicate task. In contrast, only 10 components and a power supply are needed to put the Am7910 in operation. The circuit presented here (Fig 25) is not the bare-bones implementation of the Am7910. To make the modem easy to use, this circuit adds two ICs and a few other components to the minimum configuration.

While the Am7910 uses 0 V for a logic low and +5 V for a logic high, computer equipment which adheres to the RS-232-C interface standard uses +12 V for logic high and -12 V for logic low. U2 and U3, a 1489 RS-232-C line receiver and a 1488 RS-232-C line driver, make the modem RS-232-C compatible.

A single DIP package contains S1 through S5, the mode-control switches. These switches make it easy to use any of the modes available on the Am7910. The mode-control pins are TTL compatible and draw little current. When one of the switches (S1-S5) is open, the corresponding mode-control pin is set to +5 V (logic high) via one of resistors R1-R5. When one of the switches is closed, the corresponding pin is grounded (logic low). In the grounded position, the high value chosen for R1-R5 reduces current drain from the +5 V supply. Of course, the mode of operation could be hard-wired into the circuit, but why sacrifice versatility?

The rest of the chip is wired as specified in Advanced Micro Devices application notes for the Am7910, ignoring all but one

of the "back-channel" connections. The one back-channel control line which must be connected is Back Request To Send (BRTS), pin 11. This pin must be set to +5 V, unasserting BRTS; otherwise the back channel would take control of the modem. A copy of the applications notes for the Am7910 will help you to better understand the circuit.

### Power Supply

Since the Am7910 runs on  $\pm 5$  V and the RS-232-C interface demands  $\pm 12$  V, the circuit includes a four-voltage regulated power supply. Regulators rated at 100 mA are used on all but the +5 V supply. The +5-V supply must provide more than 100 mA, so a 1-A regulator and a small heat-sink are employed. To keep the supply small, a toroidal power transformer was used. If you do not intend to mount your modem in a small box, any transformer with a 25-V, center-tapped secondary could be used. The combination of C25 and R10 causes a 5-ms rise time on the +5-V supply, as required by the Am7910. The rest of the power supply design is standard, with special attention paid to the selection and placement of bypass capacitors. For a complete discussion of regulated power supplies, see Chapter 6.

### Construction Technique

Although the circuit can be built on a perforated board using point-to-point wiring, it is recommended that you use the circuit-board layout provided (Fig 26). Use of the circuit board not only speeds construction and trouble-shooting, but results in a stable, reproducible circuit. Sockets are used for all ICs, and for the DIP switch

Table 2

### Pin-outs for P1 and P2

P1		P2	
Pin	Signal	Pin	Signal
1	GND	1	Transmit carrier (TC)
2	TD	2	GND
3	RD	3	GND
4	RTS	4	Receive carrier (RC)
5	CD		
6	CTS		
7	NC		
8	DTR		

P1 has pin 1 toward the power supply, while P2 has pin 4 toward the power supply.

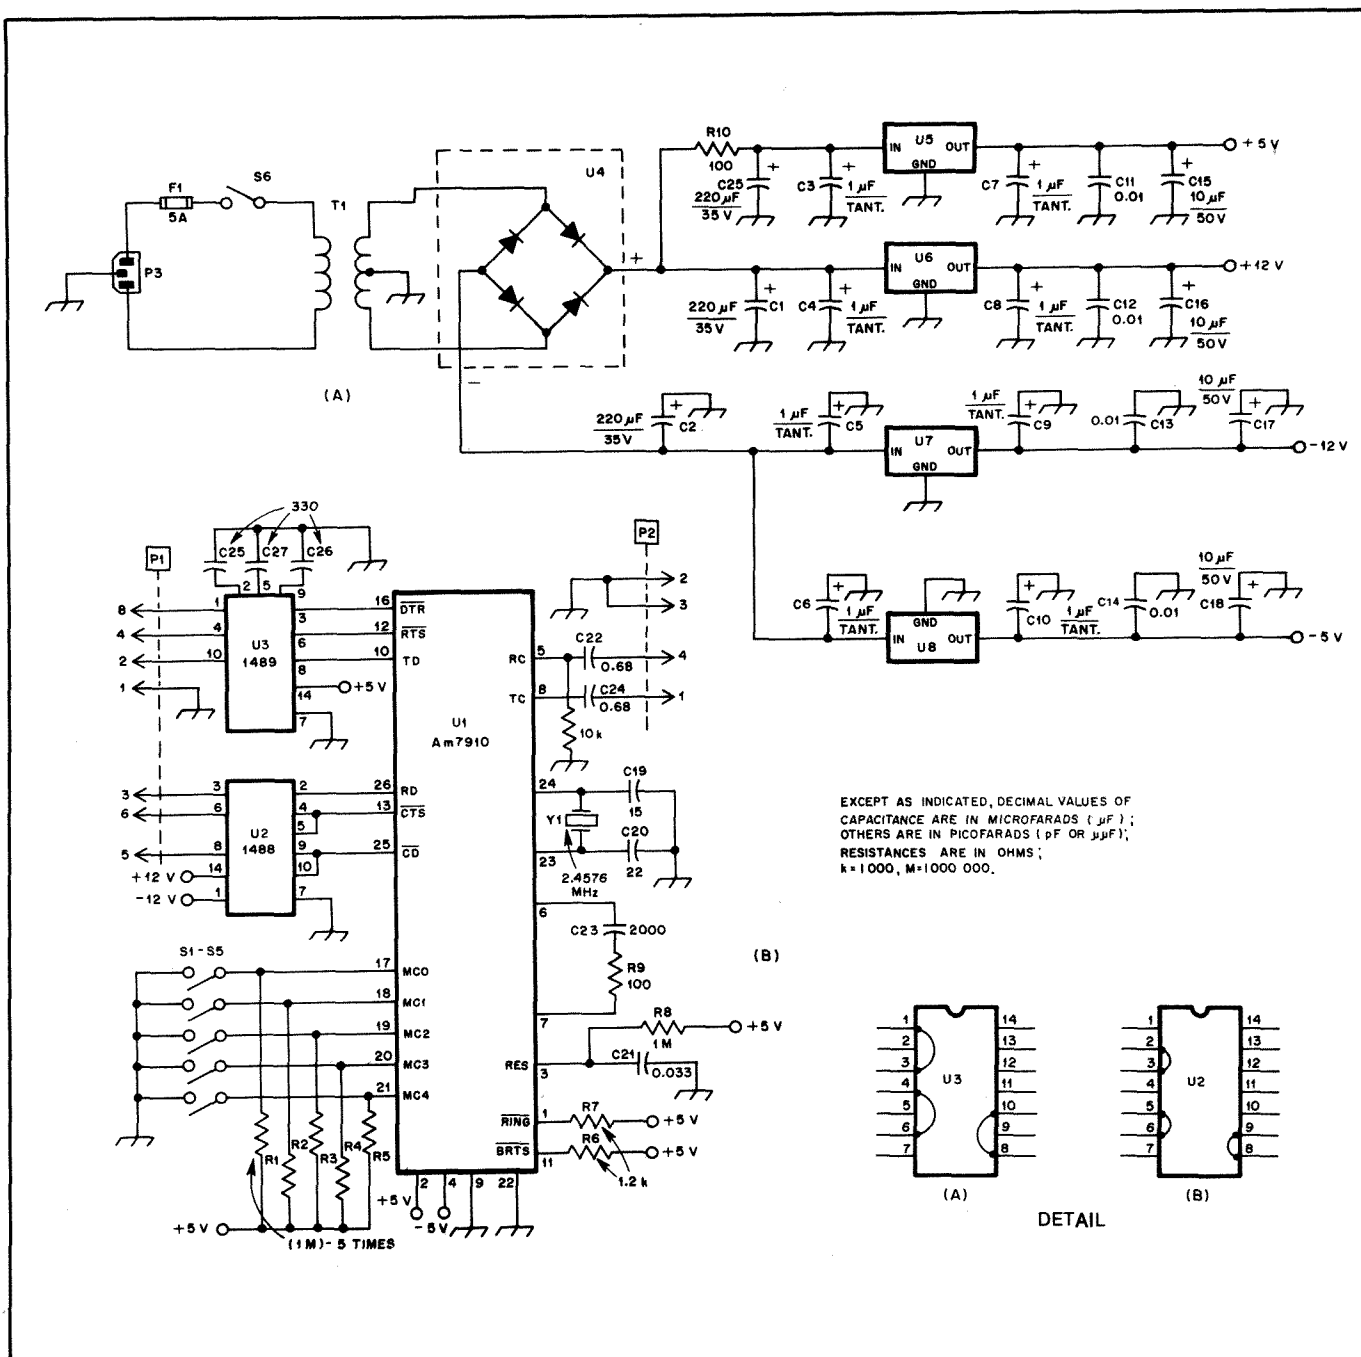

Fig 25—Schematic diagram for the Am7910-based modem and power supply. All resistors are  $\frac{1}{4}$  W.

C1,C2,C25—220  $\mu F$ , 35-V electrolytic, radial leads.  
 C3-C10—1  $\mu F$  tantalum.  
 C11-C14—0.01  $\mu F$  disc ceramic.  
 C15-C18—10  $\mu F$ , 50-V electrolytic, axial leads.  
 C19—22 pF silver mica.  
 C20—15 pF silver mica.  
 C21—0.033  $\mu F$  disc ceramic.  
 C22,C24—0.68  $\mu F$  disc ceramic.  
 C23—2000 pF disc ceramic.  
 P1—8-pin locking header (GC-41-088 or equiv.).  
 P2—4-pin locking header (GC-41-084 or equiv.).

P3—CEE-22 male, chassis mount.  
 R10—100  $\Omega$ , 2 W.  
 S1-S5—SPST, contained on a single DIP switch.  
 S6—SPST.  
 T1—Power transformer; 117-V primary, 30-V CT secondary (Cat. no. 102.152; available from Toroid Corp. of Maryland, 4720-Q Boston Way, Lanham, MD 20706).  
 U1—Advanced Micro Devices Am7910 (see text).  
 U2—1488 RS-232-C line driver. For TTL interfacing, use jumpers shown at A in detail. See text.  
 U3—1489 RS-232-C line receiver. For TTL

interfacing, use jumpers shown at B in detail. See text.  
 U4—Bridge rectifier (Radio Shack 276-1146 or equiv.).  
 U5—LM7805 +5-V, 1-A voltage regulator.  
 U6—LM78L12 +12-V, 100-mA voltage regulator.  
 U7—LM79L12 -12-V, 100-mA voltage regulator.  
 U8—LM79L05 -5-V, 100-mA voltage regulator.  
 Y1—2.4576-MHz crystal (M-Tron MP-2 or equiv. Available from M-Tron Industries Inc., P.O. Box 630, Yankton, SD 57078.).

Fig 26—Using the toroidal power transformer, the modem and the power supply fit neatly on a small PC board.

(S1-S5). Locking, polarized connectors are used for all digital and analog signals to and from the modem. See Table 2. Parts placement for the PC board is shown in Fig 27, and a full-size etching pattern appears at the back of this book.

The circuit board is mounted on the bottom plate of an 8 × 10 × 2-in chassis. Appropriate digital, audio and power connectors, and an ON/OFF switch are mounted on the chassis itself, and the chassis is then attached to the bottom plate, over the circuit board. Of particular interest is the use of a CEE-22 power connector with integral fuse holder, which saves some precious rear-panel space.

#### Circuit Check-Out

Once you have mounted all of the components on your PC board, make some tests before putting any of the ICs in their

sockets. Check for properly regulated voltages at the ungrounded ends of C15, C16, C17 and C18. Check to see that there is +5 V on pin 2 of U1 and pin 14 of U2. Check that -5 V is on pin 4 of U1. Pin 1 of U3 should be at -12 V, and pin 14 of U3 should be at +12 V. Once you have made these measurements, turn off the supply and insert U2 and U3 in their sockets. Turn on the supply, and measure the voltage at every pin on the socket for U1. None of these pins should have a voltage greater than +5 V or less than -5 V. If any of these pins are outside of the  $\pm 5$  V range, check to see that U2 and U3 are in the correct sockets, and that all PC-board jumpers are installed correctly. Only when you have ensured that no voltages too high or too low are being applied to the socket for U1 should you install U1 and attempt to use the modem. It may be hard to resist the temptation to simply plug everything in at once and "go for it"—but remember, the Am7910 is the single most expensive component on the board. Its protection is worth a few minutes delay.

#### Modem Operation

Once you have completed the preliminary check-out of your modem, connect it to a computer or (preferably) an RS-232-C break-out box. Set the mode-control switches to Bell 202 main loopback (switches 1, 3 and 4 in the ON position; switches 2 and 5 OFF). Now set RTS and DTR to +12 V. The modem should respond by setting CTS to +12 V. CD should remain at -12 V. If you now connect pins 1 and 4 on the audio connector (connecting

the transmit output to the receive input) CD should go to +12 V, and whatever voltage is on TD should also appear at RD. If all goes as predicted, hook the modem to your rig, and you're on the air!

#### Trouble Shooting

Although the Am7910 is a complex chip, and not all possible problems can be covered here, a few common problems should be mentioned.

If the modem operates well on the test bench, but erratically when connected to a radio, you have RFI problems. If the modem is not in a box, put it in one. Ground the box, and put ferrite beads on all lines into and out of the modem. Shield all of the I/O cables. Unless you have unusual amounts of RF in your shack, these precautions should eliminate the RFI.

If CTS does not go to +12 V when you set RTS and DTR, momentarily ground the case of the crystal (Y1). If this solves the problem, your crystal is not starting to oscillate when you turn on the modem. Although there is no sure fix for this problem, try varying the values of C19 and C20. Experiment with asymmetrical values between 10 and 20 pF. A high value (1-M $\Omega$ ) resistor across the leads of Y1 may also result in consistent oscillator start-up. If oscillator start-up does not seem to be the problem, check to see that you have indeed sent the correct voltages to U1: pin 12 and pin 16 should see 0.0 V (resulting from the +12-V signals on RTS and DTR being inverted and buffered by U2). Pin 11 and pin 1 (BRTS and RING) should be at +5 V, disabling the back channel and enabling the modem. If all of these conditions are met, and your modem still does not work, get the application notes from the manufacturer and start troubleshooting.

#### Non-RS-232-C Operation

Some home computers do not have true RS-232-C interface signals. These machines commonly use +5 V and 0 V for I/O. Since the Am7910 uses these same signal levels, such computers can be interfaced to the modem without U2 and U3, the RS-232-C transmitter and receiver. U2 and U3 should be replaced with jumpers as shown in Fig. 19. Remember that control signals will now be considered ON when they are at 0 V and OFF when they are at +5 V. Check to see that this is how your computer's control signals are defined. If they send +5 V when they are ON you will have to invert them before sending them to the Am7910.

#### Experiments

If you're interested in experimentation, there are some interesting things that can be tried with the Am7910. Both of these experiments should allow the modem to be used on 170-Hz RTTY. The simplest way to use the Am7910 on 170-Hz RTTY is to use one of the 200-Hz shift Bell 103 loop-back modes. The 30-Hz difference between

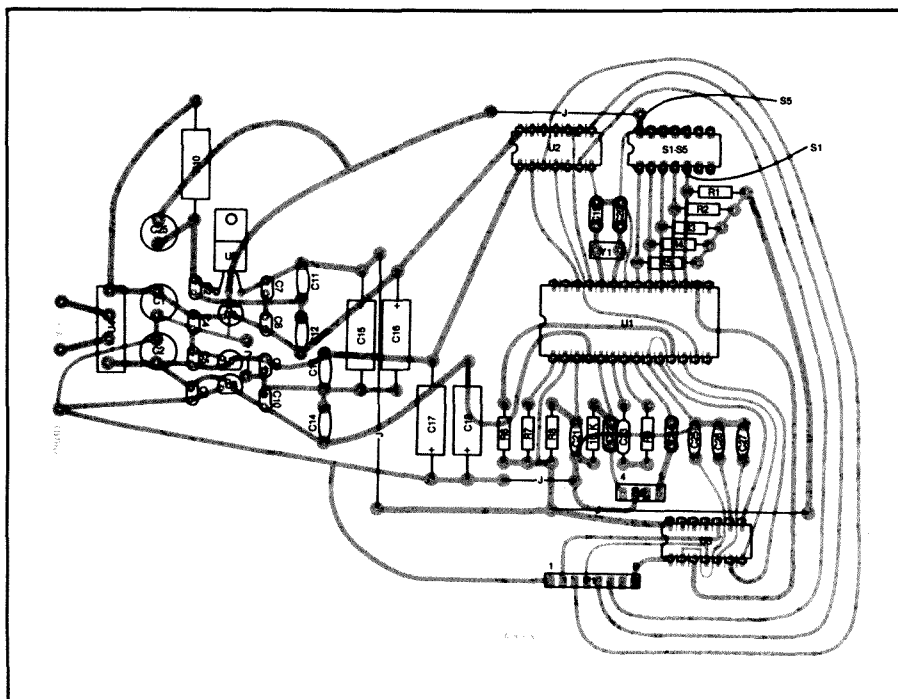

Fig 27—Parts-placement guide for the Am7910-based modem and power supply, shown from the component side of the board. A full-size etching pattern appears at the back of this book.

the amateur tones and the Bell 103 tones does not degrade performance very much. Try it and see!

Another way to put the Am7910 on 170-Hz shift would be to change the frequency of Y1. Since Y1 is the frequency reference for the entire modem, lowering the frequency of Y1 by 15% should change the 200-Hz shift to 170-Hz. This modification has not been tried yet, but that is what

home-brewing is all about! If you are going to use your Am7910 modem on HF, be sure you understand what RF tones will result if you use an SSB transmitter with the AF tones from the modem. You will want to be sure that you are listening and transmitting on the same frequencies.

#### **Conclusion**

The Am7910 modem, using the circuit

presented here, has been in use for some time on a packet-radio repeater at ARRL Headquarters. If you are interested in many facets of digital communication, this modem, with its many modes, could be the solution to your interface problems. For a state-of-the-art project that's easy to build and useful in the shack, the Am7910 "World Chip" fills the bill.

# HF Radio Equipment

In this chapter you will find descriptions of radio equipment that you can build for the amateur bands below 30 MHz. The projects fall into three broad categories: receivers, transmitters and power amplifiers.

There is much personal pride and satis-

faction in building and using a piece of radio equipment. The knowledge you gain of the workings on both sides of the front panel is another source of pleasure.

The theory necessary to understand the operation of the equipment described in

this chapter is found elsewhere in this book. Some of the chapters you may wish to review are: Chapter 10, Radio Frequency Oscillators and Synthesizers; Chapter 11, Radio Transmitting Principles; Chapter 12, Radio Receiving Principles and Chapter 15, Radio Frequency Power Amplifiers.

## A Band-Imaging CW Receiver for 10 and 18 MHz

Band imaging has long been used in Amateur Radio as a means of making a stable local oscillator (LO) do double duty. Instead of building equipment using only one LO-to-RF relationship for frequency conversion—with, for instance, only the *difference* between the LO and higher-frequency incoming signals giving output at the IF—*two* of several LO-to-RF relationships can be exploited for two-band coverage. A band-imaging receiver appeared in every edition of this *Handbook* from 1953 through 1966, from “A Two-Band Four-Tube Superhetrodyne” in 1953 to “The HB-65 Five-Band Receiver” in 1966. Each of these receivers converted the 80- and 40-meter amateur bands to a 1.7-MHz IF by means of a 5.2-5.7-MHz LO. On 80 meters, the conversion relationship in such a receiver is  $LO - RF = IF$ ; on 40, the relationship is  $RF - LO = IF$ . Both bands “tune in the same direction” with this system: The received frequencies of 3.5 and 6.9 MHz correspond to the lower limit of the LO tuning range.

Band imaging can also be used to cover the 80- and 20-meter amateur bands: A 5.0-5.5-MHz LO is used to convert each band to a 9-MHz IF. In such a system, the LO-to-RF relationship on 80 meters is  $RF + LO = IF$ ; on 20,  $RF - LO = IF$ . The drawback to this band-imaging system is that the lower band “tunes backwards”: The lower limit of the LO tuning range corresponds to 4.0 MHz on 80 meters and 14.0 MHz on 20. Nonetheless, the 80/20 band-imaging system has also been popular with radio amateurs because of the inherent sideband inversion between the image bands: The BFO-to-IF relationship that affords LSB reception on 80 meters demodulates USB on 20.

With this overview of band-imaging techniques in place, we present a band-imaging CW receiver for 10 and 18 MHz (see Fig. 1). Using a 14-MHz LO, it converts the entire 10-MHz amateur band, and the CW portion of the 18-MHz amateur band, to a 4-MHz IF. Both bands tune in the same direction. At 4 MHz, a four-crystal ladder filter provides single-signal selectivity. The design emphasizes good basic receiver performance with an eye toward compactness; hence, features such as a digital frequency display, AGC and active audio filtering have been omitted. Alignment and checkout of the band-imaging receiver requires only (1) a 51-ohm resistor; (2) a receiver capable of CW reception at 14.0-14.2 MHz and  $4\text{ MHz} \pm 1\text{ kHz}$  with an S-meter and frequency display resolution of 1 kHz or greater; and (3) a

crystal-controlled marker generator capable of providing 10-kHz markers. The performance measurements given later in this article were obtained from a receiver aligned *by ear* with such test equipment. You need not have access to a radio lab to enjoy similar results. David Newkirk, AK7M, designed and built this project in the ARRL lab.

### Circuit Description: RF Amplifiers

A separate 40673 RF amplifier is used for each band. (See Fig. 2). The circuit is electrically identical to that used for the RF amplifiers in “A High-Performance Communications Receiver,” presented later in this chapter. Several other circuits in the band-imaging receiver are based on the K51RK/W7ZO1 high-performance design. To simplify alignment of the band-imaging

Fig. 1 — The band-imaging receiver covers the CW segments of the 10- and 18-MHz amateur bands with good stability, sensitivity and single-signal selectivity. Larger controls are (l-r) TUNING, IF GAIN and AF GAIN. The two smaller controls, separated by the PHONES jack, are BAND and SIDETONE LEVEL. The TUNING scale is drawn on contact paper applied to an aluminum disc.

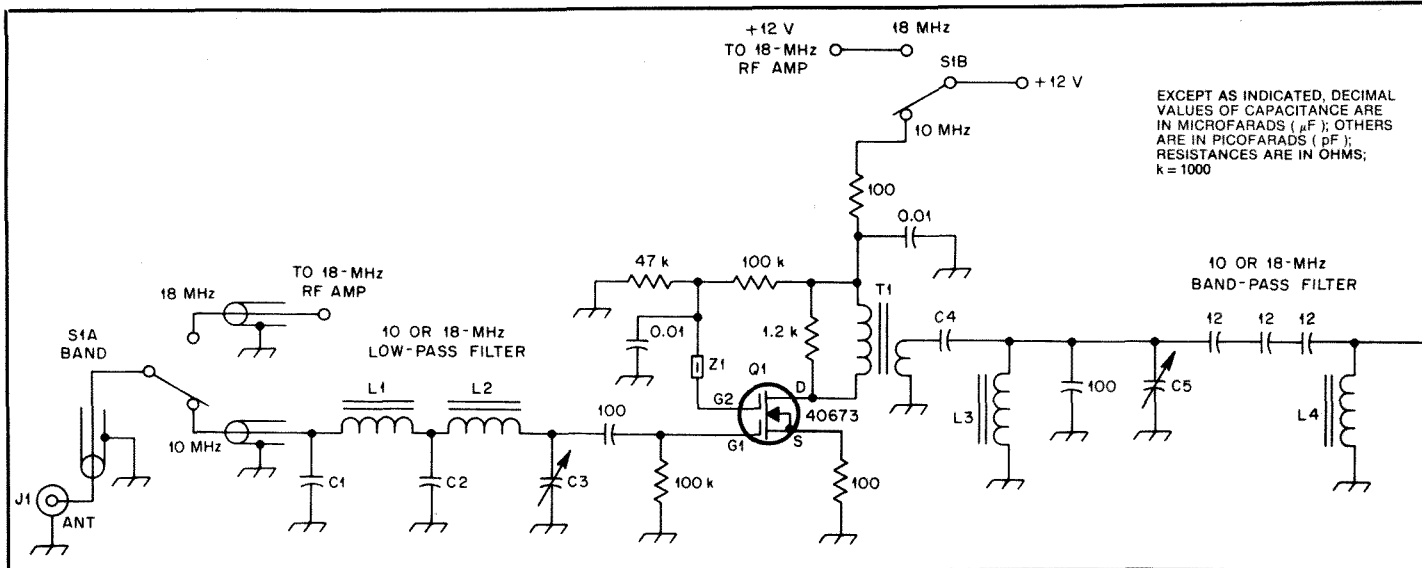

Fig. 2 — Schematic of the RF amplifiers for the band-imaging receiver. A separate amplifier is used for each band. The low- and band-pass filters may be aligned with the aid of a crystal-controlled marker generator; see text. Capacitors are disc ceramic unless otherwise noted. Capacitors marked with polarity are electrolytic. All resistors are 1/4-W, 10% units unless otherwise noted.

C1, C2, C4, C7 — Silver mica, polystyrene or ceramic capacitor; see Table 1 for values.  
C3, C5, C6 — Ceramic or mica compression trimmer. Mouser Electronics ceramic trimmer 24AA067 (12-100 pF) used for 100 pF; Mouser 24AA064 (5-45 pF) used for 45 pF.  
J1 — Coaxial RF connector.

L1-L4 — Wound on Amidon T-50-6 powdered-iron toroid core or equiv. All inductors use no. 22 enameled wire with one exception: For L2 at 10 MHz, use no. 24 enameled wire. See Table 1 for number of turns.  
Q1 — 40673 dual-gate MOSFET.  
S1 — 3PDT toggle (Radio Shack 275-661 or equiv).

T1 — Transformer wound with no. 28 enameled wire on Amidon FT-37-43 ferrite toroid core or equiv. Primary (168  $\mu$ H), 20 turns; secondary (6.7  $\mu$ H), 4 turns.  
Z1 — Ferrite bead on Gate 2 lead of Q1, Amidon FB-43-101 or equiv.

**Table 1**  
**Component Values for the Band-Imaging Receiver RF Amplifiers**

MHz	C1	L1	C2	L2	C3	C4, C7	L3, L4	C5, C6
10	300	13	680	29	100	33	17	100
18	180	10	390	22	45	22	10	100

Values listed for capacitors are capacitance in pF. Values listed for inductors are number of turns of wire required.

receiver, the variable coupling capacitor (C15 in Ch. 30, Fig. 12) between the two sections of the output filter is replaced by three 12-pF capacitors in series. Gain of this circuit is 12 to 15 dB, depending on alignment and the characteristics of Q1. Band changing is accomplished by switching RF input, RF output and dc connections between the 10- and 18-MHz amplifier boards via S1, a 3PDT toggle. Input and output (I/O) impedances of each RF amplifier board are 50 ohms.

### Mixer, IF Filter and IF Amplifiers

See Fig. 3. The band-imaging receiver uses a Mini-Circuits SBL-1 doubly balanced diode-ring mixer (U1) followed by a strong bipolar-transistor IF amplifier (Q2).<sup>1</sup> This is the circuit used in the K5IRK/W7ZOI receiver, with several modifications. In the band-imaging receiver, the bifilar 4:1 collector transformer in the original design has been replaced with a toroidal monofilar choke,

RFC1. The supply end of the 1-kΩ Q2 base bias resistor is now connected directly to the 12-V dc line at the cold end of RFC1. This removes the RF feedback present in the original circuit. Surprisingly, this feedbackless configuration results in better sensitivity and two-tone 3rd-order IMD dynamic range than the unmodified circuit affords at a 4-MHz IF. The original circuit, intended for use at an IF of 9 MHz, did not provide a comparable performance even when the inductance of its 4:1 collector transformer was scaled for 4 MHz.

The post-mixer amplifier feeds a four-crystal ladder filter via a 6-dB pad. The I/O impedances of the crystal filter are 200 ohms. Because this is a good match for the collector impedance of Q2, the step-down transformer in the original post-mixer amplifier circuit is not required. The 50-ohm 6-dB attenuator of the original circuit has been scaled to 200 ohms. This pad should not be replaced with one of lower attenuation: It assures a nonreactive wideband termination for Q2 and the crystal filter. Less attenuation here results in reduced IMD dynamic range, as confirmed by lab tests.

The crystal filter was designed using Hayward's technique (see "Simple Cohn Crystal Filters," *QST*, July 1987, pp 24-29). Measured selectivity of the prototype filter was 405 Hz at -6 dB and 1850 Hz at -60 dB, resulting in a -60 dB/-6 dB shape factor of 4.57. Insertion loss was 2 dB, and passband ripple was less than 0.4 dB. As is characteristic of simple ladder crystal filters, the upper passband slope is steeper. Because of this, the BFO must be set on the upper side of the filter for best single-signal reception. With the BFO set to provide a 550-Hz beat note for signals at IF center, rejection of the audio image in the prototype receiver was 73 dB. Ultimate attenuation was 90 dB.

No filter adjustment is necessary, but it is important that you use the specified crystals if you intend to duplicate the post-mixer-amplifier/pad/filter arrangement shown in Fig. 3. Substitutions at Y1-Y4 will require filter capacitors of other than 300 pF, resulting in I/O impedances of other than 200 ohms. Hayward states that the series-resonant frequencies of the four filter crystals must fall within a spread of no more than 10% of the desired 3-dB filter bandwidth. We chose to evaluate the performance of the filter in the more popular terms of -60 and -6 dB bandwidths; it follows that 10% spread is too generous where a given -6 dB filter bandwidth is the target. Experiments with various new and surplus 4-MHz microprocessor-clock crystals in the ARRL lab showed that the new International Crystal Mfg. (ICM) crystals provided the best

<sup>1</sup>Mini-Circuits, PO Box 166, Brooklyn, NY 11235, tel. 212-934-4500.

performance overall. Shape factors ( $-60$  dB/ $-6$  dB) for the clock-crystal filters were rarely less than 5, and sometimes more than 6. I/O impedances were between 300 and 400 ohms. Several times, four crystals within a suitably narrow frequency spread could be found only by grading 10 or more clock crystals. Custom-ground crystals offer the added advantage of resonating—within tolerance, of course—on the frequency you specify. Their unit price is higher, but they come closest to guaranteeing that your filter will perform as predicted.

Post-filter IF amplification is provided by U2, an MC1350P video amplifier IC. The 200-ohm resistor between pins 4 and 6 of U2, in conjunction with the  $0.1 \mu\text{F}$  bypass capacitor at pin 6, terminates the crystal filter output. Manual gain control is achieved by applying a variable positive voltage to pin 5 of U2 through a 27-k $\Omega$

resistor and IF GAIN control R1. Receiver muting is accomplished by means of Q3: Grounding the MUTE terminal (center conductor at J2) applies maximum gain-reduction voltage to U2. The supply voltage (nominally 12) appears across J2 with the receiver unmuted; current through the grounded MUTE line is 5 mA. IF output ( $Z \approx 50$  ohms) is available at the secondary of T2.

### Local Oscillator

The schematic of the band-imaging receiver LO is shown in Fig. 4. An MPF102 JFET, Q4, operates as a Colpitts oscillator. The oscillator signal is amplified by Q5, a 40673 dual-gate MOSFET. Bandspread is achieved by tapping the tuning capacitor, C9, down on LO tank inductor L5. Tuning range of the circuit is approximately 14.060 to 14.153 MHz. Air-dielectric trimmer C10 shifts this range for dial calibration.

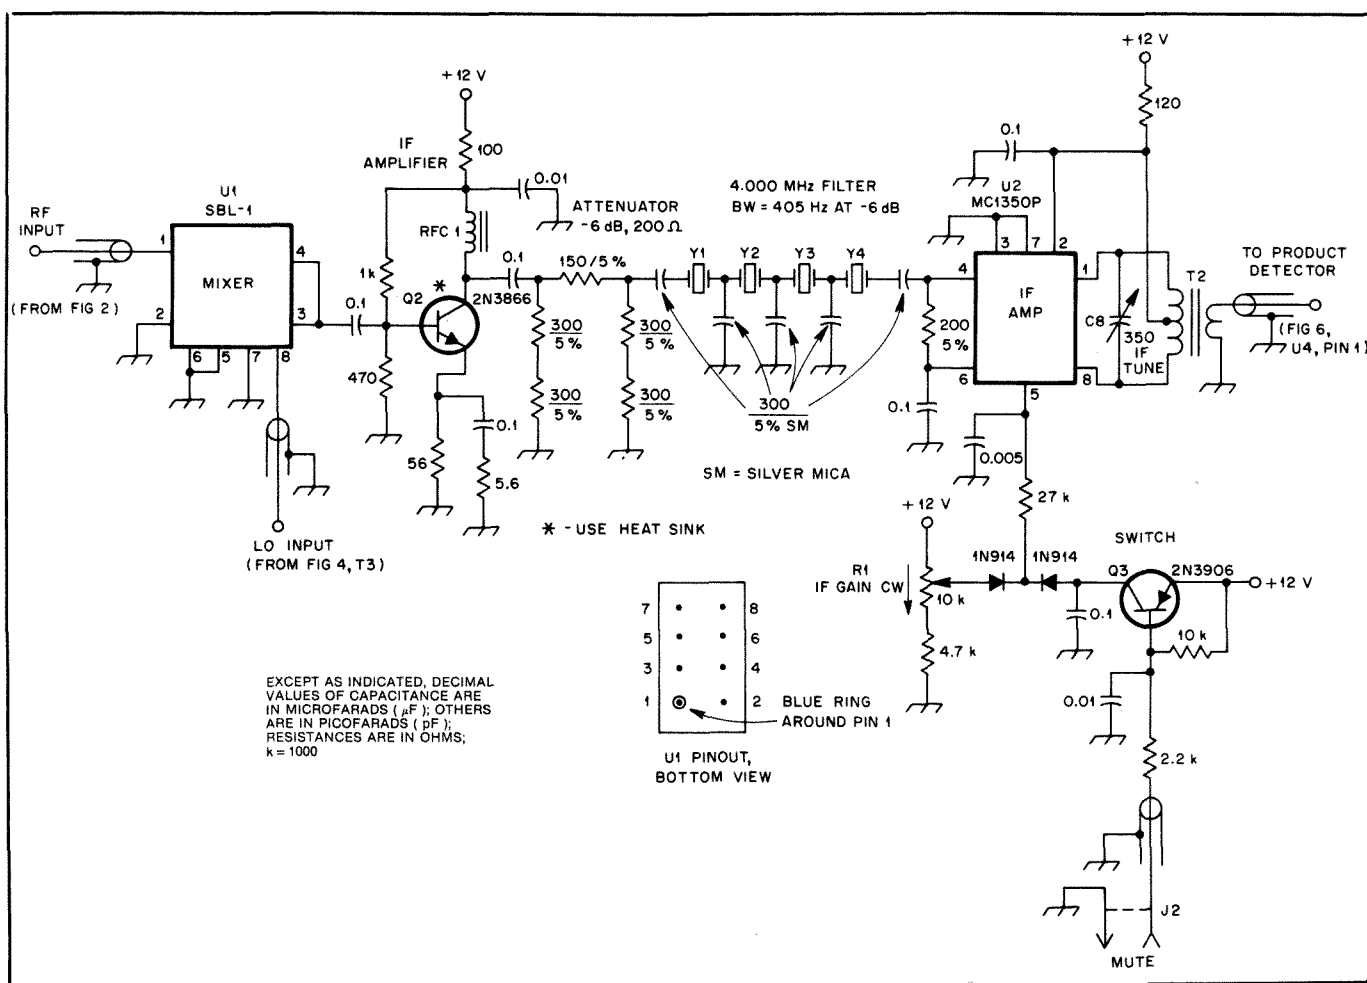

Fig. 3 — Schematic of the mixer, crystal filter and IF amplifier stages of the band-imaging receiver. Capacitors are disc ceramic unless otherwise noted. Capacitors marked with polarity are electrolytic. All resistors are  $\frac{1}{4}$ -W, 10% units unless otherwise noted.

C8 — 350-pF compression trimmer (Arco 428 or equiv).

J2 — Phono jack.

Q2 — 2N3866 or 2N5109. Use a small heat sink on this transistor.

Q3 — 2N3906.

R1 — 10-k $\Omega$  linear potentiometer.

RFC1 — 95  $\mu\text{H}$ ; 15 turns no. 24 enameled

wire on Amidon FT-37-43 ferrite toroid core.  
T2 — Transformer wound on Amidon T-68-1 powered-iron toroid core, or equiv. Primary (12.9  $\mu\text{H}$ ): 36 turns no. 26 enameled wire, center-tapped; secondary (0.9  $\mu\text{H}$ ): 3 turns no. 26 enameled wire over center of primary.

U1 — Mini-Circuits SBL-1 doubly balanced diode-ring mixer.

U2 — MC1350P video amplifier IC.

Y1-Y4 — 4.000000-MHz custom-etched crystal, 26°C calibration temperature, grade CS-1 (0.001% tolerance), F-700 holder, series resonant. International Crystal Mfg Co type 433340. See text.

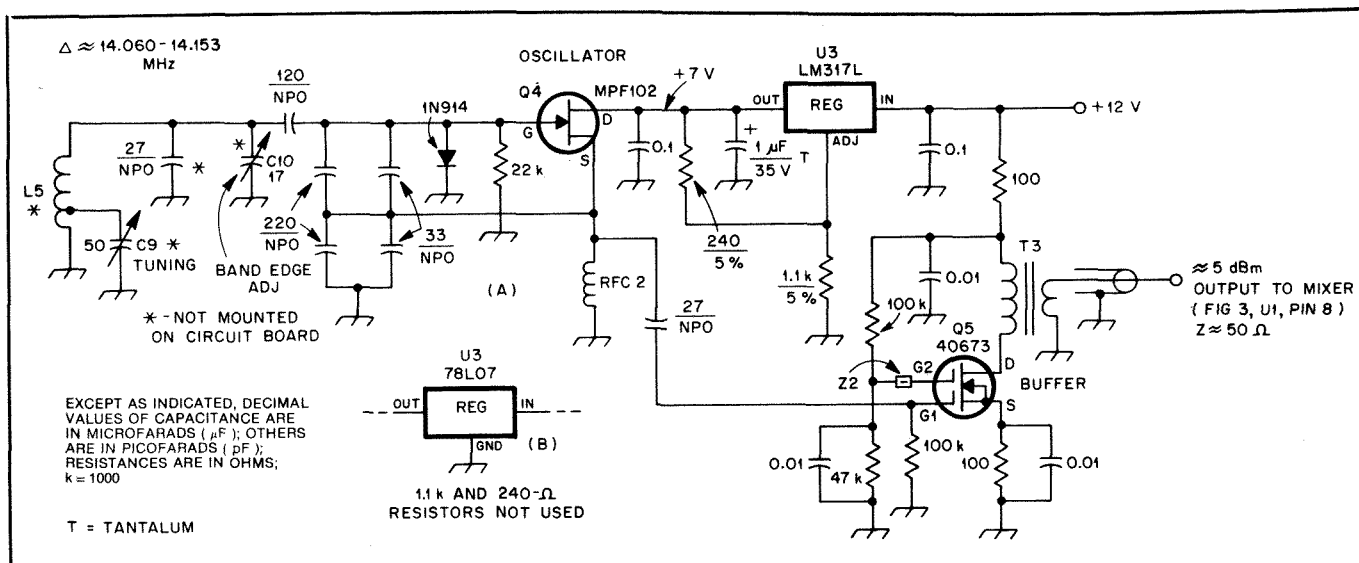

Fig. 4 — Schematic of the band-imaging receiver LO and buffer circuit. Capacitors are disc ceramic unless otherwise noted. Capacitors marked with polarity are electrolytic. All resistors are  $\frac{1}{4}$ -W, 10% units unless otherwise noted. At A, an LM317L adjustable regulator is used at U3. The inset at B shows connections for an 78L07 regulator at U3. For best stability, use only NP0 (C0G) capacitors in the circuitry associated with the gate and source leads of Q4. Space L5 by at least its diameter from other components and the LO shield box. See text and Fig. 8.

C9 — 50-pF air variable (Jackson Bros 4667-50 or equiv).  
C10 — 17-pF air trimmer (Johnson 189-506-5 or equiv).  
L5 — 1.4  $\mu$ H: 11 turns no. 22 tinned wire, 24 turns per inch (Barker & Williamson 3038 Miniductor). Tap at 2 or 3 turns from ground end. See text and Figs. 8 and 9B.

Q4 — MPF102 JFET.  
Q5 — 40673 dual-gate MOSFET.  
RFC2 — 39  $\mu$ H: Miller 70F395A1, or 24 turns no. 26 enameled wire on Amidon FT-50-61 ferrite toroid core.  
T3 — Transformer wound on Amidon FT-37-43 ferrite toroid core or equiv.

Primary (50  $\mu$ H): 11 turns no. 26 enameled wire. Secondary (3.8  $\mu$ H): 3 turns no. 26 enameled wire.  
U3 — Voltage regulator, LM317LH, LM317LZ or (with circuit changes shown at inset B) 78L07.  
Z2 — Ferrite bead on Gate 2 lead of Q2, Amidon FB-43-101 or equiv.

Despite the relatively high LO operating frequency, stability is good. Measured drift of the point-to-point-wired prototype oscillator was  $\sim 530$  Hz in the 45-minute period after turn-on, 460 Hz of which occurred in the first ten minutes. Over the next three hours, this oscillator drifted approximately  $\sim 20$  Hz. Stability was even better with the circuit rebuilt on an etched circuit board: Drift for the ten minutes after turn-on was only  $\sim 256$  Hz. *The key to this stability is the use of NP0 (C0G) ceramic units for all fixed capacitors associated with the gate and source of Q4.* Although silver-mica or polystyrene capacitors may be hand-picked for low drift, only NP0 capacitors offer minimum drift "off the shelf." Oscillator stability is further improved by the use of a three-terminal regulator to stabilize Q4's drain supply, and by enclosing LO and buffer in a shield box to slow the effect of changes in ambient air temperature.

### BFO, Detector and Audio Stages

The K5IRK/W7ZOI crystal-controlled BFO is used in this receiver with one modification: The secondary of T4 in Fig. 5 carries only RF and no dc. Y5 is an inexpensive 4-MHz microprocessor clock crystal. Every such crystal we tried worked well in this circuit; a custom-ground crystal is unnecessary here.

The detector and AF stages of the band-imaging receiver are shown in Fig. 6. The product detector (U4) is a Mini-Circuits SBL-1 doubly balanced diode-ring mixer. RFC3 and the 0.001- $\mu$ F capacitor provide RF filtering ahead of the AF preamp, U5, an NE5534 low-noise audio op amp. The

parts list for Fig. 6 specifies a "wind-it-yourself" toroidal choke for RFC3; pi-wound chokes tried here were prone to pickup of 60-Hz harmonics.

U6, an LM380N-8, serves as the AF power amplifier. Its output is connected to a front-panel stereo headphone jack, J4,

and a rear-panel phono connector, J5. J4 is wired to accept stereo headphones; monaural phones may be used if inserted no farther than the first detent. The 1-k $\Omega$  resistor from the output lead to ground serves to charge U6's 470- $\mu$ F output coupling capacitor at power-up if a head-

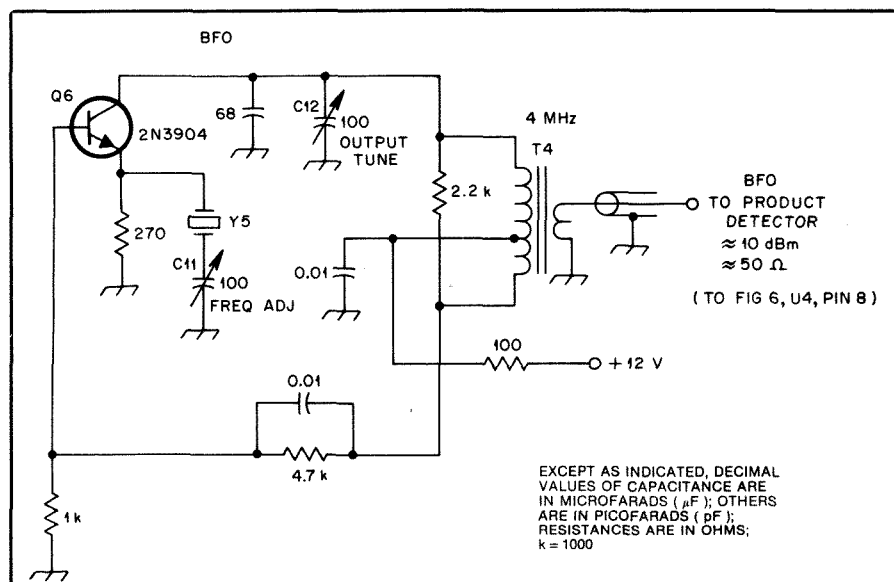

Fig. 5 — Schematic of the band-imaging receiver BFO. Capacitors are disc ceramic unless otherwise noted. Capacitors marked with polarity are electrolytic. All resistors are  $\frac{1}{4}$ -W, 10% units unless otherwise noted.

C11, C12 — 100-pF ceramic or mica compression trimmer. Mouser Electronics 24AA067 (12-100 pF) suitable.  
Q6 — 2N3904.  
T4 — Transformer wound on Amidon T-68-2

powdered-iron toroid core or equiv. Primary (19.8  $\mu$ H): 59 turns no. 28 enameled wire, tapped at 12 turns. Secondary (0.98  $\mu$ H): 9 turns no. 28 enameled wire over tap end of primary.

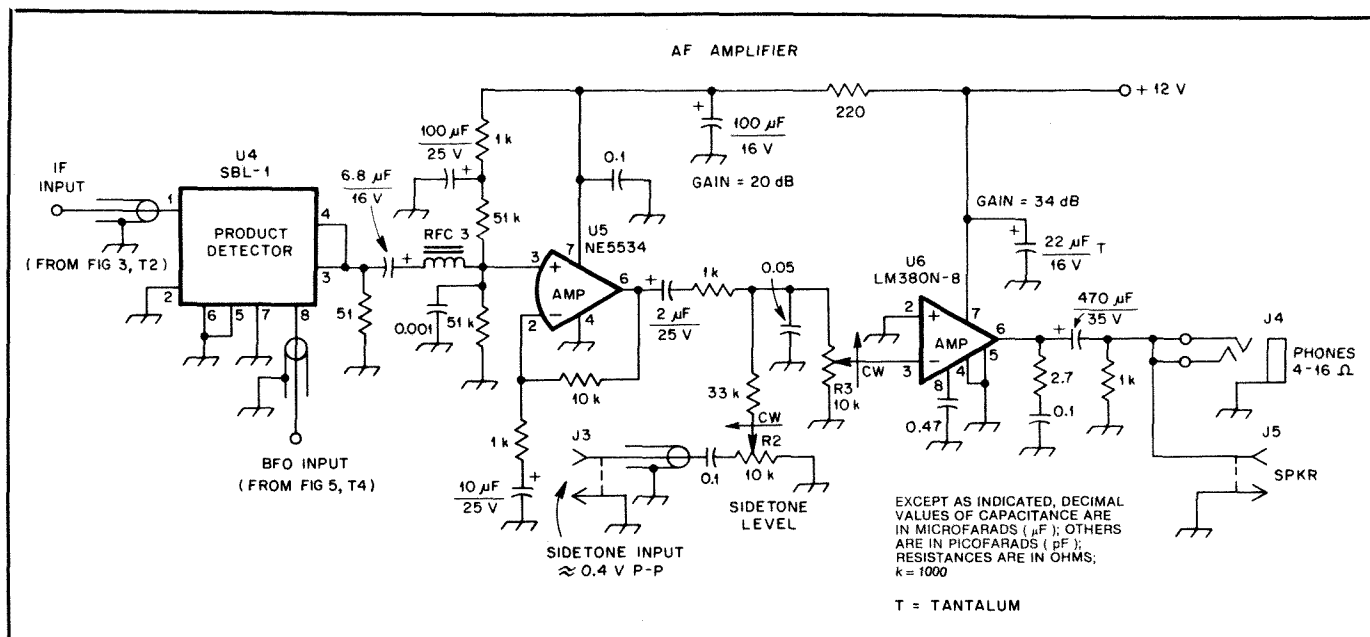

Fig. 6 — Schematic of the product detector and audio amplifiers for the band-imaging receiver. Capacitors are disc ceramic unless otherwise noted. Capacitors marked with polarity are electrolytic. All resistors are 1/4-W, 10% units unless otherwise noted.

J3, J5 — Phono jack.

J4 — Stereo headphone jack.

R2, R3 — 10-kΩ audio-taper potentiometer.

RFC3 — 1-mH RF choke: 34 turns no. 30 enameled wire on Amidon FT-37-72 ferrite toroid core or equiv.

U4 — Mini-Circuits SBL-1 doubly balanced

diode-ring mixer.

U5 — NE5534 low-noise audio op amp.

U6 — LM380N-8 audio power amp.

phone or speaker load has not already been installed at J4 or J5. Without this resistor, the capacitor would charge on connection of the audio transducer, resulting in a loud thump.

As mentioned earlier, no active audio filtering is included in the band-imaging receiver. The higher audio components in detected IF amplifier hiss are reduced by the 0.05-μF capacitor connected between the hot end of the AF GAIN control, R3, and ground.

Sidetone can be injected into the audio chain at J3. Sidetone level is adjusted from the front panel by R2. Setting R2 to minimum shunts the AF GAIN control with a 33-kΩ resistor; this reduces overall audio gain by less than 1 dB. A 400-mV signal at J3 provides more than enough sidetone audio at normal AF GAIN settings.

This receiver requires, but does not include, a regulated dc power supply capable of providing a maximum of 220 mA at 12 V. See Chapter 27, Power Supply Projects, for suitable circuits.

## Construction

The receiver was prototyped using point-to-point and "dead bug" modular construction (see Fig. 7). Later, circuit boards were designed and debugged.<sup>2</sup> You may use either method for building your receiver, with good results. The following construction hints are based on the circuit-board version of the receiver, but much of the information here will be of use to builders using either style of construction.

Parts for this receiver are available from

Fig. 7 — The band-imaging receiver prototype. The LO is in the left foreground; just behind it, the 10- and 18-MHz RF amplifiers. At center, the mixer/filter/IF amplifier module, with the detector/AF amplifier module at far right. The smallest module, upper right, is the BFO. Performance was good even though etched circuit boards were not used.

a number of sources. Virtually everything can be obtained from RadioKit, Mouser, Radio Shack, DigiKey and Circuit Specialists. See the parts suppliers list at the end of Chapter 35 for addresses and telephone numbers of these suppliers.

See Fig. 8. The receiver is housed in a Hammond 1590F diecast aluminum box (approximately 7 1/4 × 7 1/4 × 2 1/2 inches). Threaded standoffs are used to mount all circuit boards except the detector/audio board; spade lugs are used to mount this module vertically. Miniature 50-ohm coaxial cable (RG-174) is used for all RF connections between modules except the LO-mixer line. Here, miniature Teflon® -dielectric cable is used because of

Teflon's high melting point (see Fig. 9A). RG-174 is also used to connect J3, SIDETONE INPUT, to the detector/audio board. Connections from this board to the AF GAIN and SIDETONE LEVEL controls are made with stranded hookup wire in three colors. This makes for more compact wiring than miniature coax allows and causes no problems with hum or crosstalk. The IF GAIN control and audio output connections are also made in this way. Dc wiring is stranded hookup wire; binding posts are used to bring dc into the receiver.

We recommend that you build, test and install the band-imaging receiver modules in this order: (1) LO; (2) detector/audio and BFO; (3) mixer/filter/IF amplifier; (4)

<sup>2</sup>Circuit-board templates are available from the ARRL Technical Department secretary for \$3.00 and a no. 10 s.a.s.e.

Fig. 8 — The band-imaging receiver just fits into a Hammond 1590F diecast aluminum box. In this top view, the LO (in its shield box, shown here with cover removed) dominates the layout. The RF amplifier boards are at top, one above the other. The BFO is to the left of the LO, with the detector/audio amplifier board (edge-on) to the right. At far right, the mixer/filter/IF amplifier board. The two capacitors and resistor beneath the mixer/AF board have since been incorporated into the board design. For a similar view of the band-imaging receiver in full color, see the cover of July 1987 QST.

Fig. 9 — The detail drawing at A shows installation of the LO output lead. Miniature Teflon coax is recommended here because its dielectric will not melt during soldering. The shield must be flared and soldered to the inner wall of the LO shield box. At B, details of the LO inductor, L5, are shown. Taps are made by pushing in adjacent turns of the coil stock. The untrimmed plastic bars preserve the Q of L5 by holding the Miniductor away from the shield box bottom. Before counting the 11 turns necessary for the coil, unwind enough turns from the uncut Miniductor stock to allow L5 to stand above the shield-box bottom by its diameter. The plastic bars are fragile; they may be impregnated with Duco or similar cement for greater strength. The completed L5 is cemented to the shield-box bottom after the LO tuning range has been set.

RF amplifiers. The LO comes first because its installation entails the majority of the metalwork necessary to build the receiver. The sequence allows you to use completed modules as part of your test equipment for the modules later in the sequence.

The LO shield box is made of double-sided copper-clad circuit board. The 10:1 epicyclic reduction drive is a Jackson Bros 5857. Because the sides of the Hammond diecast aluminum box are not perpendicular to the bottom, special construction techniques are needed to ensure that the TUNING capacitor shaft is perpendicular to the front panel of the box. The following construction sequence resulted in a smooth-tuning, no-backlash LO installation in the ARRL lab version of the band-imaging receiver:

- 1) Mount the 10:1 reduction drive on the front panel.

- 2) Build the LO shield box (four sides and bottom), soldering only the side and

rear pieces into place on the bottom. The front and rear pieces of the shield box must butt the shield box sides as shown in Fig. 8. *Tape* the front side into place. Drill four mounting holes in the shield box bottom plate.

- 3) Chisel the molded-in printing from the center of the diecast-box bottom to smooth the box floor. Sanding may also be necessary to achieve this.

- 4) Locate the C9 (TUNING capacitor) mounting hole in the LO shield box front by pushing the box up against the reduction-drive coupler. Size this hole slightly larger than the capacitor mounting bushing. This allows later adjustment of C9's position. Temporarily mount the capacitor in the front side of the shield box and keep this assembly taped to the rest of the box.

- 5) Place the LO box in the diecast box so that C9 is inserted into the reduction-drive coupler. By feel, be sure that the

capacitor is about 1/16-inch short of full insertion into the coupler sleeve. This allows leeway for later adjustment. Mark the diecast box to pass the LO mounting screws through the holes in the shield-box bottom plate. Drill these holes now.

- 6a) Remove the taped-on front of the shield box. Build and install the LO/buffer circuit board, including the LO output cable and 12-V dc line, in the partially completed shield box. The output cable consists of a 6-inch piece of miniature Teflon coaxial cable (see Fig. 9A) Fig. 9B shows how to prepare LO inductor L5 from a length of B & W Miniductor.

- 6b) Temporarily install C9, C10, L5 and the 27-pF NP0 LO-tuned-circuit capacitor to the LO/buffer board by short leads. Terminate the LO output cable with a 51-ohm resistor. Verify operation of the LO/buffer board by applying dc power and tuning in the LO signal on the 14-MHz test receiver. Adjust C9 and C10 as necessary

to bring the signal into your receiver's tuning range. You may need to add or remove fixed capacitors in the LO tuned circuit. Don't spend time now on setting the LO tuning range; that comes later.

6c) Once LO performance has been verified, disconnect C9, C10, L5 and the fixed tuned-circuit capacitor from the LO/buffer board. Install the board into the LO shield box.

7) Install C10 flat to the shield box floor by soldering down its rotor tab. Be sure to allow clearance for C9. Bend the C10 stator tab up to clear the box bottom. Connect C10 to the LO/buffer circuit board with tinned no. 18 solid wire. Solder L5 into the circuit; it will be cemented to the box floor later, but do not do this yet.

8) Bolt the LO into the diecast box. Loosely mount C9 in the front side of the LO box. Slide the front LO box side into place, and at the same time, slide the C9 shaft into the reduction-drive coupler to about 1/16 inch short of full insertion. *Do not* tape the LO box front into place as before.

9) Adjust the reduction drive to bring its coupler worm screws to approximately 10 and 2 o'clock. Set C9 to maximum capacitance without disturbing the reduction drive. Now, with C9 loose in its mounting hole, tighten the worm screws in the reduction-drive coupler.

10) Tighten C9 to the front of the LO shield box.

11) Using the reduction drive, turn C9 back and forth through its range several times to settle the LO box front into position. Depending on how tightly the front is held in place by the LO box sides, you may need to push the sides apart slightly to free the front piece. By eye, the front of the LO box should appear parallel to the front of the diecast box. If all looks well,

12) Solder the front side of the LO box into position.

Final tuning-range and anti-backlash adjustments will be made during alignment and testing of the receiver.

The circuit board placement shown in Fig. 8 works well. Although the position of the LO shield box left little choice as to the placement of the rest of the circuit boards, maximum spacing between the BFO and mixer/filter/IF amplifier boards was decided on *beforehand* to keep the BFO signal out of the IF amplifier circuitry.

### Alignment

Test equipment necessary for aligning the band-imaging receiver is a 51-ohm resistor, a receiver capable of CW reception at 14.0-14.2 MHz and 4 MHz  $\pm$  1 kHz with an S-meter and frequency display resolution of 1 kHz or greater, and a crystal-controlled marker generator capable of

providing 10-kHz markers. Equip the coaxial input of the test receiver with a short test cable terminated with alligator clips.

**Detector/audio amplifier and BFO.** The audio amplifiers require no adjustment. Align the BFO as follows: Without connecting the BFO to the detector, connect a 51-ohm resistor across the secondary of T4. Set C11 (FREQ ADJ) and C12 (OUTPUT TUNE) to midrange. Apply 12 V dc to the BFO. Set the test receiver for CW reception at 4000 kHz and attach the shield clip of its test cable to the BFO ground foil. Leave the center-conductor clip unconnected. Next, tune in the BFO on the test receiver. Adjust C12 for maximum received signal as indicated by the test receiver S-meter. Adjust C11 to put the BFO at approximately 4000.5 kHz. This completes alignment of the BFO for now. Remove the 51-ohm resistor from the T4 secondary and connect the BFO to the detector with RG-174 cable.

**Mixer, filter and IF amplifier.** The IF amplifier requires only one adjustment: With 12 V applied to the mixer/filter/IF amplifier board and later stages, adjust C8, IF TUNE, for maximum noise in the speaker or headphones.

**Local oscillator tuning range.** Connect the LO output cable to the mixer, and apply 12 V to the LO. Tune C9 to the low end of its range, and set the test receiver to 14.060 MHz. Connect the test cable shield clip to the LO box, but leave the center-conductor clip unconnected. Adjust C10 until you hear the LO in the test receiver. Be sure that the unconnected test-cable lead is far enough from the LO tuned circuit to have no effect on the LO frequency. Set the test receiver to 14.155 MHz. Tune the LO upward in frequency until you hear it in the test receiver. With luck, the TUNING capacitor will be nearly at minimum capacitance. Depending on the exact values of the capacitors in the Q4 gate circuitry, however, your LO may not have enough tuning range, requiring that you search downward for it with the test receiver even with the TUNING capacitor at minimum capacitance. If this is so, move the tap on L5 from 2 to 3 turns above ground and readjust the 14.060-MHz band edge with C10. This will increase the tuning range. (You may need to add capacitance in parallel with the 27-pF LO tuned-circuit capacitor to allow C9 to hit the band edge.) C10's tuning range is much larger than that of the TUNING capacitor, so adjust it carefully. With experimentation, you should be able to achieve a TUNING range of between 90 and 150 kHz. Remember that you'll need to make your final band-edge adjustment *after* installation of the LO box cover; be sure to provide a hole in the cover for this purpose, but leave the cover off for now. After you have set the LO tuning range, cement the base of each L5 pillar to

the shield-box bottom with Duco® (or similar) cement.

**RF amplifiers.** Install the 10-MHz RF amplifier in the receiver, and solder a 51-ohm resistor from the center conductor of J1 to ground. Connect the crystal calibrator, set for 10-kHz markers, to J1. Set the BAND switch to 10 MHz. Tune in a marker near the center of the tuning range and adjust C3 for maximum signal. Tune in the lowest marker in the range; adjust C5 for maximum signal. Tune in the highest marker in the range; adjust C6 for maximum signal. Because the C5 and C6 adjustments interlock somewhat, repeat them several times for good measure. Now, install the 18-MHz RF amplifier board and repeat this procedure at 18 MHz with C3 (at band center), C5 (at the lowest marker) and C6 (at the highest marker). This completes alignment of the RF amplifier boards.

**Anti-backlash adjustment.** With luck, the TUNING control will turn freely and require the same input torque across the tuning range. Backlash should be imperceptible throughout the range. If backlash is present, try loosening the reduction-drive coupler screws and tightening them again. Backlash in the ARRL lab version of this receiver was done away with by loosening and retightening the tuning capacitor in its mounting hole, *and* by slipping the TUNING capacitor several degrees to one side in the drive coupling sleeve before retightening the coupler worm screws.

**Dial calibration.** Calibrate the tuning dial *after* the tuning range has been set *and* any backlash has been ironed out. In the model shown in Fig. 1, calibration of the 10- and 18-MHz TUNING scales differs by the width of a dial marking. The left edge of each mark is used during 18-MHz tuning (18 MHz L); the right edge is used during 10-MHz reception (10 MHz R). Calibration of the full TUNING capacitor rotation (360°; 180° for each band) would make this unnecessary, but one band would tune "backward" relative to the other.

### Performance

Measured performance of the band-imaging receiver at 10 MHz: Minimum discernible signal (MDS), -140.5 dBm; two-tone 3rd-order IMD dynamic range (20-kHz spacing), 89.5 dB; blocking dynamic range, 134 dB; image rejection, 74 dB. At 18 MHz: MDS, -140.0 dBm; two-tone 3rd-order IMD dynamic range, (20-kHz spacing), 90.0 dB; blocking dynamic range, 131 dB; image rejection, 82 dB. With a signal tuned in on the 10-MHz band, dropping the receiver three inches to the operating table produced *no discernible shift* in the pitch of the received signal. Maximum audio output was 0.66 W into an 8.2- $\Omega$  test load. Current drain at 12 V dc was 95.1 mA with no input signal, 220 mA at maximum audio output.

# A High-Performance Communications Receiver

The receiver described here is the work of W7ZOI and K5IRK, and was presented in November 1981 *QST*. A progressive

system was used in the *QST* version, starting with a simple (but very useable) direct conversion receiver and concluding with a

multiband superheterodyne. This approach is highly recommended for those who may lack construction experience.

(A)

(B)

Fig. 10 — A 5-band, SSB version of the high-performance communications receiver constructed by K5IRK. In the top view, the VFO is located in the center with the input filter, mixer and IF boards to the left. The board at the far right contains the product detector and audio stages. The two boards to the right of the VFO are active audio filters (A). The bottom view shows the converter and oscillator boards. The BFO is contained in the shielded box at the left and the mixer board is at the lower center (B).

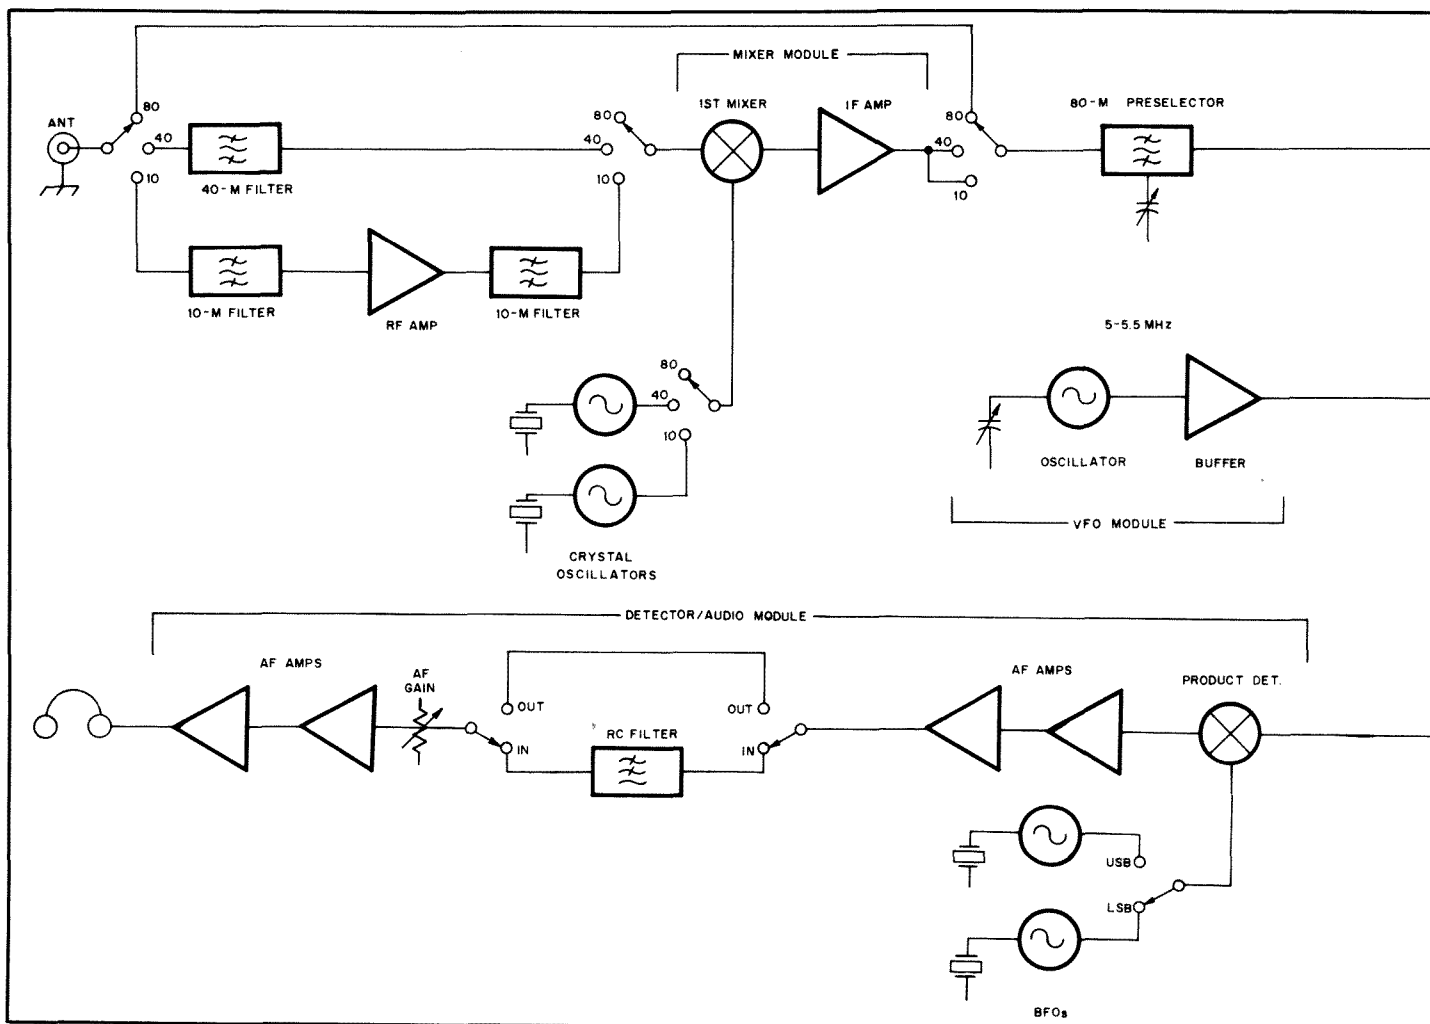

Fig. 11 — Block diagram of the W7ZOI/K5IRK communications receiver.

Shown in Figs. 10 through 19 is the receiver in its final form. The overall layout is shown in the block diagram, Fig. 11. On 80 meters the receiver functions as a single-conversion superheterodyne, with reception of the higher bands provided by higher-performance crystal-controlled converters. All of the converters use the same mixer module, switching only the converter filter and crystal oscillator modules. As shown, the 40-meter converter does not use an RF amplifier — it is unnecessary and it degrades dynamic range. The lower noise figure obtained with the RF stage is required on the bands above 7 MHz, however.

Many criteria were used in the design of this receiving system, but first and foremost were simplicity and ease of duplication. To this end, readily available components were used throughout. Alternative components are suggested where appropriate, and the circuits are insensitive to transistor type, allowing freedom in substitution. This does not in any way imply that the performance has been compromised; indeed, this receiver can equal the strong-signal performance of many of the high-priced receivers

on the market today.

### Circuit Description: The Converter, Filter and RF Amplifier

Preselection for the individual converter sections is provided by the circuit shown in Fig. 12. The optional RF amplifier is shown in A, and the version without the amplifier is shown in B. The same circuit board layout can be used for both versions.

Each filter module uses two types of filters. The first is a 5-pole low-pass, necessary to prevent spurious responses from VHF TV and FM broadcast signals. The second filter provides the majority of the front-end selectivity. It is a double-tuned circuit comprised of L7, L8 and their related capacitors. A variable capacitor is used at C15 because the small, non-standard values required here are difficult to obtain; a 1- to 5-pF variable is readily available and can be preset to the value given in Table 1 or adjusted during alignment.

The RF amplifier uses a dual gate MOSFET and modified-input low-pass filter. The first section is a simple low-pass filter, while the second section is a pi net-

work that transforms from 50 to 2000 ohms with a Q of 10. This provides an optimum driving impedance for the amplifier. The output uses a broadband transformer to provide a 50-ohm output impedance, ensuring proper termination for the following double-tuned circuit.

The filters may be aligned with a signal generator or crystal calibrator. If a calibrator is used, the input of the receiver should be terminated with a 50-ohm resistor. Initially, C15 is set near minimum capacitance, and the receiver is tuned to the center of the band. C14 and C17 are then adjusted for maximum response. C15 is then partially meshed, and C14 and C17 are again peaked for maximum response. The filter bandwidth is estimated by observing the response as the receiver is tuned toward band edges. This procedure is repeated until the desired bandwidth is realized. The input pi network used with the RF amplifier is adjusted by setting C22 for maximum response at the center of the band.

### Mixer Module

The two mixer modules used in the composite receiver are identical, each being comprised of a doubly balanced diode-ring mixer, U2 of Fig. 13, followed by a 9-MHz IF amplifier. The IF amplifier, Q9, is one of the more critical stages in the receiver. It must have a reasonable noise figure, low IMD, and a 50-ohm input and output impedance. A bipolar transistor with negative feedback is used to establish the gain and impedances. The 6-dB pad at the output preserves the input and output match of the stage. The moderately high bias current used ensures low distortion.

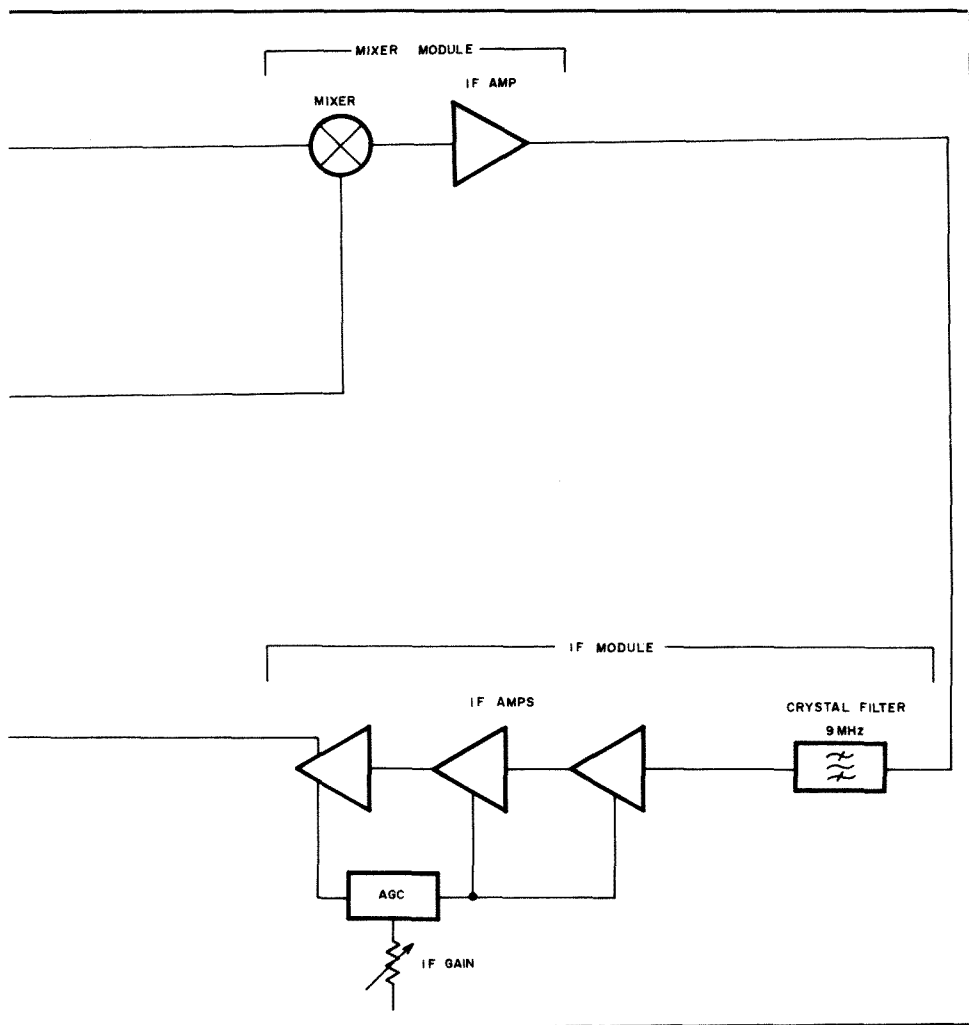

The transistor type used for Q9 is critical. It should have an  $F_t$  of at least 500 MHz. The 2N5109, 2N3866 and 2SC1252 are all suitable.

Amplifier gain, including the loss of the pad, is about 16 dB. The mixer has a loss of about 6 dB, leaving a net module gain of 10 dB. The amplifier output intercept is about +30 dBm. Careful measurements have shown that a diplexer is not required between the mixer and the amplifier.

### Crystal Oscillator Module

Shown in Fig. 14 is the circuit used for all of the crystal oscillators in the receiver. One or two of the modules are used for the BFO, and one module is used with each converter. The circuit is a Hartley oscillator with the crystal in series with the feedback tap from the coil. A trimmer capacitor in series with the crystal adjusts the operating frequency of the oscillator. If a single BFO is used, the 12-volt operating bias is applied through the output link as shown in Fig. 14B. When more than one module is used, as with the converters, operating voltage is applied through the bandswitch, Fig. 14C. Only the oscillator in use has power applied to it.

This circuit will deliver an output power

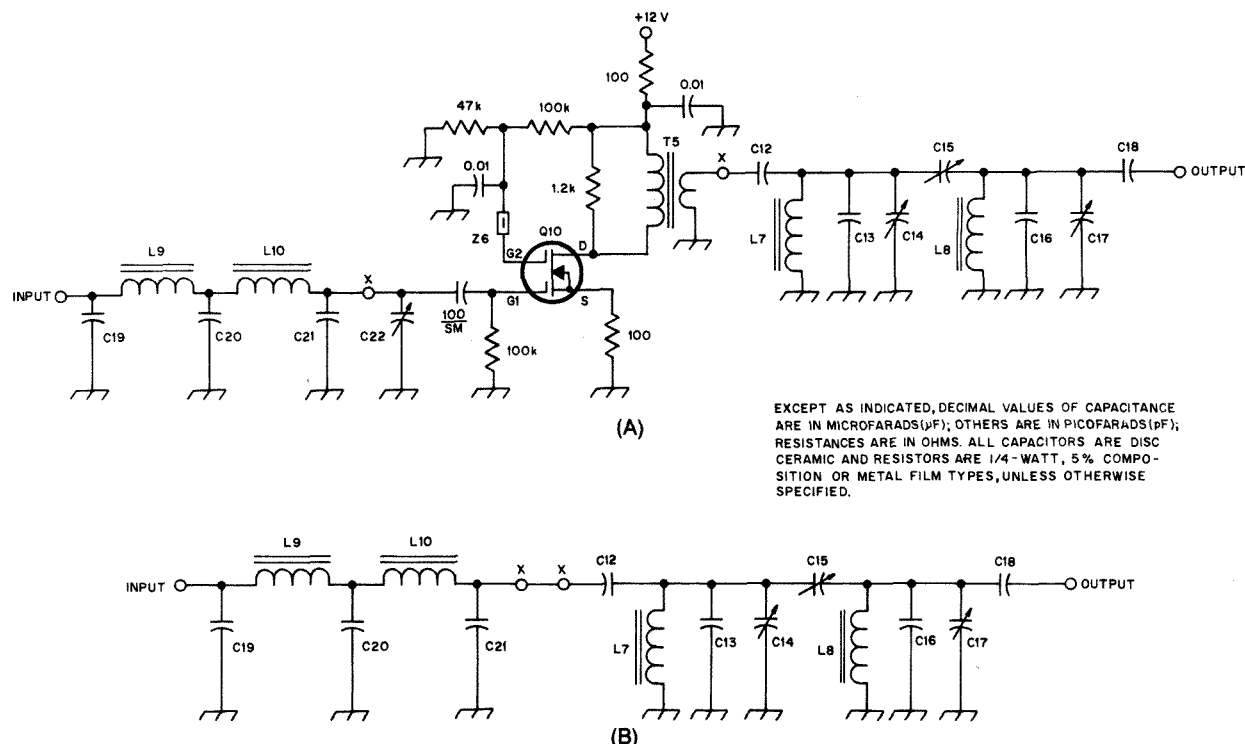

Fig. 12 — Circuit diagram of the converter filter and optional RF amplifier used in the W7ZOI/K5IRK receiver. The circuit using the RF amplifier is shown in A, while the configuration without the amplifier is shown in B.

C12, C13, C16, C18-21 — Silver mica or ceramic, see Table 1 for values.  
C14, C17, C22 — Mica compression trimmer or similar variable, see Table 1 for values.  
C15 — Air variable, 1 to 5 pF.

L7-10 — No. 22 enamel wire wound on Amidon T50-6 core, see Table 1 for number of turns.  
Q10 — Dual gate MOSFET, 40673, 3N211, 3SK40 or similar.

T5 — Ferrite transformer, 20 turns primary, 4 turns secondary, on Amidon FT37-43 core.  
Z6 — Ferrite bead on lead of Q10. Amidon type FB43-101.

of about +10 dBm, which is more than enough to drive the diode mixers. Adjustment of the oscillators should be done with the mixer attached. C11 is tuned for maximum output and proper starting of the oscillator. The series capacitor is then adjusted for the correct operating frequency. This capacitor may be eliminated in those modules used with the converters. In these cases, the crystal is connected directly to ground.

### 80-Meter Preselector Filter

The 80-meter preselector filter is shown in Fig. 15. It consists of two cascaded filters: The first is a 7-pole, high-pass (3-MHz cutoff), composed of the components between the two 650-pF capacitors. This filter suppresses spurious responses from AM broadcast signals. The second part of the filter, while basically a low-pass type, was designed for a very pronounced peak, resulting in a sharp, bandpass-like response. C6 is a 365-pF broadcast capacitor mounted on the front panel.

### VFO Module

The variable frequency oscillator, Fig. 16, uses a JFET in a Hartley circuit, followed by a dual-gate MOSFET buffer. For best temperature stability, type SF material (Amidon -6 code) is used for the inductor

Note: Other filter parts are identical to that without the amplifier. Values listed for capacitors are capacitance in pF. Values listed for inductors are the number of turns of wire required.

core, as this material has a lower temperature coefficient than the usual slug-tuned inductor. All of the capacitors in the tuned circuit should be NP0 ceramics, as they have the lowest temperature coefficient of any readily available type. Silver mica and polystyrene types should not be used in this circuit.

The resonator (tuned circuit) should be

lightly loaded; to this end, the coupling capacitor to the gate of the JFET is kept as small as possible. If the specified 2.7-pF NP0 ceramic cannot be obtained, a small air variable of similar value can be substituted. Following these precautions will ensure excellent stability. Typical warm-up drift is under 200 Hz over a period of 10 minutes. After warm-up, drift

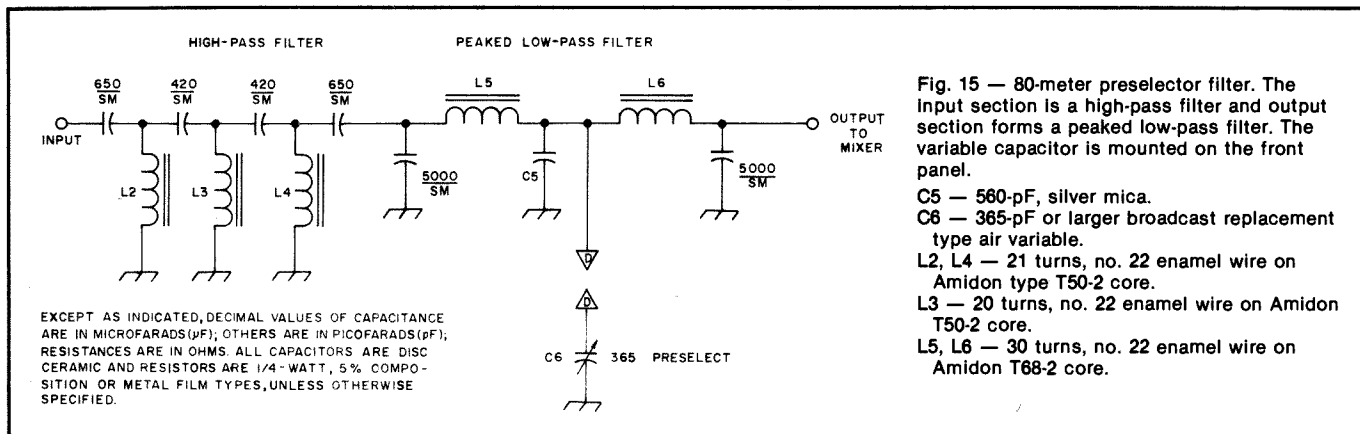

D1. When large signals are present, the detected voltage from D1 appears at the base of Q16, discharging the timing capacitor, C24. The voltage change at C24 is coupled to the line through a diode, and reduces the gain of Q11 and Q12. R10, the "AGC set," is adjusted for a dc potential of 0.4- to 0.5-volt at the base of Q16. This adjustment is made with the AGC on, with no signals present. When measured with a high-impedance voltmeter, the AGC line should show about 6 volts at maximum gain.

Two transistor switches are contained in the amplifier. Q17 is used to defeat the

3N140, 3N211, 3SK40 or similar.

Q13, Q14 — PNP silicon transistor, 2N2907A, 2N3906, 2N4403 or similar.

Q15-17 — NPN silicon transistor, 2N2222A, 2N3904, 2N4401 or similar.

R10 — 1-kΩ PC-board mount variable resistor linear taper.

T6 — Ferrite transformer, 15-turn primary,

3-turn secondary, no. 28 enamel wire on Amidon FT37-43 core.

Z3 — 9-MHz crystal filter, 500 ohm impedance level: For SSB, KVG type XF-9B, Yaesu XF-92A or Fox-Tango Corp., eq. For CW, KVG type XF-9M or XF-9NB, Yaesu XF-90C or Fox-Tango Corp., eq.

Z4, Z5 — Ferrite bead on lead of MOSFET, Amidon FB43-101 or similar.

AGC. It is activated by a positive voltage applied to the "AGC off" line. The other switch, Q15, is attached directly to the AGC line. A positive voltage applied to its input shorts the AGC line to ground, muting the receiver. The extra diodes allow muting to occur quickly while not discharging C24. The IF returns rapidly to full gain after muting periods.

The AGC response is more than adequate and overshoot is minimal. Recovery time is relatively independent of signal level. The recovery time may be shortened by decreasing the value of C24 or the associated 1-megohm resistor.

#### Detector Audio Module

The IF section of the receiver is followed

by the detector and audio amplifiers, shown in Fig. 18. The detector used here is a doubly balanced diode-ring mixer, a Mini-Circuits Labs SBL-1. Mixers from other manufacturers or homemade equivalents will work as well. The excellent balance provided by this type of mixer helps eliminate problems with the AGC system caused by BFO leakage.

The detector output is applied to a diplexer network formed by RFC1 and related components. This network ensures that the detector is properly terminated at all frequencies from audio to VHF.

The first audio amplifier is somewhat unusual in that it uses the common-base configuration. When biased for an emitter current of about 0.5 mA, it provides the

50-ohm input impedance necessary to properly terminate the detector. The second audio stage, Q2, is a direct-coupled PNP amplifier. The receiver may be muted by shorting the collector of Q2 to ground. This is done by applying a positive voltage to the muting input, saturating Q5. The output of Q2 drives the audio gain control, which is mounted on the front panel. If the optional RC active filter is used, it is connected between the output of Q2 and the gain control.

Q3 functions as a common-emitter amplifier, while Q4 is an emitter follower. Q4, biased for an emitter current of about 30 mA, provides sufficient audio output to drive low-impedance (4 to 16 ohms) headphones. If high-impedance headphones are

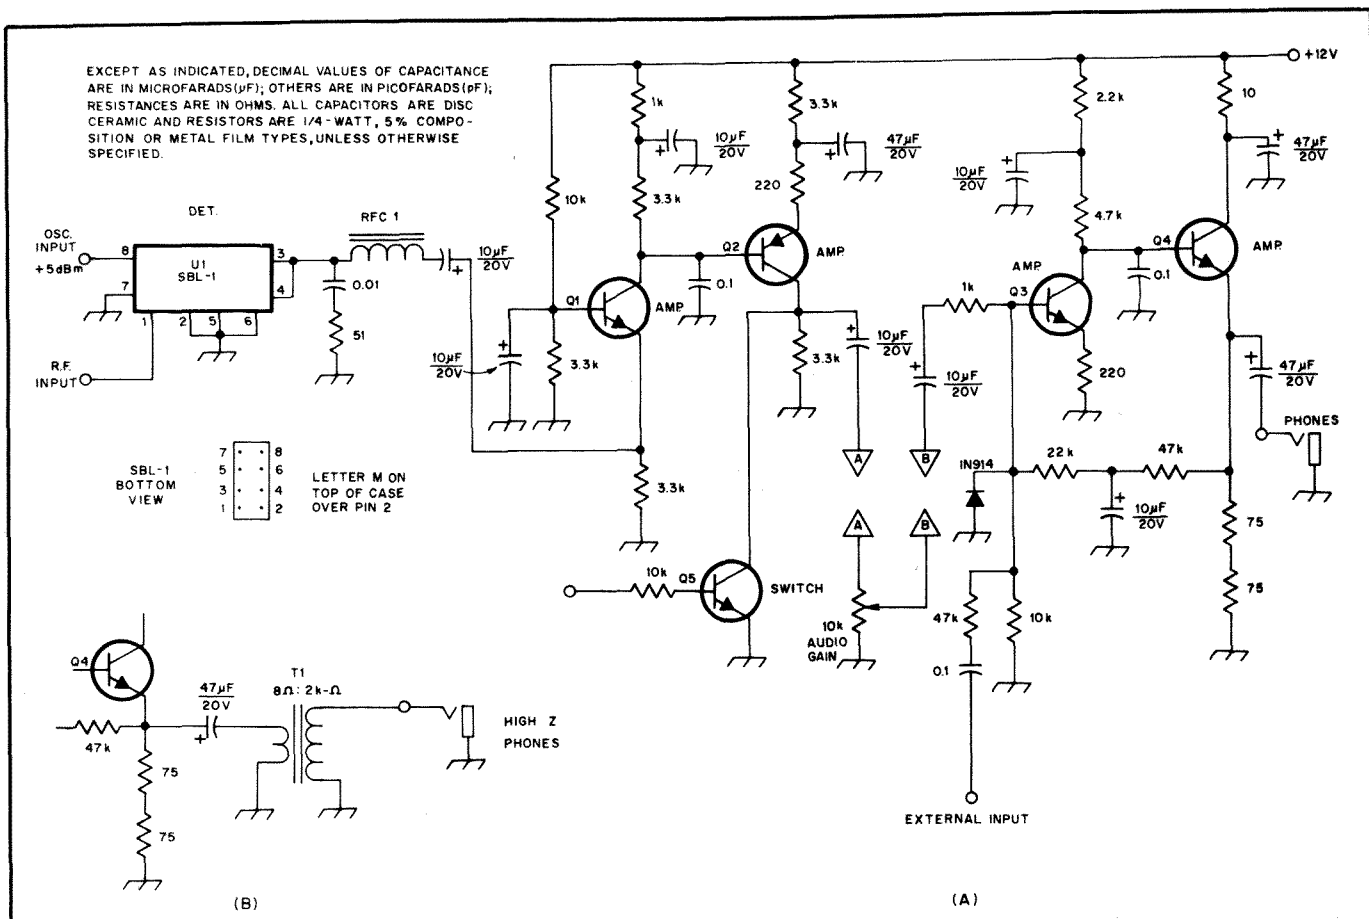

Fig. 18 — Schematic diagram of the product detector and audio amplifier. If high-impedance headphones are to be used, the output circuit shown in B is recommended.

Q1, Q3 — Low-noise NPN, 2N3565 or similar.  
Q2 — General-purpose PNP, 2N3906 or similar.

Q4 — TO-5 or TO-39 NPN, 2N3053 or similar with small heat sink.  
Q5 — 10-k $\Omega$  audio taper.

RFC1 — 20 turns no. 28 enamel wire on Amidon FT37-43 ferrite toroidal core.

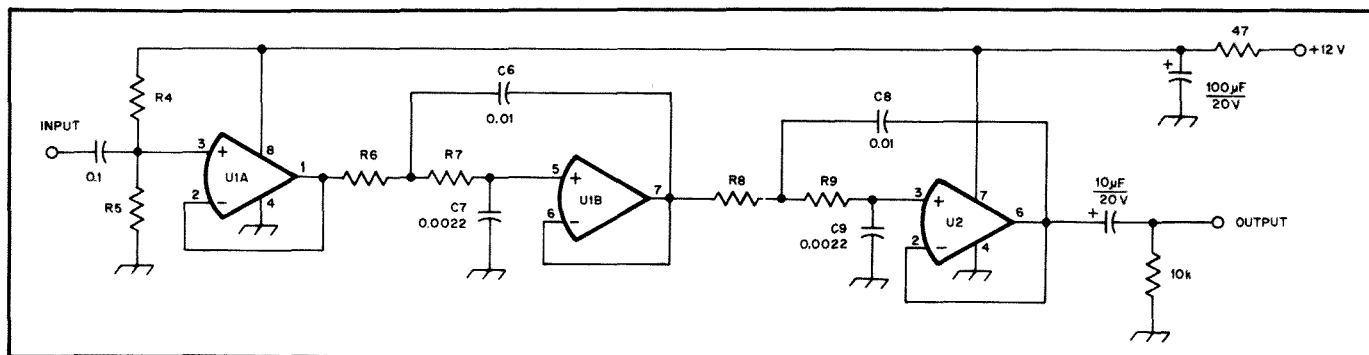

Fig. 19 — Schematic diagram of the optional RC active audio filter. A 4-pole low-pass filter is shown here. Additional sections may be added for improved performance.

C6, C8 — 0.01- $\mu\text{F}$ , 10% or better tolerance, ceramic or polystyrene.

C7, C9 — 0.0022- $\mu\text{F}$ , 10% or better tolerance, ceramic or polystyrene.  
R4-9 — 33-k $\Omega$  for CW or 15-k $\Omega$  for SSB filter.

U1 — 1458 or similar, dual op-amp.  
U2 — 741, or similar, op-amp.

to be used, a step-up transformer should be used to increase the system voltage gain. This is shown in Fig. 18B. An auxiliary input to the audio amplifier is provided for injection of a sidetone signal for CW monitoring.

The optional RC active filter shown in Fig. 19 can be used to improve selectivity during CW reception, especially when the

IF filter is of bandwidth suitable for SSB operation. As shown in Fig. 19, the filter has a single pole of high-pass filtering and four poles of low-pass response. The cutoff frequency is about 1-kHz for CW or 2-kHz for SSB. The filter bandwidth is determined through proper choice of resistor values. Values for both bandwidths are given in Fig. 19. The filter may be expanded to

many more sections for improved skirt selectivity.

### Construction

Mechanical details, such as the type of cabinet and dial drive, are left to the discretion of the builder. Band switching is not critical, as all of the switched points occur at low impedance levels. A multi-wafer

Table 3

RF amplifier assumed to have a 3 dB noise figure, a 15 dB gain and a +22 dBm output intercept. Circuits marked with (\*) are measured cases. All measurements done at 14 MHz.

rotary switch will work well. Small coaxial cable, such as RG-174/U, should be used for all signal lines.

The version shown here was built by K5IRK. The bulk of the 80-meter part of the receiver is mounted above the chassis. The VFO is contained in an aluminum box, providing both shielding and mechanical strength. The BFOs are below the chassis in a box constructed of scrap circuit-board material. The converters are mounted below the chassis.

Homemade, etched circuit boards were used in the K5IRK model, while "ugly-but-quick" breadboards were utilized by W7ZOI in the construction of his receiver.<sup>1,2</sup> "Ugly boards" are easily built, with scraps of unetched circuit-board material serving as ground foil. The circuitry is supported by those components that are normally grounded. Additional

support is provided by suitable tie points. Large-value resistors serve well for this purpose, especially in RF circuits where the impedance level is low. All of the circuitry for the receiver was initially breadboarded using this method. While not as "professional" in appearance, the performance was identical to that of later circuit board versions. In few cases where a performance difference could be detected, the ugly breadboards were superior, usually a result of improved grounding.

#### Performance

It should be emphasized that, although relatively simple, this receiver is not a toy. It features excellent stability, selectivity consistent with the filter used by the builder, adequate sensitivity, and a dynamic range that rivals or exceeds that of many commercially available equivalents. The only major compromise is the utilization of dual conversion on the higher bands. The penalty is small, because the gain distribution has been carefully planned.

System measurements were made on the receiver at various stages of development.

This data is summarized in Table 3. Both measured data and calculated results are presented to give the prospective builder some feel for the performance to be expected. The table shows the system noise figure, input intercept, minimum detectable signal and the two-tone dynamic range. Both CW and SSB bandwidths are considered in both single- and dual-conversion designs, with and without an RF amplifier. Measurements and calculations generally agree within 1 dB.

Table 3 reveals no surprises. The nature of the trade-off between single and dual conversion is well illustrated, as is the effect of adding an RF amplifier. The system showing the largest dynamic range is the single-conversion design without an RF amplifier. It should be noted that this data pertains only to the modules described. Changes in gain, noise figure or intercept of any stage will change the results. The table should not be used for general comparisons.

The dual-conversion systems are about 5 dB "weaker" than the single conversion ones; this is typical. It should be understood that this observation applies only to dual-conversion systems with a wide bandwidth first IF. Modern systems using a crystal filter at the first IF will display performance much the same as a single-conversion receiver, even if they utilize several conversions. No gain compression was measureable in the single-conversion model with no RF amplifier, even with an input signal of -10 dBm. VFO phase noise was measured to be -152 dBc/Hz at a spacing of 10 kHz.

Operationally, the receiver is pleasing to use, offering a clean, crisp sound that is not always found in commercial equivalents. Of greatest significance is that the receiver should be easily duplicated at a cost well under that of commercial units.

<sup>1</sup>Circuit board templates are available from ARRL for \$1 and a large s.a.s.e.

<sup>2</sup>Circuit boards, negatives and many parts for this receiver are available from Circuit Board Specialists, P.O. Box 969, Pueblo, CO 81002.

# High-Performance Receiver Design Concepts

Amateur Radio design technology is changing so rapidly today that it is impossible to publish a high-performance receiver circuit that remains timely when the work is committed to print. As new components and active devices are introduced to the market, better designs become possible. These advances make obsolete many of the circuits found in current amateur literature. Therefore, this section is devoted to design objectives, circuit techniques and some practical examples. This will serve as the basis for individual designs which can be carried out by the more experienced amateur.

The interest in building homemade receivers of the more complex variety has waned tragically during the past decade. This has been brought on by an increased interest in operating, and through the availability of sophisticated receivers and transceivers found on the commercial market. For this reason it seems prudent to devote this portion of the *Handbook* to design approaches. The information given here is based on circuit and performance investigations in the ARRL laboratory. It is slanted toward the practical side of design and application in order to be of use to amateurs who have no formal background in electronics.

## Performance Objectives

What should an amateur look for in terms of high performance when building a receiver? A subjective outlook would call for "bells and whistles" with which to play, but a discerning operator is interested in performance under all of the adverse conditions one might encounter in the course of operating an amateur station. The following are representative of the major considerations in receiver performance:

1) High dynamic range. This is the ability of the receiver to perform well in the presence of strong signals within and outside the amateur band of interest. Poor dynamic range results in cross-modulation effects, receiver desensitization and spurious responses from the mixer, which appear in the tuning range as additional signals (mixer IMD).

2) Good selectivity. This feature includes the receiver front end (RF amplifier and mixer) along with the IF and audio selectivity. The object is to have the receiver pass only those frequencies to which it is tuned, while rejecting all others. This Utopian goal cannot be realized, but it can be approached closely enough to ensure good performance.

3) Low noise figure. The noise figure should be such that it is somewhat below the level of the receiver antenna noise under typical "quiet" band conditions. This means that the noise generated within the

receiver — notably the early stages — should be kept to an absolute minimum so that it does not mask weak incoming signals.

4) High order of stability. All of the receiver oscillators, whether crystal-controlled or LC types, should, ideally, be drift free. Since this is practically impossible, maximum drift should not exceed 50 to 100 Hz in a good design. The greater the IF selectivity, the more important the oscillator stability. Self-oscillations should not be allowed to take place in any part of a receiver.

5) Wide-range AGC. The AGC circuit should engage at low signal levels and hold the receiver output at a plateau over a wide range of input-signal levels. For example, the audio output should remain constant in amplitude over a range of input signal from less than a microvolt to better than 10,000  $\mu$ V, depending on the external noise level which reaches the receiver front end. The AGC attack time should be set so that "pumping" and "clicking" is not noted when strong signals are received.

6) Local oscillator. Not only must the local oscillator be stable, it needs to have low noise and good spectral purity at the output. Ideally, the LO noise floor should be 80 to 100 dB below the peak output voltage. Spurs and harmonics in the output should fall at least 50 dB below peak output. LO output energy must be confined to the mixer by means of appropriate shielding and filtering.

7) IF amplifiers. An IF amplifier strip needs to have sufficient gain to drive the detector and provide ample excitation to the audio channel. The design should include active devices which can operate with a collective 80 dB or greater AGC swing over the input-signal range mentioned in item 5.

Wideband noise is generated within most IF amplifier chains. An improvement in receiver "noise bandwidth" can be realized by adopting the W7ZOI filter "tailending" scheme which calls for use of a second IF filter immediately after the last IF amplifier. The second filter can have slightly greater bandwidth than the filter used ahead of the first IF amplifier. The tailend filter will reduce wideband noise components. This technique is discussed in greater detail in *Solid State Design for the Radio Amateur*, by the ARRL.

8) IF filters. In order for a filter to function, there must be some insertion loss (IL) if a passive network is being used. The IL is typically highest when a mechanical filter is used. This factor must be taken into account when planning the receiver gain distribution. Most mechanical filters have an IL of 8 dB or greater, whereas a well designed crystal-lattice filter has a

characteristic IL of less than 5 dB.

In some designs the IF filter is the limiting factor in obtaining high performance in mixer IMD. This is because of the movement of the mechano-electrical contacts within the filter, which generate IM products which are independent of those in the mixer. Laboratory investigations indicate that mechanical filters were somewhat worse than crystal filters in this respect, limiting the receiver IMD profile to roughly 95 dB. The crystal holders in lattice filters must be able to provide positive electrical contact with the quartz element and the circuit to minimize the generation of IM products.

Careful attention must be given to correct filter termination and input/output resonance to ensure minimum passband ripple: Most filters require a specified external terminal capacitance to resonate the input and output transformers within the filter module. Similarly, each filter has a characteristic input and output impedance which must be matched to the source and load.

9) Detector and audio channel. An otherwise excellent receiver can be spoiled by an inferior product detector or audio-amplifier strip. The detector must be able to handle the highest output signal from the IF strip without saturating. Although active product detectors are sometimes used, they are the most prone to this malady. The preference of most designers is a passive diode detector of the singly or doubly balanced variety. This type of detector can handle high signal levels with large amounts of BFO injection. Since the detector is the lowest-level part of the audio channel, hum and noise should be minimal at this point in the circuit. Passive detectors do not need operating voltages; hence one primary source of hum is avoided.

A low-noise audio preamplifier should follow the detector in a quality design. It should be able to withstand the maximum output from the detector at peak receiver input signal without operating in a non-linear manner. The audio gain control can be used to the best advantage when it is located after the AF preamplifier. If it is used ahead of the preamplifier, the noise figure of the audio channel may be degraded at low settings of the gain control.

Audio shaping is normally applied to the AF channel to provide a low-frequency rolloff at some frequency well above 60 or 120 Hz. This greatly reduces the chance of power-supply ripple appearing in the audio output. Also, there is little need for low-frequency response below, say, 300 Hz in a communications receiver. Similarly, the high-frequency response should be restricted so that rolloff starts around 2000 Hz. A satisfactory tailoring of the audio

passband can often be done by proper selection of the R and C components in that part of the circuit.

All of the audio stages must operate linearly up to peak signal levels. This will minimize distortion and aid weak-signal reception greatly. It is prudent, therefore, to use an output stage which is capable of delivering greater undistorted power output than will ever be needed. Cross-over distortion is also to be avoided. The effects of this are most apparent under weak-signal conditions. The signal has a "fuzzy" sound when this type of distortion is present. Some of the audio-power ICs have significant cross-over distortion which can not be corrected. This is because the biasing is done within the IC, and it can't be changed. For this reason it is helpful to use discrete devices in the audio channel. This enables the designer to bias the amplifiers for minimum distortion.

Tuned audio amplifiers can be used to provide steep skirts outside the desired passband. An example of a simple application of this, using a single pot-core inductor with variable Q, was described by K1TX in April 1979 *QST*. Various types of passive LC filters can be used to obtain CW or SSB selectivity at audio.

RC active audio filters with variable Q and adjustable peak frequency offer an excellent means for limiting the audio bandwidth, minimizing wide-band noise and reducing QRM. Ideally, these filters should be contained in the low-level part of the audio channel rather than at the receiver output. This will prevent overloading of the filter, which can impair the performance and introduce intolerable amounts of distortion.

10) Structural considerations. There can be considerable latitude in the mechanical approach one takes when laying out a high-performance receiver. Aesthetics have no place in this discussion. We will address the matter of structure versus performance and leave the beauty of the front panel to the builder.

The major points of concern are rigidity of the overall assembly and shielding against incidental pickup and radiation. The chassis and panels should be strong enough to prevent undue stress on the PC boards during flexing or vibration. In a like manner, the local oscillator should be relatively immune to any mechanical stress which is imposed on the receiver.

An excellent assembly technique is one that uses a modular approach for the various key circuit assemblies in the receiver. Each module is contained in its own shielded box. All signal leads entering and leaving the various modules are made from RG-174/U or similar coaxial cable. The shield braid is grounded at each end of each cable. Leads which carry dc are decoupled where they leave the module

shield. LC or RC decoupling networks are suitable in most instances. Feed-through capacitors can be mounted on the box walls of each module to serve as terminal connections for the dc voltages, while also functioning as parts of the decoupling networks. Since 50- $\Omega$  miniature cable is suggested for interconnecting leads, the points to which they connect in the circuit should be designed for a similar impedance.

This form of modular construction and shielding greatly reduces the chances for "birdies" by keeping RF energy where it belongs. It also prevents unwanted external signals from being picked up by low-level parts of the circuit. Miniboxes or die-cast aluminum boxes are excellent for use in modular work. Homemade enclosures can be fashioned inexpensively from pieces of double-sided PC board. Modular construction permits the amateur to try new circuits within the receiver without disrupting the remainder of the circuitry.

11) "Bells and whistles." This discussion does not include such themes as synthesizers, IF passband tuning, noise blankers, computer-programmed functions and digital frequency readout. These are primarily subjective matters, however useful they might be.

For reasons of practicality, the builder must decide whether he will use analog or digital readout of the receiver frequency. There are two disadvantages with analog systems: (1) Quality dial mechanisms are scarce and highly expensive. (2) Readout resolution is usually poor if more than 200 kHz of any band is covered. The major advantages of analog frequency readout are reduced circuit complexity, lower cost (sometimes) and less current drain from the receiver power supply. Heating is diminished also — a definite benefit to stability.

A frequency counter and a digital display, on the other hand, permit 500-kHz frequency spreads with good resolution. A shaft encoder is needed for synthesized LO systems to avoid thumb-wheel frequency selection. But, it is easy to use parts of the synthesizer circuit for the frequency counter, thereby making the two circuits compatible. In this type of system, or in one which has a conventional LO and a counter, a 10:1 vernier drive without detectable backlash is almost mandatory to keep the tuning rate within practical limits.

It should be stressed here that counters can create noise and spurious responses if they aren't designed and used correctly. Careful shielding and filtering must be applied to prevent the counter from affecting the other parts of the receiver circuit.

The same general considerations apply to synthesizers. The design must be carried out with care to minimize phase noise, which can degrade the mixer noise figure and the ultimate IF selectivity.

Three *QST* articles are offered as

references on high-performance receivers. They contain information which will be of value to the amateur designer.<sup>3</sup>

## RF Amplifiers

When it is deemed necessary to use an RF amplifier ahead of the receiver mixer, thought must be given to gain, linearity, signal-handling ability and noise figure. The choice between bipolar transistors and FETs is another consideration. An RF amplifier should not be necessary in a properly designed receiver, even if a passive mixer is used, provided the input networks are not highly lossy and are matched to the source and load. This rationale applies to frequencies up to approximately 14 MHz. At 20 meters and higher, an RF amplifier may be needed to ensure an acceptable receiver noise figure.

As a rule, the designer should use no more gain in the RF stage than is necessary to obtain an acceptable noise figure. The higher the stage gain, the greater the sensitivity. But, more gain than is needed will degrade the receiver dynamic range markedly, by virtue of the mixer being fed larger amounts of input signal than if no RF amplifier was used. So, even at the very early part of a receiver it is vital to pay attention to *gain distribution*. This fundamental rule applies from stage to stage through the receiver.

There should be sufficient selectivity ahead of the RF amplifier (and in most instances between it and the mixer) to restrict passage of signals outside the amateur band of interest. This will greatly reduce the probability of unwanted images in the tuning range. Furthermore, it will help prevent very strong out-of-band commercial signals from entering the receiver front end and impairing performance. This form of selectivity is called "preselection." It can take the form of LC circuits which are very narrow in bandwidth, and tracked manually from the front panel. Alternatively, fixed-tuned LC filters can be used to provide selective circuits. A band-pass filter or tuned circuit is the choice of most designers because rejection is offered above and below the frequency band of interest.

The choice between small-signal FETs and bipolar transistors in an RF pre-amplifier is more than arbitrary. FETs exhibit low noise figures at HF and they consume less dc power than bipolars for an equivalent output intercept. Generally speaking, FETs are less subject to blocking in the presence of strong input signals.

<sup>3</sup>Wes Hayward, W7ZOI, "A Competition-Grade Receiver," *QST*, March and April 1974. Doug DeMaw, W1FB, "His Eminence the Receiver," *QST*, June and July 1976. Jay Rusgrove, W1VD, "Human Engineering the Station Receiver," *QST*, January 1979.

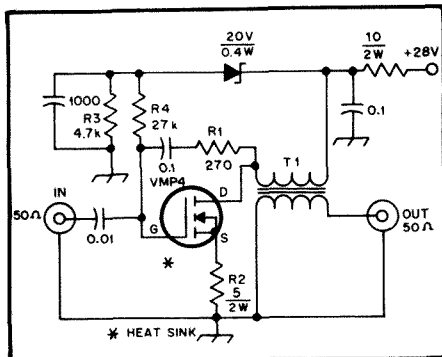

Fig. 20 — Diagram of the Class A large-signal RF amplifier which uses a VMOS power FET. T1 has 9½ turns of no. 30 enamel wire on a Stackpole no. 57-9130 ferrite balun core.

Bipolar transistors, on the other hand, have rather well defined input and output impedances and can be used more easily with negative feedback than can FETs. These features make them ideal for ensuring a proper and constant filter termination. A common-source FET which operates in the HF spectrum can not meet the foregoing condition. The use of negative or degenerative feedback in a bipolar-transistor preamplifier makes possible a low noise figure and a good input and output match.

Bipolar transistors which are designed for CATV and UHF oscillator work, such as the 2N5179 (biased for about 20 mA) and the 2N5109 (biased for roughly 50 mA) are excellent for use as RF amplifiers ahead of a mixer.

Fig. 20 shows a high-performance RF amplifier which uses a VMOS VHF power FET. (Oxner, May 1979 *QST*, p. 23). The circuit is designed with feedback and is structured for a source and load impedance of 50 Ω. The stage gain is determined by the designer's needs. Once this parameter is chosen, the values for R1 and R2 can be obtained from

$$Q = \frac{\sqrt{R_S R_L}}{2} \quad (\text{Eq. 1A})$$

$$X = \frac{\sqrt{G}(R_S + R_L)}{\sqrt{2 R_S R_L}} \quad (\text{Eq. 1B})$$

$$R1 = Q \times [\sqrt{G} + \sqrt{G + 4(1 + X)}] \quad (\text{Eq. 1C})$$

$$R2 = \left( \frac{R_S R_L}{R1} \right) - \frac{1}{G_M} \quad (\text{Eq. 2})$$

where

G is the desired stage gain for the amplifier, and

G<sub>M</sub> is the forward transconductance value of the transistor expressed in siemens (Y<sub>21</sub> real).

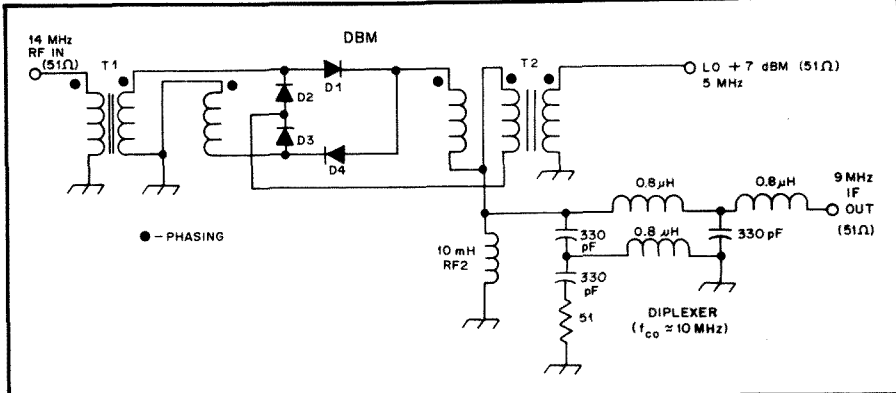

Fig. 21 — Practical circuit for a doubly balanced diode-ring mixer. The components are discussed in the text.

The equations don't yield standard resistance values in most instances. In an amateur application the nearest standard value will often suffice. R2 of Fig. 20 consists of six 30-Ω resistors in parallel to obtain 5 Ω. Three are soldered from one source tab to ground, and the other three go from the remaining source tab to ground. This helps reduce stray inductance in that part of the circuit. A power gain of approximately 13 dB results with the component values shown. Noise figure is 4 dB at 30 MHz. A 1-dB saturation power output of 3.7 watts was observed, indicating the suitability of this type of circuit for high signal-handling applications.

The VMP4 is a fairly expensive M/A COM transistor. It is likely that one of the lower-priced devices, such as the VN66AK, would provide good service at HF in the circuit of Fig. 20.

### High Performance Mixers

Doubly balanced diode-ring mixers (DBMs) of the type discussed earlier are often used to obtain high dynamic range. Among the advantages are low noise (diode mixers generate very little noise) and broadband characteristics. The mixer noise figure is approximately the conversion loss of the diode ring — typically 7 to 8 dB. The balanced mixer circuit provides port-to-port isolation which is not possible with single-ended or singly balanced mixers. This feature can aid the mixer IMD and help to minimize spurious responses resulting from the LO energy entering other parts of the receiver circuit.

The main shortcomings of diode mixers are the high level of LO injection needed (approximately +7 dBm for most) and the necessity of proper mixer termination, especially at the IF output port. This type of mixer is subject to harmonic mixing — another trait the designer must deal with.

Some high-level diode-ring mixers are available commercially. They require a high

amount of injection power (+17 dBm for acceptable performance). Laboratory analysis suggests that high-level mixers misbehave as a result of diode imbalance at specific current levels. The effect is one of the IMD not dropping 3 dB when the input tones are lowered 1 dB in level. This phenomenon could be caused in part by saturation of the broadband input and output transformers at specific power levels. A thorough discussion concerning diode mixers and their behavior is presented in the League's book, *Solid State Design for the Radio Amateur*, Chapter 6. Fig. 21 shows a practical circuit for a DBM. It includes a diplexer at the IF port to establish a 51-Ω termination for the mixer. This offers an improvement to the IMD level by a few decibels over a similar mixer with no diplexer.

The diodes can be HP2800 hot-carrier types. Carefully matched 1N914s are sometimes used as substitutes. T1 and T2 are broadband toroidal transformers (baluns). For wideband use in the HF spectrum the cores should have a high permeability. A 0.37-inch-diameter ferrite core (Amidon FT37-43) with a mu of 950 will work nicely. Ten trifilar turns of no. 30 enamel wire can be used for the windings. Output intercept for this circuit is typically +13 dBm with the LO injection at +7 dBm. This provides an input intercept of 20 dBm (output intercept plus the 7 dB conversion loss = 20 dBm). Calculations for a high-level diode mixer, assuming a +17 dBm LO level (recommended), indicate the output intercept will be +23 dBm. Again, assuming a 7-dB conversion loss, the input intercept becomes quite desirable: +30 dBm. This is based on the respective performances of the commercially available SRA-1 and SRA-1H DBMs. It can be seen from the foregoing that better mixer performance can be realized at the higher LO-injection levels. The actual LO power applied will depend upon the current-handling ability of the diodes.

# 160-Meter Linear QSK Transverter

The 160-m QSK transverter shown in Figs. 22 through 28 was designed and built in the ARRL lab by Zachary Lau, KH6CP/1. A prototype was used in the ARRL 160-m contest to make 56 contacts from a second floor apartment. It is designed for use with a 7-MHz QSK CW/SSB rig such as the Ten-Tec Argonaut, although any rig that operates on 7 MHz can be adapted for use. It features very low distortion; the unit pictured has IMD products at least 48 dB down at its rated output of 2-W PEP. The circuit is easy to duplicate: Several versions were constructed with good results. With just an RF probe and multimeter for measurements, an IMD performance of -42 dB can be obtained.

Fig. 22 — This QRP 160-m transverter features QSK and low distortion.

## Circuit Details

The schematic diagram of the transverter is shown in Figs. 23 and 24. A pair of Mini-Circuits SBL-1 mixers is used to convert between 7 and 1.8 MHz. Q1 generates the 5.2-MHz local-oscillator signal that feeds the splitter circuit composed of T1 and R4.

After the 1.8-MHz signal is generated using U1, the 7-MHz IF signal, and the local oscillator, it is amplified by a pair of broadband amplifiers with roughly 44 dB of total gain. Q3 runs fairly warm, since it dissipates about 1.3 W. The large standing current is necessary to obtain the excellent IMD performance. A 2-pole band-pass filter is used to remove the unwanted mixer products. Better IMD performance may be obtainable by using filters at both the input and output of the amplifier strip, but more parts are required and the adjustment procedure may be more involved. Care must be taken to properly terminate the mixer if this approach is taken.

A matched pair of MRF476 transistors is used to take the low-level output of roughly 20 mW up to 2 W PEP. The biasing is slightly unusual in that an LM317T current source is used. It is essential that diode D3 be thermally coupled to the transistors, since it is supposed to draw current away from the transistors as the circuit heats up. Surprisingly, it is the driver stage and not the output transistors that limits the IMD performance. An IMD performance of -54 dB has been measured at a power level of 4-W PEP output when the final stage was driven by a pair of signal generators. See Fig. 25.

A 7-element low-pass filter removes the harmonics from the output signal and eliminates the receiver image signals. A series-resonant circuit is used to pick off the receive signal. This technique has been

described by Roy Lewallen, W7EL.<sup>1</sup> Despite the simplicity of this circuit, the unwanted RF at the receiver during transmit is only -15 dBm. As one might expect, the third order input intercept of the mixer is degraded to +2.5 dBm, but this is more than adequate for casual QRP work. The output of the mixer feeds the receiver directly, since an IF receiver with a tuned input will reject most unwanted mixer products.

## Construction

Construction of the transverter is straightforward. It requires stuffing two PC boards, attaching the connectors, and mounting everything in a shielded box. Figs. 26 and 27 show the parts placement for these boards. When you are drilling the amplifier board, don't forget to drill the no. 33 or 1/8-inch holes to mount the heat sink.

The box used is a Ten-Tec BU-625. Its design allows the final amplifier to be well shielded from the driver stages. This shielding is necessary because of the very high gain on a single frequency. It is necessary to use heat sinks for all of the transistors except Q1. Q3 runs fairly warm and requires a hefty heat sink such as a Thermalloy 2215B. The heat sink for the MRF476 transistors is a strip of aluminum that also acts as a mounting bracket. Nylon screws and insulating washers are used to electrically isolate the MRF476 transistors from the grounded aluminum strip. Greaseless TO-220 insulators seem to work well in this application, although standard mica insulators would work if heat-sink compound was used. D3 should be mounted so as to ensure good thermal contact with the MRF476 transistors. Figs. 28 and

29 show the mounting arrangement.

## Testing

A good preliminary check is a measurement of the current drawn by the four stages. Q1 should draw 9 mA; Q2 draws 40 mA; Q3 draws a hefty 110 mA. These values were measured on the prototype and may vary slightly because of component tolerances. If the current for Q3 is significantly higher and operation at 13.8 V is intended, R14 should be increased from 15 to 18 ohms. R5 should be adjusted so that the MRF476 transistors have a bias current of 40 mA; The current through jumper W2 should be 40 mA with no signal applied at the amplifier input.

An RF probe or oscilloscope should be used to adjust the oscillator trimmer (C3) for maximum output measured at point A of T1, consistent with quick oscillator starting.

A wattmeter or dummy load/RF probe can be used to align the band-pass filter trimmers (C15 and C17). With a signal of roughly 2 mW applied to the transverter input, alternately peak the trimmers for maximum output at 1833 and 1965 kHz (7033 and 7165 kHz input, respectively). It usually helps to use one trimmer for peaking at the low end and the other for peaking at the high end of the band. Approximately 2 W output should be noted. Lower pass-band ripple can be obtained by peaking at 1826 and 1956 kHz, but the output will fall off rapidly past 1983 kHz.

## Operation

The transverter requires an input of roughly 2 mW PEP. If desired, R5, R6, and R7 can be changed to make the unit as much as 30 dB more sensitive. This lowers the requirement to 2  $\mu$ W PEP. Like any linear amplifier, the transverter must not be overdriven when used on SSB or the

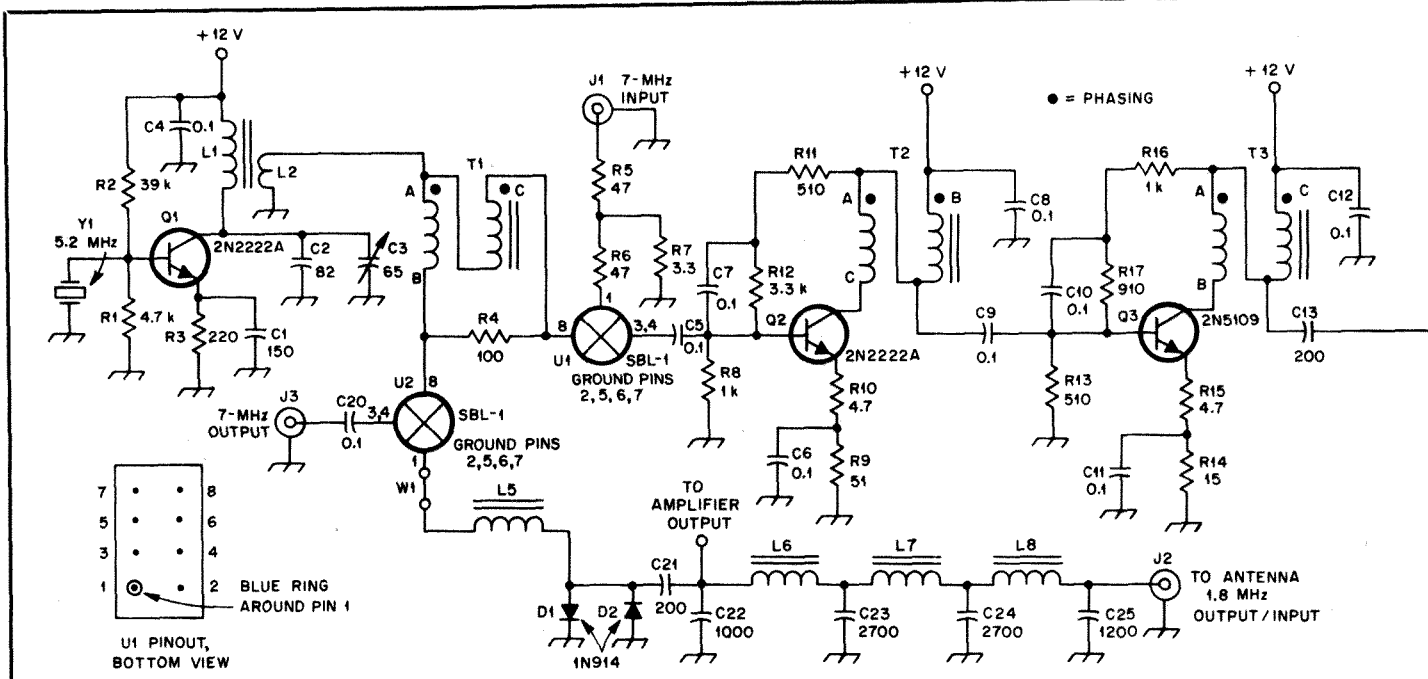

Fig. 23 — Schematic diagram of the 160-m transverter. All resistors are  $\frac{1}{4}$ -W, 10% units unless otherwise noted. All capacitors are disc-ceramic units unless otherwise marked. Capacitors marked with polarity are electrolytic.

C3, C15, C17 — 9- to 62-pF trimmer capacitor.

C13, C14, C16, C18, C19, C21-C25 — Silvermica, NP0 disc or polystyrene capacitor.

D1, D2 — High-speed silicon diode (1N914 or 1N4148). Do not use Schottky diodes.

J1-J3 — Female chassis-mount BNC connector.

L1 — 40t no. 28 enam wire on an Amidon T-37-2 core.

L2 — 5t no. 28 enam wire over the +12 V side of L1.

L3, L4 — 21.6  $\mu$ H,  $Q_u = 224$  @ 1.9 MHz; 59t no. 26 enam on an Amidon T-68-2 core.

L5 — 61t no. 28 enam wire on an Amidon T-50-1 core.

L6, L8 — 5.4  $\mu$ H; 34t no. 28 enam wire on an Amidon T-37-2 core.

L7 — 6.4  $\mu$ H; 37t no. 28 enam wire on an Amidon T-37-2 core.

R14 — 15- $\Omega$ ,  $\frac{1}{2}$ -W resistor. See text.

Q1, Q2 — 2N2222A.

Q3 — 2N5109.

T1 — 6t no. 26 enam wire bifilar wound on an Amidon FT-37-43 or FT-23-43 core. Palomar F-37-43 or F-23-43 cores should also be suitable.

T2, T3 — 8t no. 26 enam wire bifilar wound on an Amidon FT-50-43 core.

U1, U2 — Mini-Circuits SBL-1 doubly balanced diode mixer.

Y1 — 5.2-MHz fundamental crystal, 32-pF load capacitance (International Crystal no. 433115 or equiv.).

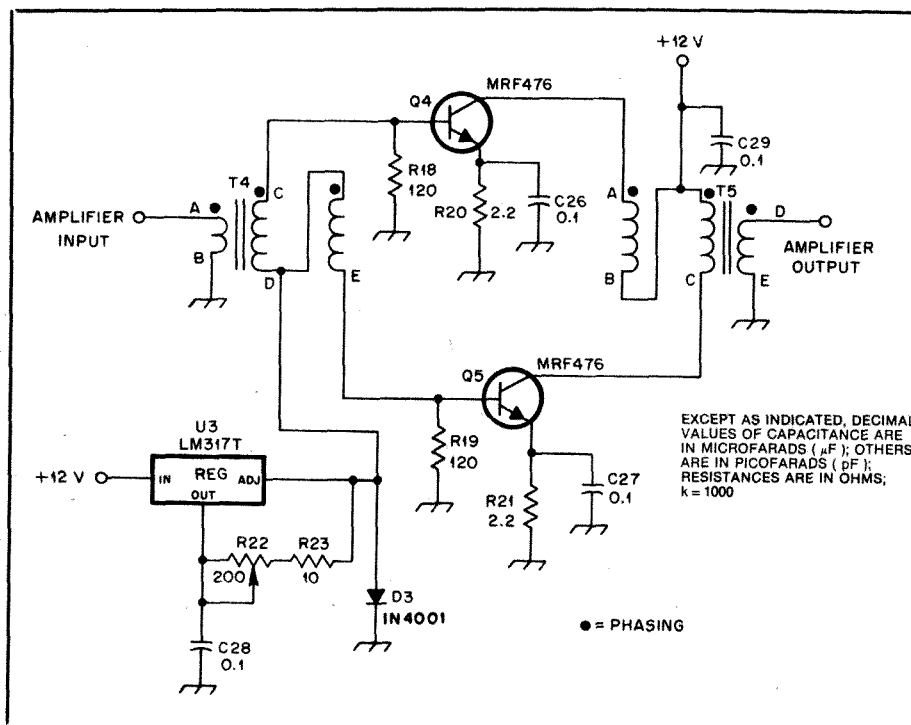

Fig. 24 — Schematic diagram of the 160-m transverter power amplifier. All resistors are  $\frac{1}{4}$ -W, 10% units unless otherwise noted. All capacitors are disc-ceramic units unless otherwise marked. Capacitors marked with polarity are electrolytic.

D3 — 1-A rectifier diode. Voltage rating not important (1N4001 or equiv.). See text for mounting instructions.

Q4, Q5 — Matched pair of MRF476 transistors.

R18-R21, R23 —  $\frac{1}{2}$ -W resistors

R22 — 200- $\Omega$  PC-mount potentiometer.

May also use a 100- $\Omega$  trimmer and choose R23 appropriately.

T4 — Primary: 2t no. 22 enam wire on an Amidon BLN-73-302 core. Secondary: 2t no. 22 enam wire bifilar wound.

T5 — Primary: 2t no. 22 enam wire bifilar wound on an Amidon BLN-73-302 core. Secondary: 4t no. 22 enam. wire.

U3 — LM317T adjustable regulator.

EXCEPT AS INDICATED, DECIMAL VALUES OF CAPACITANCE ARE IN MICROFARADS ( $\mu$ F); OTHERS ARE IN PICOFARADS (pF); RESISTANCES ARE IN OHMS;  $k=1000$

Fig. 29 — Top interior view of the 160-m transverter showing the mounting of the amplifier board with a long aluminum heat sink.

**Table 1**  
**Two-Tone IMD Performance of the 160-m Transverter**

$P_{OUT}$ (W)	3rd-order IMD (dB)
2.0	-52
2.5	-47
3.0	-45
3.5	-40
3.8	-32
4.0	-28

$P_{OUT}$ (W)	Voltage (V)	3rd-order IMD (dB)
2.0	14.0	-52
2.0	13.0	-50
2.0	12.0	-48
2.0	11.0	-47
1.9	10.0	-46

IMD performance will be severely degraded. The transverter IMD performance is relatively insensitive to fluctuations in supply voltage. See Table 1. The IMD measurements at varying supply voltages were made with a constant RF input level. The IMD characteristics also vary with frequency, as the driver IMD performance worsens as the band-pass filter becomes more lossy. As a result, the IMD varies between -48 and -52 dB.

QSK is obtained by connecting the transmitter port of the transverter to the output of a QSK rig such as a Ten-Tec Argonaut and connecting the receiver port directly to an internal receiver connection after the T/R switch. It would also be possible to use a separate receiver and transmitter, but receiver muting during transmit would probably be required.

Although the receive performance was adequate despite a broadcast station less than a mile away, jumper W1 may be replaced with a filter to improve AM broadcast-band rejection. Unfortunately, little can be done to eliminate interference from the second harmonic of a broadcast station if it falls within the 160-m band.

# A High-Performance AGC Circuit

Fig. 30 contains the circuit of an IF strip and AGC chain that offers excellent performance. This circuit was designed by W7ZOI for use in his Competition-Grade CW Receiver. The complete receiver circuit is found in *Solid State Design for the Radio Amateur*, Chapter 9.

This AGC circuit employs a full "hang" action. The AGC is defeated by means of

S1. The time constant is selectable at S2. R1 at U3 should be set for +5 volts at pin 6 of U3 with the AGC off. With Q5 and Q6 as part of the circuit, the receiver is practically silent after a strong signal disappears from the passband. But, after a timing period associated with network C1-R2, the receiver will return to full gain in roughly 50 milliseconds. This is very advantageous when loud pulses of noise

enter the receiver. The effect is similar to that of a noise blanker. A detailed description of this type of AGC circuit can be found in Chapter 5 of *Solid State Design for the Radio Amateur*, by the ARRL.

A less complex AGC circuit for use with RCA CA3028A IF amplifiers is provided in Chapter 12. It does not incorporate the hang feature used in Fig. 30.

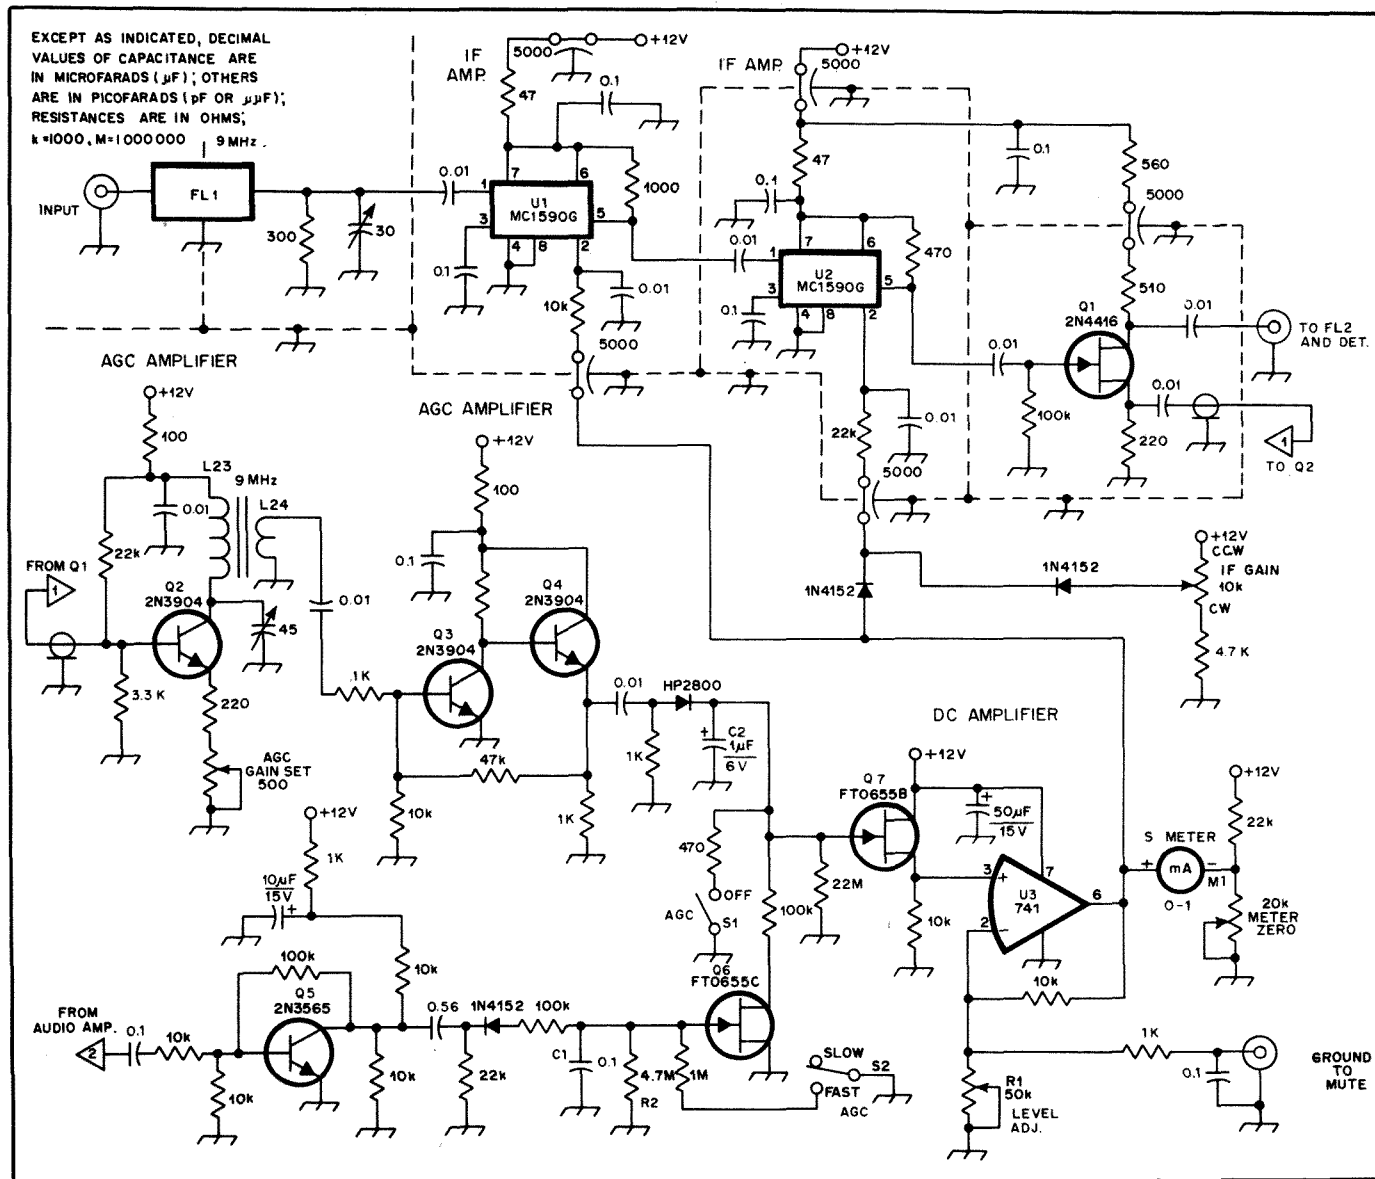

Fig. 30—Circuit details of the W7ZOI IF amplifier and high-performance AGC system. This circuit provides full-hang AGC characteristics.

# A BC-Band Energy-Rejection Filter

Inadequate front-end selectivity, or poorly performing bipolar-transistor RF amplifier and mixer stages, can result in unwanted cross-talk and overloading from adjacent commercial or amateur stations. A simple cure for this problem is to install a filter between the antenna and receiver to attenuate the out-of-band signals but pass those signals of interest with little or no attenuation.

If the receiver is designed for reception of frequencies below and above the broadcast band, a 550- to 1600-kHz band-stop filter will be required. However, if reception is desired only below or above the broadcast band, then a less complex low- or high-pass filter will suffice. Because a majority of ham receivers are used only for reception above 1600 kHz, a high-pass filter will generally be preferable to the band-reject filter. For the same number of components, the high-pass filter performance is superior to that of the band-reject type.

Since the power level of broadcast stations can be quite high, the stop-band attenuation of the high-pass filter should also be high, preferably in excess of 60 dB. The cutoff frequency should be selected so less

than 1 dB of attenuation occurs above 1800 kHz, the start of the 160-meter band. Receivers are generally designed to present a 50-ohm load to the antenna. The filter should also be designed for the same impedance level. The rate of attenuation rise, SWR, passband ripple, and number of filter components are all interrelated and many design choices are possible. In the high-pass design to be discussed, the maximum SWR of the filter was selected to be 1.353. To obtain adequate stop-band attenuation and a reasonable rate of attenuation rise, a filter of 10 elements was necessary. Finally, to simplify construction, only those designs permitting the use of standard-value capacitors were considered.

## Building the Filter

The filter layout, schematic diagram, response curve, component values used and toroidal-inductor winding specifications are shown in Fig. 31. The standard-value capacitors used are listed under the filter schematic diagram. Note that all standard values are within 2.8 percent of the design values. Since the maximum deviation between the actual capacitance used and the design value will be only 5.3 percent, there

should be little or no difficulty in obtaining the desired response. If the attenuation peaks ( $f_2$ ,  $f_4$  and  $f_6$ ) at 0.677, 1.293 and 1.111 MHz are not obtained, a slight squeezing or separating of the toroidal-inductor windings should be all that is required to tune the series-resonant circuits.

Note that series circuit C6-L6 should resonate at  $f_6 = 1.111$  MHz, but from the response curve it actually resonated at about 1.130 MHz. This frequency error of about 2 percent is small enough to ignore. The  $A_S$  value was selected to be 58.3 dB, and examination of the response curve shows the measured filter response to be in good agreement. The measured values of cutoff frequency (at the attenuation level of 0.0988 dB) and the measured value of  $f_{A_S}$  (the frequency where  $A_S$  is first reached) are also in good agreement with the calculated values. The measured pass-band loss was less than 0.8 dB from 1.8 to 10 MHz. Between 10 and 100 MHz, the insertion loss of the filter gradually increased to 2 dB. The measured input impedance versus frequency was in good agreement with the calculated input impedance between 1.7 and 4.2 MHz. (The frequency range above 4.2 MHz was not tested.) Over the range tested, the input impedance of the filter remained within the 37 to 67.7 ohms input-impedance window (equivalent to a maximum SWR of 1.353).

Construction of the filter is relatively simple, as shown in Fig. 32, and no difficulty should be experienced if the Mallory SXM polystyrene capacitors are used. These capacitors have a standard tolerance of 2.5 percent and are available through all Mallory distributors. The Micrometals powdered iron T50-2 toroidal cores are available through either Amidon or Palomar Engineers. This material originally appeared in a February 1978 *QST* article by Ed Wetherhold, W3NQN.

Fig. 31—Filter-response curve, insertion loss, layout and schematic diagram. Terminal impedance is 50 ohms for this 1.7-MHz, high-pass filter.

Fig. 32—The filter is built on perfboard in a 2 x 2 x 5-inch Minibox. The filter can be made smaller if desired, and phono connectors can be used in place of the BNC fittings shown here.

# A Computer Controlled Shortwave Converter

Imagine a computer-controlled, general-coverage receiver that can be tuned in 10-Hz increments, hold an unlimited number of frequencies in memory and be programmed to suit individual needs. The project described here is a general-coverage receiving converter that can turn any 10-meter amateur receiver or transceiver into a 100-kHz to 20-MHz general-coverage receiver. It uses a synthesizer that is controlled by an Apple II personal computer. As shown in Fig. 33, this compact receiving converter makes extensive use of surface-mounted device (SMD) technology. It was designed and built by Lee Snook, WIDN.

The converter design goals included:

- 1) Tuning that is controlled from a flexible BASIC language computer program
- 2) High resolution: 50 Hz for CW and SSB
- 3) Simplicity: no counters, BFO, IF or AGC
- 4) Good strong-signal handling and sensitivity.

The final design is a "black box" converter and synthesizer that tunes the spectrum from 100 kHz to 20 MHz in 10-Hz steps. (It can tune the entire range from 0 to 20 MHz, but the local oscillator (LO) is the only signal heard below 100 kHz.) The converter receives signals and converts them to 28.620 MHz, where they can be heard on virtually any 10-meter amateur receiver.

The only connections to the converter are for antenna input, 28.620 MHz output, power (12-V dc at 250 mA) and computer control. There are no front-panel switches. The computer does all the work. Since the converter/synthesizer is connected to the computer through a single 16-wire ribbon cable (only 6 lines are used), it can be put in any out-of-the-way location in the shack.

Operation is simple. Tune the transceiver to 28.62 MHz and boot the computer with the converter program disk. The monitor displays a menu of options. A box in the center of the screen shows the current operating frequency in Hz. The user can scan through any range of frequencies at several rates, or disk options can be selected to store or recall a maximum of 800 frequencies in memory under 20 different file names. The screen format used here limits the maximum number of files to 20, with 40 stations per file. (More could be stored using another format.) More on this later.

## CIRCUIT DESCRIPTION

The circuit can be broken down into two distinct parts: the three-loop synthesizer and the converter. Each will be discussed in the following sections.

### Synthesizer

For a description of basic synthesizer

(A)

(B)

Fig. 33 — The photo at A shows the top of the synthesized receiving converter; the photo at B shows the reverse side. Most of the components are surface mounted on the top side. PC board material is used to shield the various compartments. Starting at the left of the board: The 16.38-MHz reference oscillator is in the lower left corner. Above it is the power supply and Apple II interface circuitry. Next are the coarse and fine synthesizer loops, then the output loop. Along the upper right edge is the converter circuitry. The only components on the bottom of the board are RF chokes and a few interconnecting cables. Partitions similar to those on the top of the board will help reduce birdies and other spurious signals.

operation see references 1, 2 and 3. Fig. 34 shows the synthesizer block diagram. The heart of the circuit is the Motorola MC145159 sample-and-hold synthesizer IC. Two of these are used (for the coarse and fine tuning loops), along with a third loop employing the phase detector in an RCA CD4046. A 16.38-MHz crystal oscillator is used as the reference for the synthesizers, as well as for the second injection frequency for the converter. This oscillator is not temperature compensated, so its accuracy is approximately  $\pm 20$  ppm with variations in temperature. The overall frequency accuracy is about  $\pm 400$  Hz at 20 MHz. This is well within the accuracy of the analog dial on the FT-101E the

author used as an IF receiver. A temperature-compensated crystal oscillator (TCXO) or another standard could be used for greater frequency accuracy.

The MC145159 is the latest in a series of 20-pin DIP synthesizer chips from Motorola. It features serial data loading and a sample-and-hold phase detector. The MC145159 has a programmable 14-bit reference (R) counter, as well as programmable 10-bit divide-by-N and 7-bit divide-by-A counters. See Fig. 35. The counters are programmed serially through a common data input and latched into the appropriate counter latch. If the last bit (the control bit) is a logic high, then all three counters are latched. If the last bit is

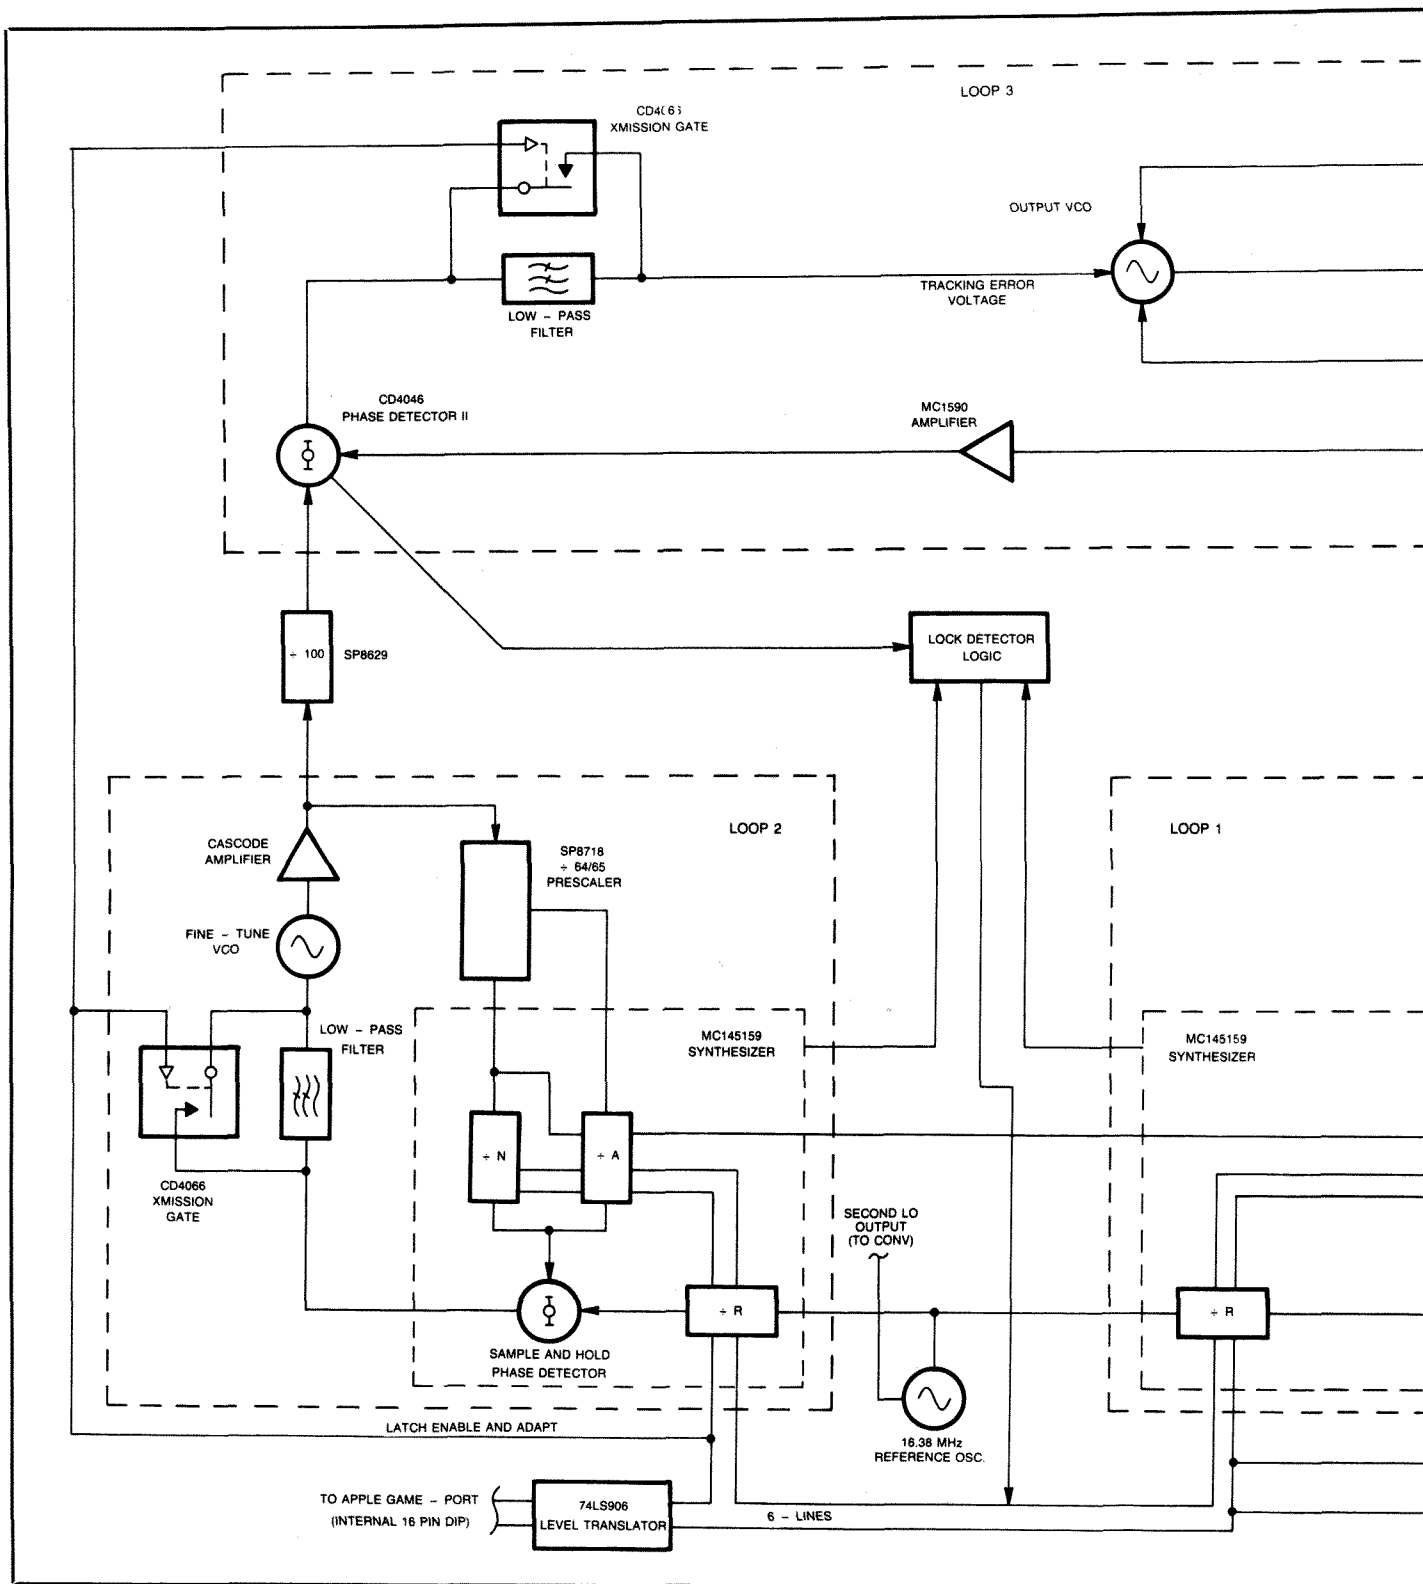

Fig 34 — Block diagram of the triple-loop synthesizer.

a zero, then only the N and A counters are latched. This is done to speed up data entry if the R counter never changes. In this case, the R counter is loaded every time.

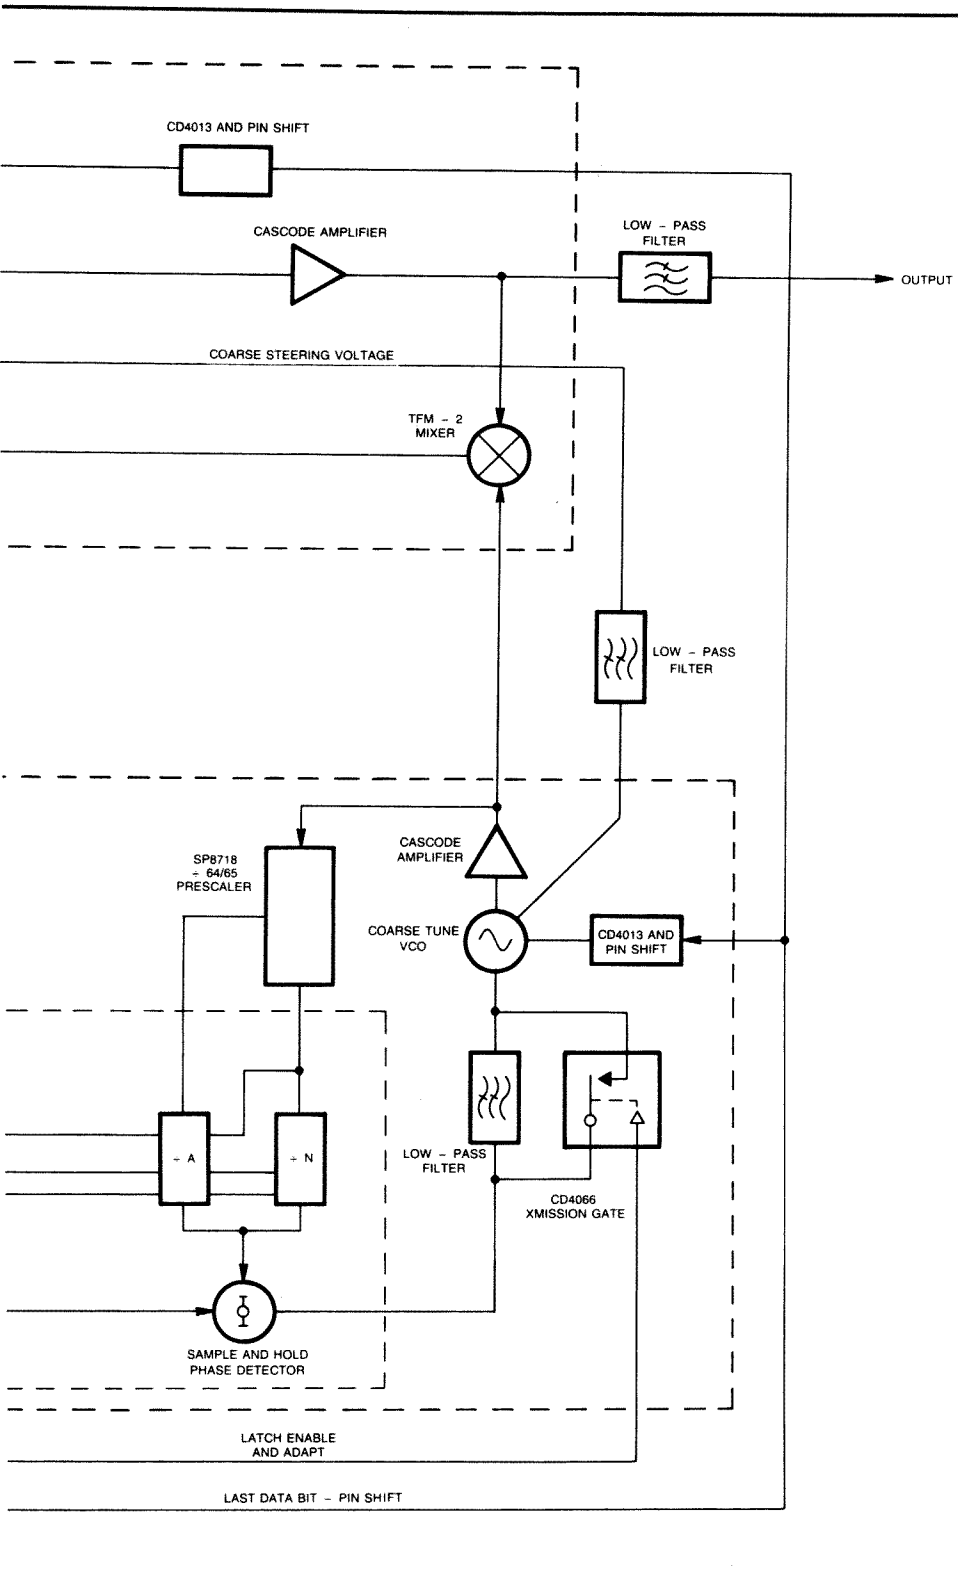

When this synthesizer chip is used with an adaptive loop filter, it has fast frequency/phase acquisition and good reference suppression. The adaptive loop filter uses a CD4066 transmission gate to bypass

the low-pass filter when changing frequencies or when the loop loses lock. The CD4066 is nothing more than four single-pole switches in an IC package. The switches are activated by a logic high on their control lines. In the adapt mode, with the low-pass filter bypassed, the filter circuit's cutoff frequency is greatly increased for a period of 10 ms. This allows

the output of the phase detector to sweep the VCO (voltage-controlled oscillator) to the desired frequency.

When combined with a loop filter and VCO, the MC145159 can provide all the remaining functions for a PLL frequency synthesizer operating up to the device's frequency limit (approximately 15 MHz). For higher-frequency operation, a down

mixer or a dual modulus prescaler can be used between the VCO and the MC145159.

The data is loaded serially at pin 12. Each bit is advanced into the register on a low-to-high transition of the clock, pin 11. The last bit allows the reference counter information to be loaded into its 14-bit latch. If the clock continues pulsing after the 32 bits are loaded, the data is shifted

out of pin 14. This arrangement allows for a serial connection of two or more synthesizers that can be loaded from a single data line. The data in each register is then latched on the positive edge of the pulse on pin 13 (LATCH ENABLE). Fig. 36 shows the data format used to load the two synthesizers for this project.

Two additional functions are performed

with the data lines. The LATCH ENABLE line is also connected to the control pins of the transmission gate. This allows the LATCH ENABLE to function as an adapt pulse, switching the bandwidth of the loop filters as required. The DATA line is also connected to a CD4013 edge-triggered flip-flop. One extra bit at the end of the data stream sets the flip-flop either high or low. This extra bit does not enter the MC145159 because it is not accompanied by a clock pulse. The flip-flops are used to turn a PIN diode switch on and off. This switch shifts the VCO frequency to extend its range.

The gain of the sample-and-hold phase detector is set with two external components,  $R_f$  (pin 20) and  $C_f$  (pin 15). See reference 4. A graph and formula given in the data sheet were used to calculate the values used for this project.

The MC145159's internal sample-and-hold phase detector operates in two states. One is the linear state where the loop is very near its final settling frequency and is trying to lock. In this case, the voltage from the phase detector is essentially a transient dc voltage that pulls the VCO phase closer to that of the reference.

In the second state, where the loop is not locked (the two inputs to the phase detector are not at equal frequencies), the output of the detector is a sawtooth waveform with a frequency equal to the difference between the two inputs. This ramp serves to sweep the VCO closer to its lock frequency. The problem is that the low-pass filter between the detector and the VCO attenuates this ramp because the filter has a very low cutoff frequency. This is the reason for including the transmission gate to form an adaptive loop filter to increase the cutoff frequency of the low-pass filter while the PLL is trying to lock.

Pin 9 provides a lock detector output. When locked, it is in a high state. When it is not locked, it produces a pulsed wave with a frequency equal to the difference between the two phase detector inputs.

### Dual Modulus Prescaler

As mentioned previously, the input frequency to the MC145159 synthesizer is limited to about 15 MHz. The VCO operates from 45 to 65 MHz, so it must be converted to a lower frequency by mixing or by means of a prescaler. This circuit uses a dual modulus prescaler. A dual modulus prescaler is nothing more than two high-frequency dividers with different divide ratios that are connected in parallel in a single package. (Note: The terms divider and counter are used interchangeably in this article). A logic level on the modulus control line determines which divider is used.

The prescaler used in this project is a Plessey SP8718 divide-by-64/65 prescaler IC. (See reference 5.) To illustrate how and why it was used, an example follows.

Suppose we wish to generate frequencies

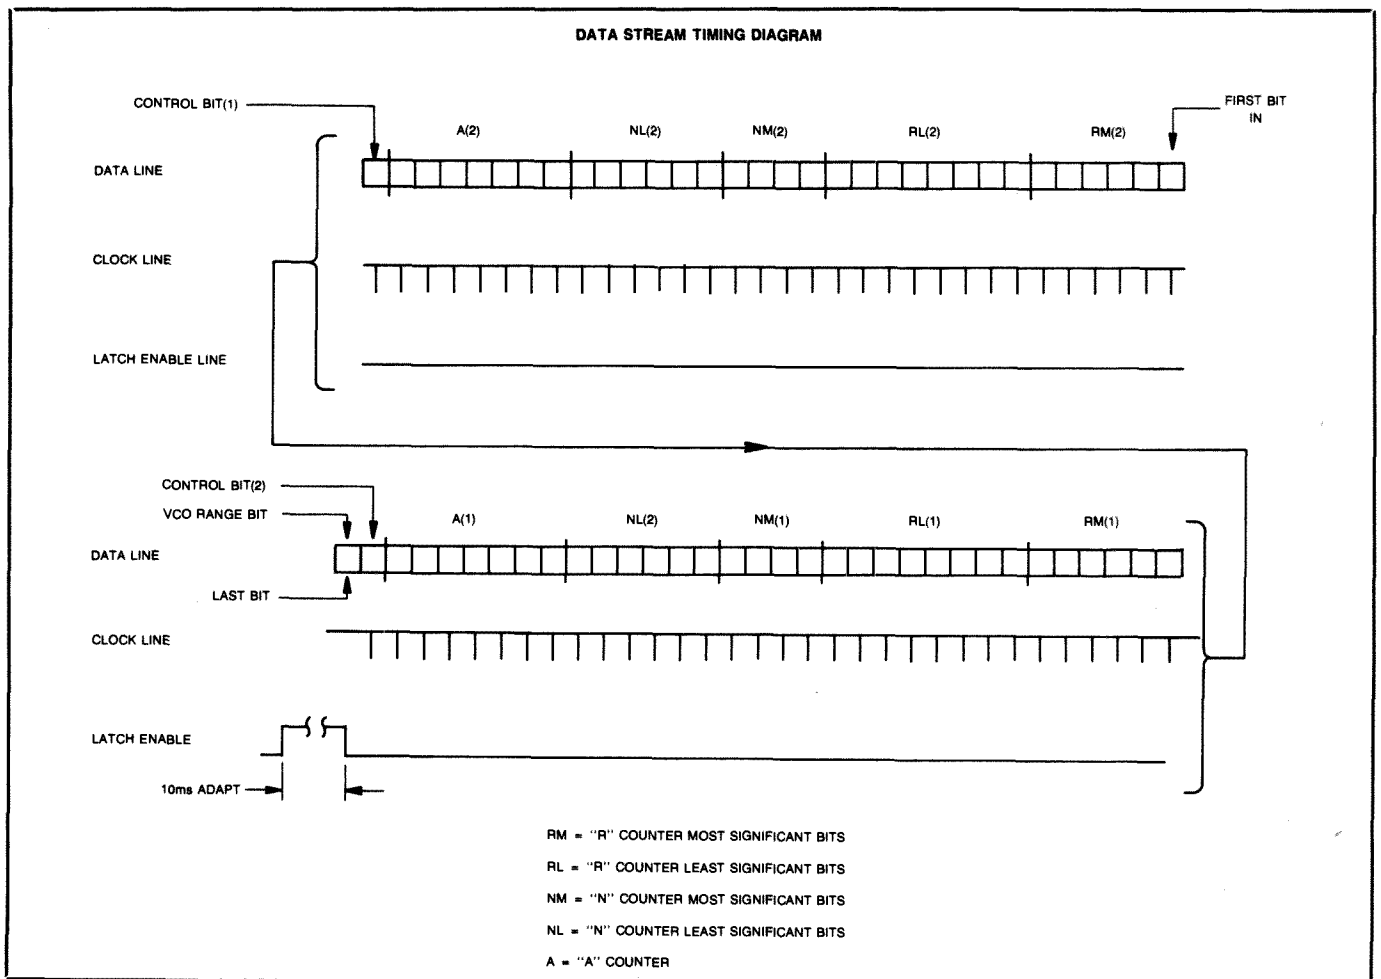

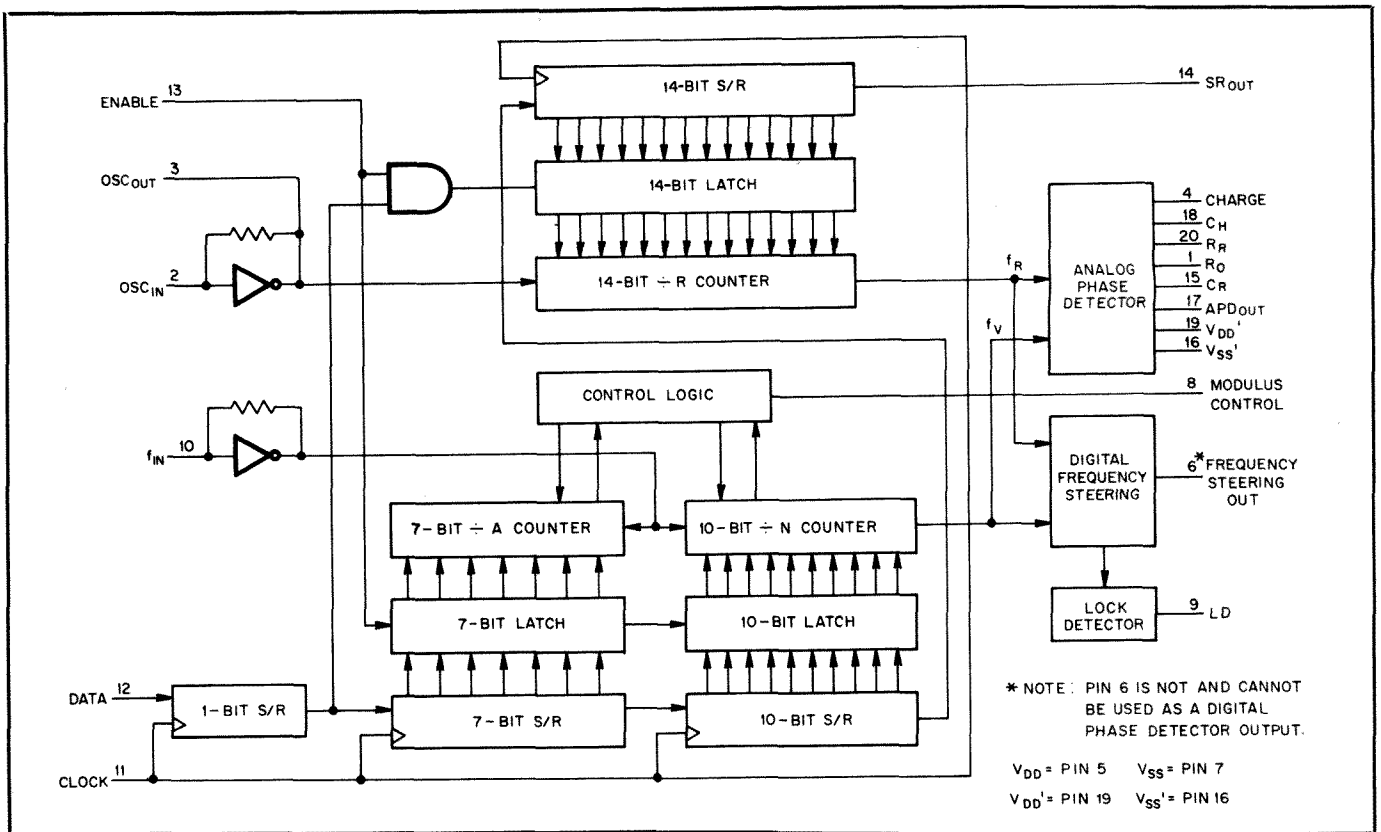

Fig. 36 — Data stream timing for the synthesizer.

from 46.1 to 47.1 MHz in 10-kHz increments. Since the synthesizer output frequency (F) is equal to the reference frequency (F<sub>r</sub>) multiplied by an integer number N<sub>t</sub>,

$$F = F_r \times N_t$$

or,

$$N_t = \frac{F}{F_r}$$

If the MC145159's internal dividers could divide signals from a VCO operating from 46.1 to 47.1 MHz, all we would have to do is program the dividers to divide by numbers between 4610 and 4710. The MC145159 can only operate to 15 MHz, however. High-frequency dividers could be placed between the VCO and the MC145159, but they would have to be programmed, adding to the complexity of the circuit. Why not use a fixed divider?

Let's say we use a divide-by-10. Now the programmable dividers in the MC145159 will see 4.61 to 4.71 MHz, well within range. What will the dividers in the MC145159 have to be programmed to?

$$N_t = \frac{(F/10)}{F_r}$$

$$N_t(\min) = \frac{(46.1 \text{ MHz}/10)}{10 \text{ kHz}} = 461$$

$$N_t(\max) = \frac{(47.1 \text{ MHz}/10)}{10 \text{ kHz}} = 471$$

Can we still program 10-kHz steps? If we increase the N count by one, what will the output be?

$$\begin{aligned} F &= F_r \times (10 N_t) \\ F &= 10 \text{ kHz} \times [10 \times (461 + 1)] \\ &= 46.2 \text{ MHz} \end{aligned}$$

The frequency has changed by 100 kHz instead of 10 kHz. With a fixed prescaler, the resolution is decreased by the value of the fixed divisor.

The alternative is to use two fixed prescalers with different divide ratios and then switch between them at the appropriate time to give a fractional divide ratio. Inside the MC145159 is a control circuit that uses the N and A counters to decide when to switch. Its output is the modulus control line (pin 8).

How can we divide by 4610 using this method? Let us say we are using a divide-by-64/65 prescaler. If we divide by 65 for A times and divide by 64 for (N - A) times, we will get

$$4610 = (65 \times A) + [64 \times (N - A)] \quad (\text{Eq. 1})$$

Now let us find the values of N and A. Let A = 0, since we have one equation and two unknowns.

$$4610 = 64 N$$

or

$$N = 72.03125$$

A divider can only divide by an integer number, so let N = 72. Substituting N = 72 into Eq. 1 and solving for A, A = 2.

This means that if we divide by 65 for 2 times and then divide by 64 for (72 - 2) times, we will have effectively divided by 4610. Have we still maintained the 10-kHz channel spacing? If we increment A by one count, we have

$$N_t = (65 \times 3) + [64 \times (72 - 3)] = 4611 \text{ and}$$

$$\begin{aligned} F &= N_t \times F_r = 4611 \times 10 \text{ kHz} \\ &= 46.11 \text{ MHz} \end{aligned}$$

The increment is 10 kHz.

The equation for N<sub>t</sub> can be simplified to

$$N_t = [(P + 1) \times A] + [P \times (N - A)] \text{ or}$$

$$N_t = (N \times P) + A$$

In these equations, P is the lower prescaler number (in this case, 64). We have accomplished a great deal with the dual modulus prescaler and the MC145159 internal control logic. The MC145159 N divider has the capability to divide between 16 and 1023, and the A divider between 0 and 127 (provided that A is less than N). So,

$$\begin{aligned} \text{From } N_t &= (N \times P) + A \\ N_t(\min) &= (16 \times 64) + 0 = 1024 \\ N_t(\max) &= (1023 \times 64) + 127 = 65599. \end{aligned}$$

Therefore,

$$\begin{aligned} \text{From } F &= F_r \times N_t \\ F(\min) &= 10 \text{ kHz} \times 1024 = 10.24 \text{ MHz} \\ F(\max) &= 10 \text{ kHz} \times 65599 \\ &= 655.99 \text{ MHz!} \end{aligned}$$

This range is with 10-kHz channel spacing! Of course, the VCO and prescaler must be able to cover such a great range.

The price? We need a machine to calculate all the N, A, and R values, given an output frequency. It must also convert these numbers to serial data, pulse the adapt line, know when to switch the VCO to a different range and know when to flag an unlocked synthesizer. That's what the Apple II computer does.

### Triple Loop Approach

Why can't we use just one loop to generate 10-Hz resolution? One reason is that the N divider would have to be very large to multiply the reference (10 Hz) up to the 45- to 65-MHz range. Remember: F = F<sub>r</sub> P N. If F<sub>r</sub> = 10 and P = 64, then N = 101,562. This is clearly larger than the allowed maximum of 65,599.

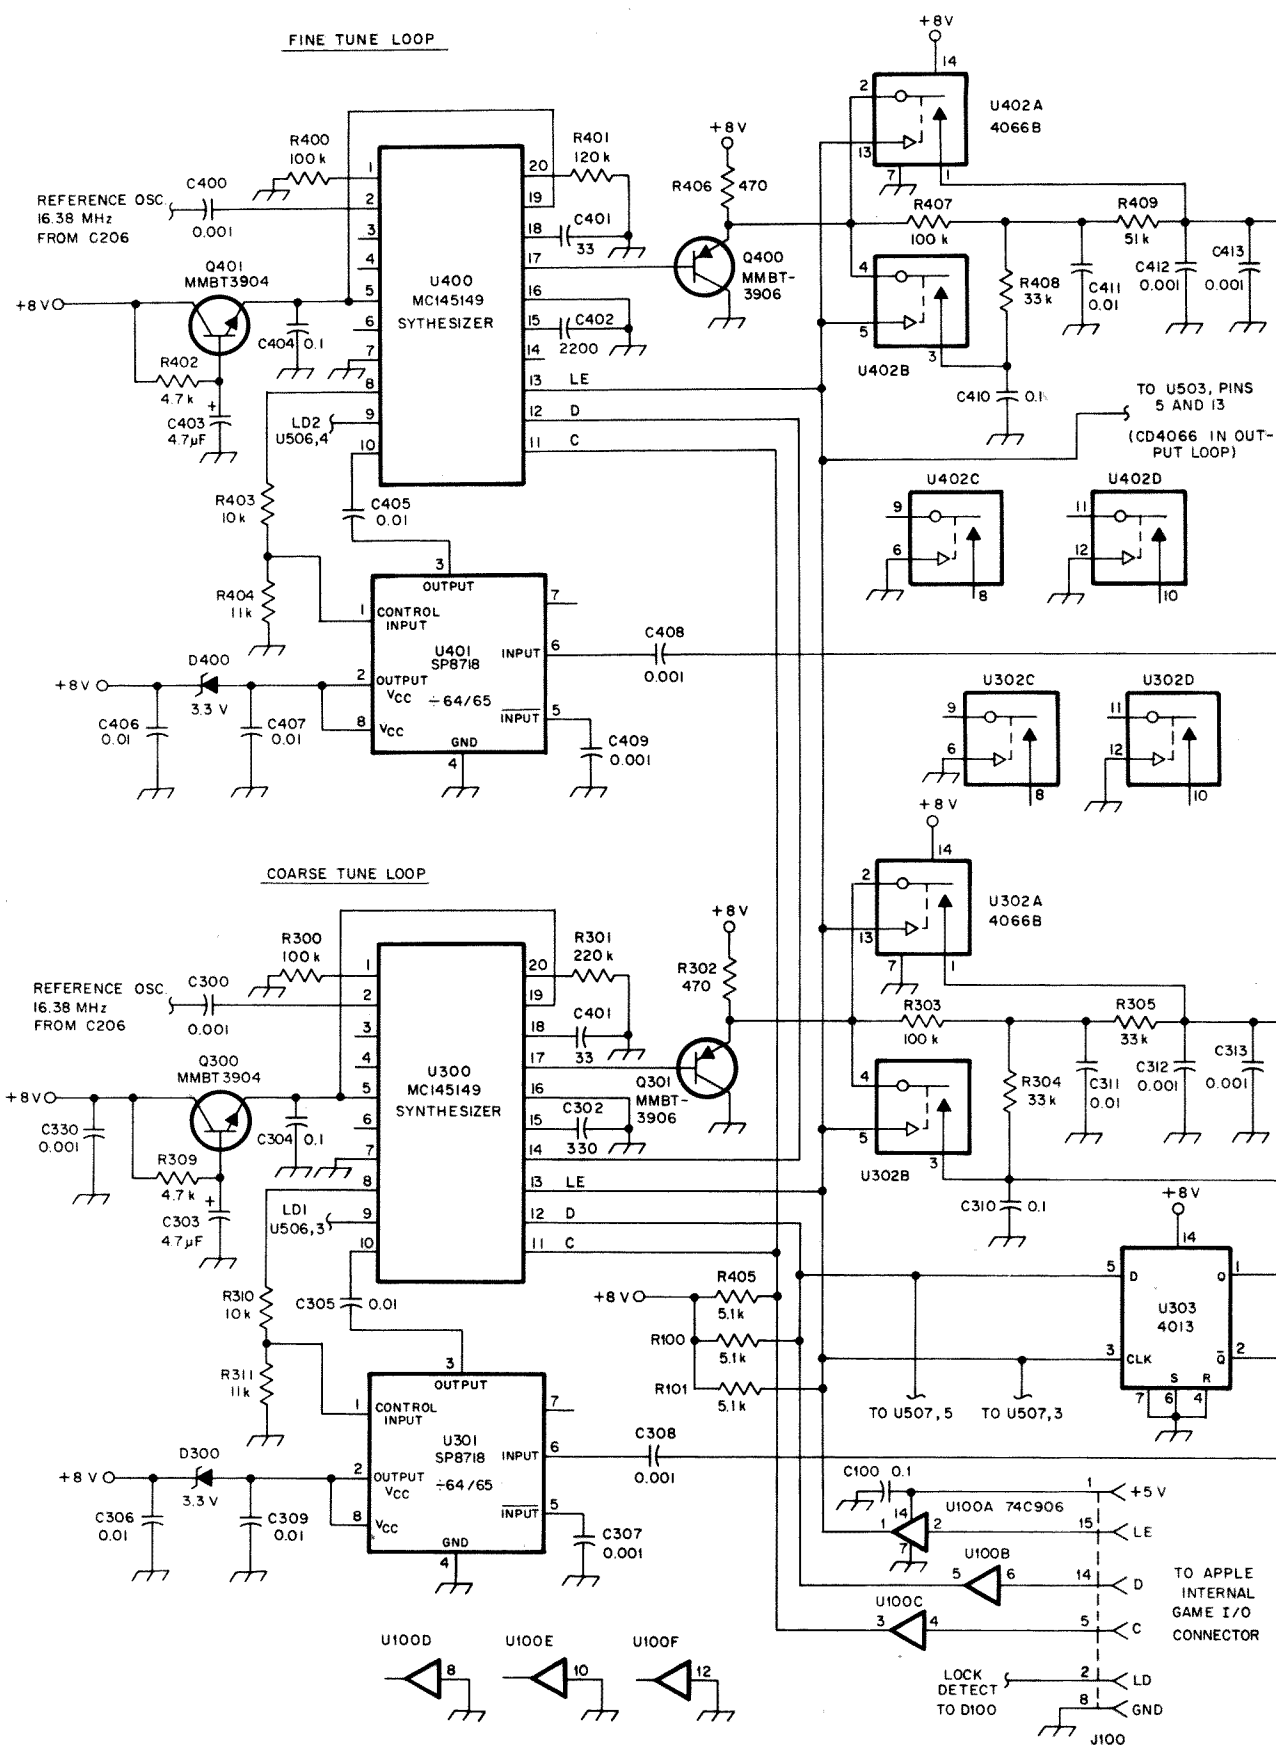

The second reason is that the loop filter would have to have a cutoff frequency of much less than 10 Hz to attenuate the reference leakage through the phase detector before it reaches the VCO. This causes many problems. The loop natural frequency would have to be so low that the loop would be susceptible to microphonics.

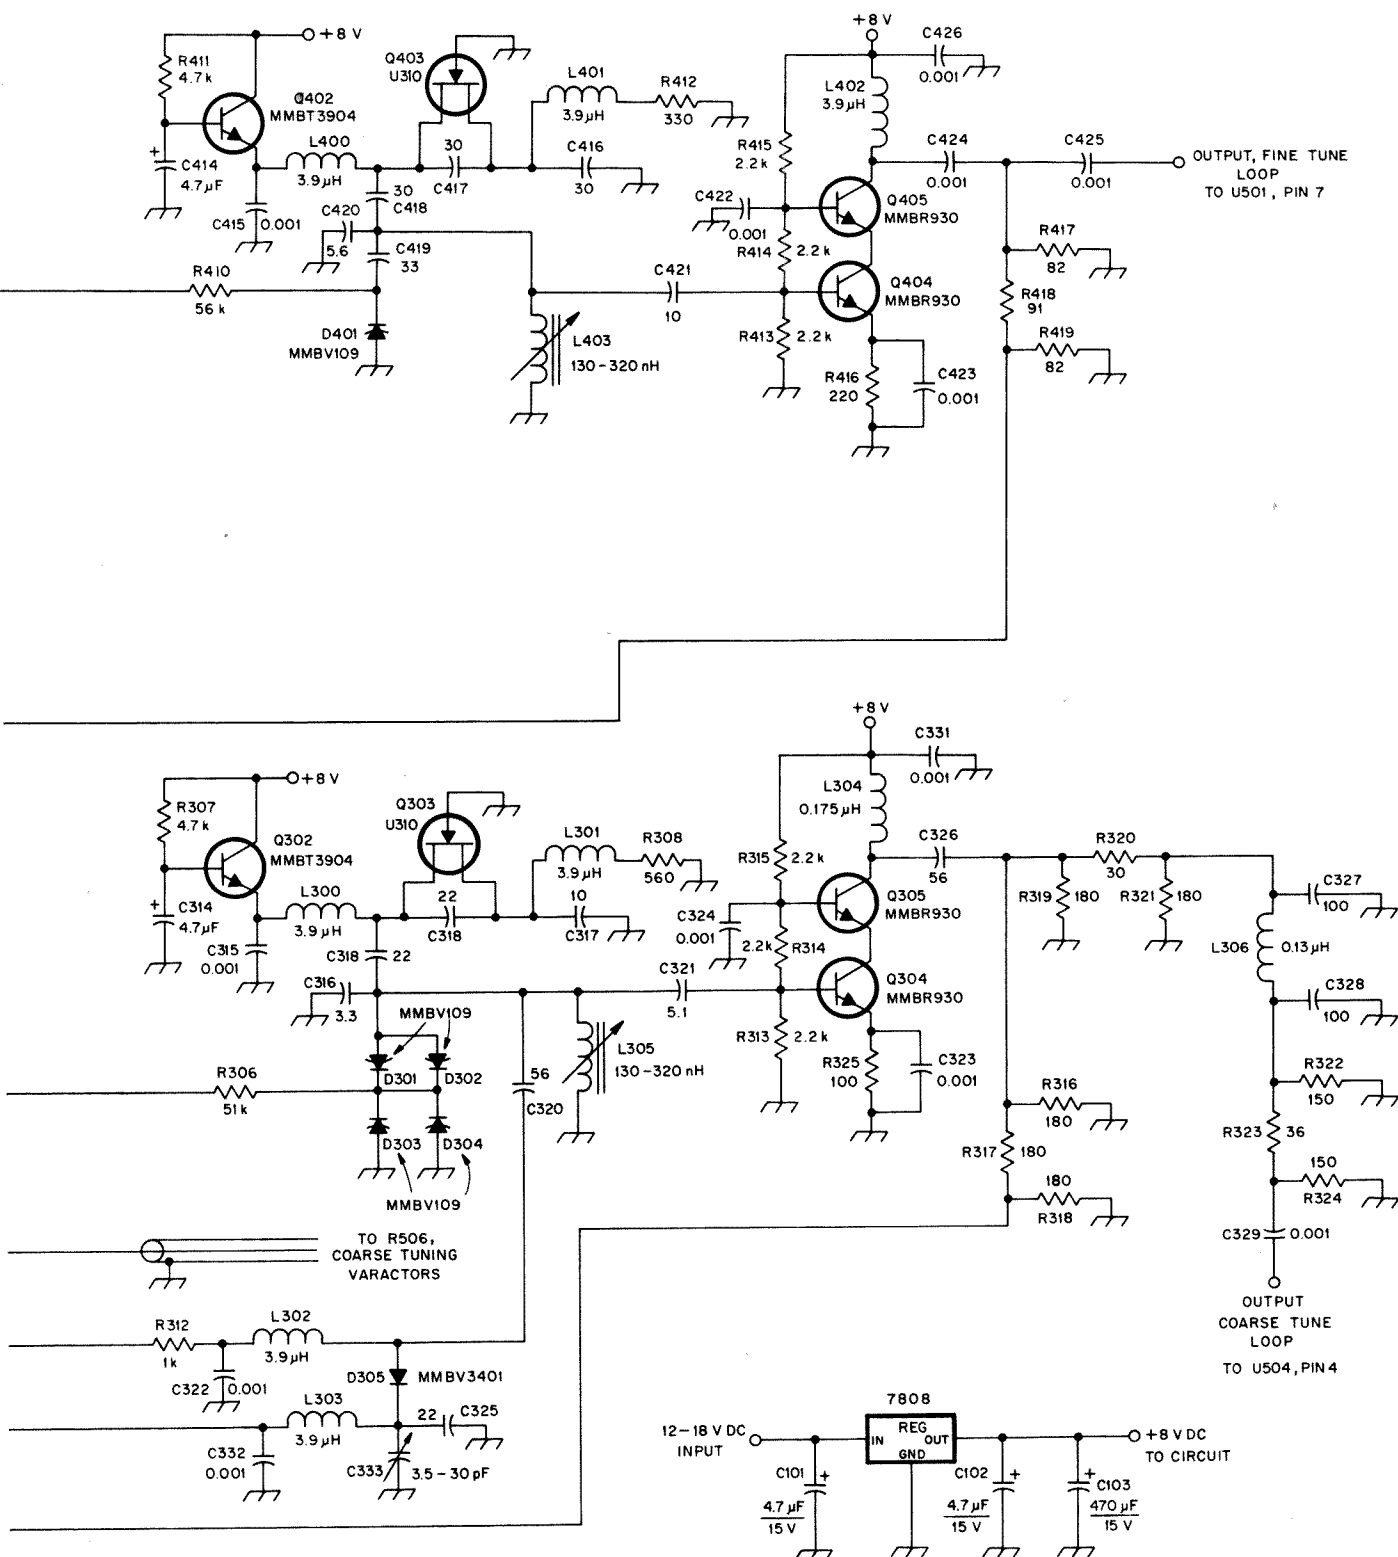

To ensure stability, the loop gain would have to be low, thereby causing slow lockup time.

(Fig. 37 appears on next page)

Fig. 37 — Schematic diagram of the coarse and fine synthesizer loops. Components marked with an asterisk (\*) are surface-mounted devices.

EXCEPT AS INDICATED, DECIMAL VALUES OF CAPACITANCE ARE IN MICROFARADS ( $\mu$ F); OTHERS ARE IN PICOFARADS (pF OR  $\mu$ pF); RESISTANCES ARE IN OHMS; k = 1000, M = 1000000

## 30-32 Chapter 30

Q504, 505 — \*MMBR930 NPN transistor (Motorola).

R102 — \*5.1 k $\Omega$ .

R500 — \*470  $\Omega$ .

R501, 513, 515 — \*10 k $\Omega$ .

R502 — \*20  $\Omega$ .

R503 — \*0  $\Omega$ .

R504, 506, 507 — \*51 k $\Omega$ .

R505 — \*4.7 k $\Omega$ .

R508, 512, 514 — \*1 k $\Omega$ .

R509 — \*10  $\Omega$ .

R510, 522, 523 — \*2.2 k $\Omega$ .

R511 — \*330  $\Omega$ .

R516, 518 — \*68  $\Omega$ .

R517 — \*160  $\Omega$ .

R519, 521 — \*150  $\Omega$ .

R520 — \*36  $\Omega$ .

R524 — \*1.3 k $\Omega$ .

R525 — \*100  $\Omega$ .

R526 — \*100 k $\Omega$ .

U500 — CD4046BCN phase-locked loop (RCA).

U501 — SP8629 divide-by-100 prescaler (Plessey).

U502 — \*14066B quad bilateral switch (Motorola).

U503 — MC1590G op amp (Motorola).

U504 — Mini-Circuits TFM-2 doubly balanced mixer.

U505 — CD4001BCN quad NOR gate (RCA).

U506 — MC14023B quad NAND gate (Motorola).

U507 — \*14013 dual-D flip-flop (Motorola).

Fig. 39 — Spectrum of synthesizer output. The vertical scale is 10 dB per division; the horizontal scale is 1 MHz per division. Leakage of the 500-kHz reference signal (and its 1 MHz second harmonic) through the balanced mixer is better than 65 dB down from the carrier.

A multiple-loop synthesizer solves these problems. See Figs. 34, 37 and 38. Two MC145159 ICs are used to form independent serially loaded synthesizer loops, one coarse tuned (U300) and one fine tuned (U400). The third loop, the output loop, tracks the coarse loop with an offset from the fine loop. A CD4046 phase detector (U500) is used to generate the control voltage for the output loop.

The coarse loop tunes from 44.5 to 64.5 MHz in 10-kHz steps. Its control voltage is used to steer the output VCO about 500 kHz above the coarse VCO. The construction of both the coarse and output VCOs should be as close as possible to allow good tracking. The output of the tracking VCO is amplified and mixed with the coarse loop VCO output in U504, a Mini-Circuits TFM-2 doubly balanced diode-ring mixer. The difference signal at the mixer output is amplified by the MC1590 (U503), clipped and used as one input to pin 3 of U500, the CD4046. The

fine tune loop, divided by 100 in U501, an SP8629, feeds the other phase detector input (pin 14) with a signal of 0.50 to 0.50999 MHz in 10-Hz steps. An extra 40 dB of 1-kHz reference suppression is obtained by dividing by 100.

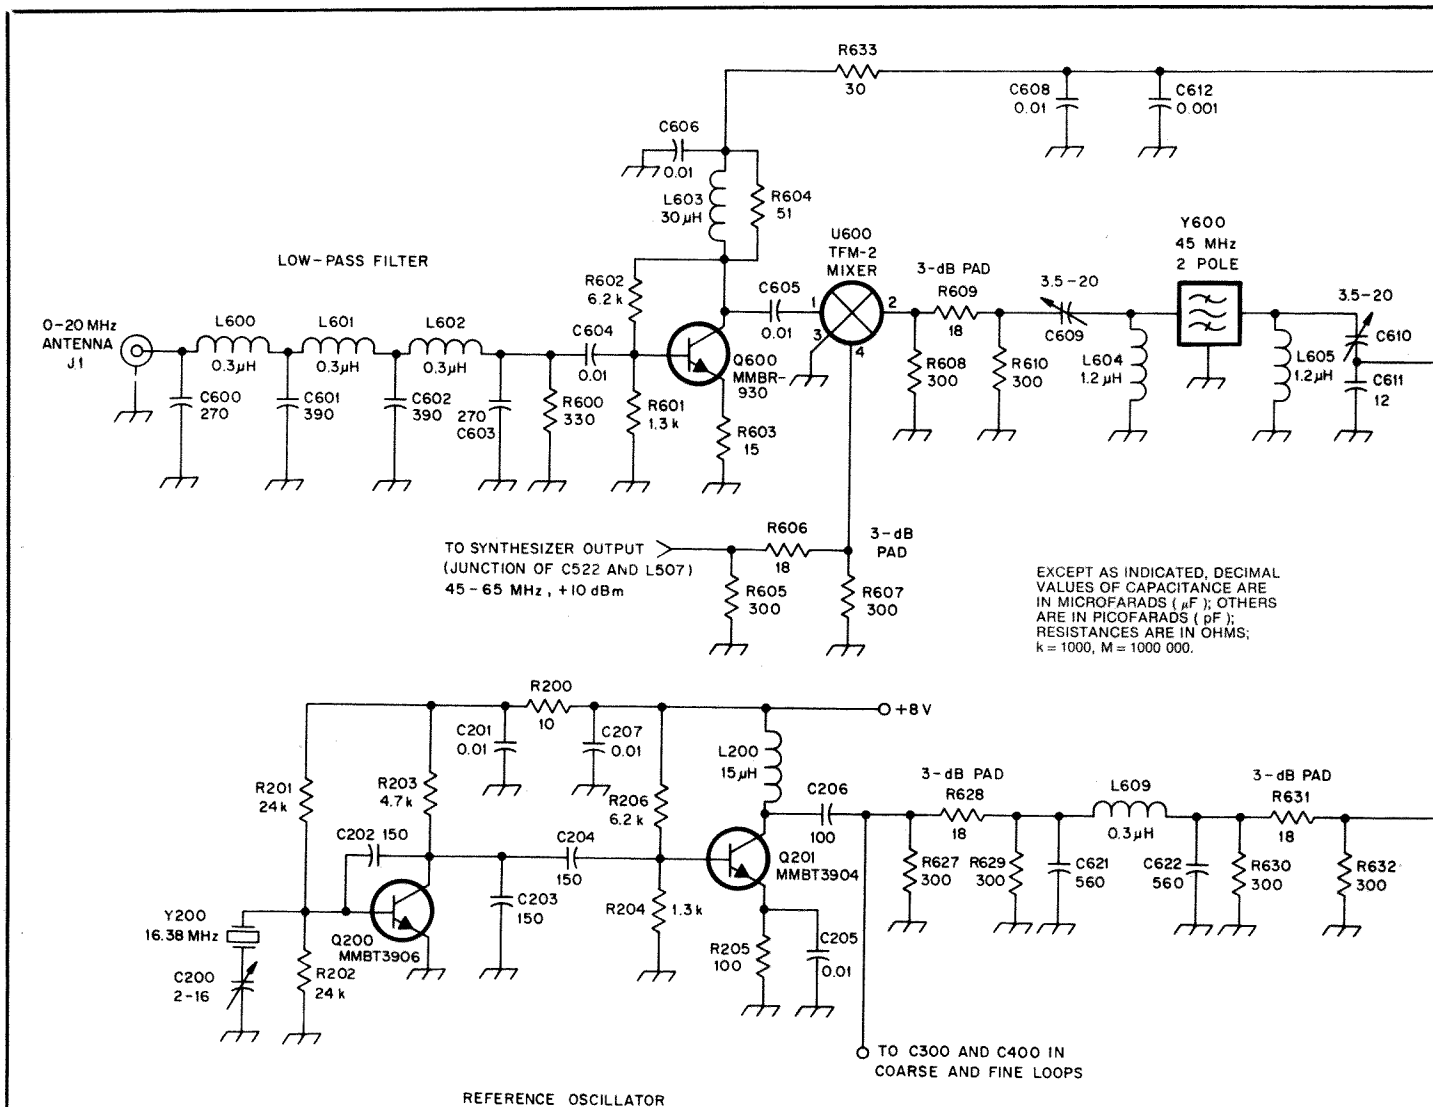

When it is locked, the output VCO generates a frequency that, when mixed with the coarse VCO, produces a mixer output that is equal to the fine loop divided by 100. What we end up with is the output frequency equal to the coarse loop frequency plus the fine loop frequency divided by 100.

$$F = F1 + \frac{F2}{100}$$

where

- F = output frequency
- F1 = coarse loop frequency
- F2 = fine loop frequency.

The output VCO frequency should track the coarse-tune VCO plus the fine-tune

frequency. Any error in tracking is compensated for by the CD4046 phase detector. The detector produces a waveform whose average value is a dc level when filtered by the low-pass filter. This voltage is applied to a varactor that pulls the VCO closer to the correct frequency/phase. To extend the range of the VCOs in the output and coarse loop, the tank circuits are shunted by a PIN switching diode in series with a variable capacitor. The capacitor is switched into the tank when the output frequency is to go below 53 MHz.

A lock detector is formed by a CD4001 NOR gate (U505) and a CD4023 three-input NAND gate (U506). If any of the three loops lose lock, the detector causes the PB(0) switch input on the Apple game port (see Fig. 41 later in this writeup) to go low through a bipolar switch (Q100) pulled up by a 220- $\Omega$  resistor to +5 V. The PB(0) input is in parallel with the "open apple" key internally pulled to ground through a 560- $\Omega$  resistor. D100, at the output of the

bipolar switch, keeps the lock detector from loading the "open apple" line when the receiver is not in use. A low voltage at PB(0) (out of lock) causes a value of less than 127 to appear in location -16287. The BASIC program periodically scans this location and reloads the synthesizers if an "out of lock" is detected. At the same time it displays "unlock" on the screen.

Colpitts grounded-gate oscillators (Q303, Q403 and Q 503) are used in all three VCOs to give excellent phase noise characteristics, approximately -80 dBc at 1 kHz from the carrier in a 1-Hz bandwidth. This configuration adds fixed capacitance in parallel with the varactor tuning, making the tuning bandwidth narrower than with other oscillator configurations. Cascode buffer amplifiers (Q304/305, Q404/405 and Q504/505) are used after the VCOs for approximately 40 dB of reverse isolation.

All three loops use adaptive filtering to bypass the low-pass filters when changing

frequency. Although the CD4046 phase detector can acquire lock without the adaptive filter, its lock time is sped up with the filter. The output frequency is within 1 kHz of the settling frequency in approximately 10 ms after a frequency jump of 20 MHz.

Keeping the spurious signal levels down in the synthesizer was a problem. The coarse VCO leaked through the balanced mixer and appeared at the output as 500 kHz spurs. These spurs were attenuated by increasing the level from the output VCO and then padding this output to the balanced mixer. The pad not only provided some isolation between the mixer and the output, but provided a better match to the mixer. The better match results in improved port-to-port isolation. Spurious products are at least 60 dB below the carrier. See Fig. 39. The other buffer stages provided more output power than was needed, so 50- $\Omega$  pads were used to terminate the inputs and outputs of each low-pass filter.

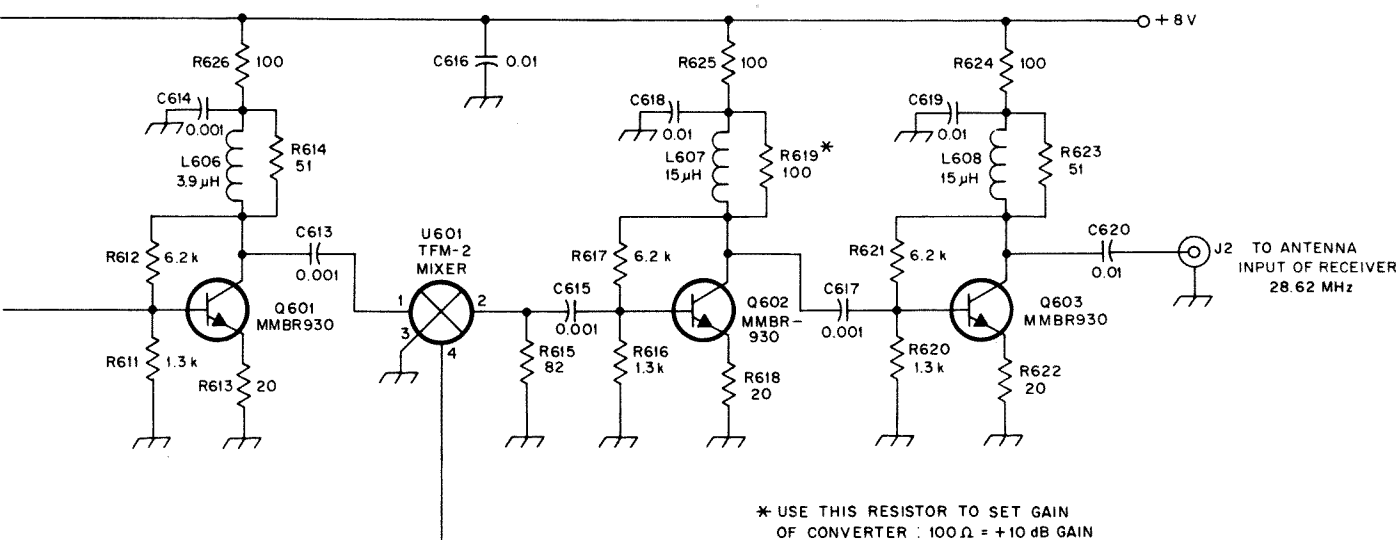

Fig. 40 — Schematic diagram of the receiving converter. Components marked with an asterisk (\*) are surface-mounted devices.

C200 — 1.9-15.7 pF air variable (Johnson C187-0109-005 or equiv.).

Y600 — 45-MHz, 2-pole crystal filter, Piezo Technology model 2843A or 2844A.

## Converter

Not much time was spent designing the converter, as the emphasis was placed on the synthesizer and the program. Although a converter with better performance could be designed, this one has good enough dynamic range to work within the wide front-end passband of the converter and not be overloaded by the crowded RF environment below 20 MHz.

Fig. 40 is a schematic diagram of the converter. Two stages of conversion are used in an upconverting design. The first stage converts the input from the antenna (100 kHz to 20 MHz) to 45 MHz by mixing with the 45- to 65-MHz output of the synthesizer. This occurs in U600, a TFM-2 doubly balanced diode-ring mixer. The second stage, U601 (another TFM-2), mixes the 45-MHz first IF with the 16.38-MHz reference-oscillator signal (from Y200/Q200/Q201) to produce the 28.62-MHz output to the IF receiver. See reference 6 for further discussion of the upconverting technique.

A 7-pole, 3-dB ripple low-pass filter (L600-602, C600-603) is used prior to the first RF amplifier (Q600) for attenuation of any 45-MHz signals and for image rejection above 90 MHz. The filter response is 40 dB down at 45 MHz and greater than 80 dB down at 90 MHz.

The gain of the first RF amplifier, including losses in the low-pass filter, is 8 dB. The RF-amplifier input impedance is shunted with a 330- $\Omega$  resistor to set the filter passband ripple to 3 dB. The RF amplifier has a noise figure of about 6 dB and a third-order intercept of +20 dB relative to its output. The RF amplifier presents a broadband 50  $\Omega$  output for the mixer input, and the mixer output is terminated with a 50- $\Omega$  3-dB pad (R608-610). A 50- $\Omega$  3-dB pad (R605-607) is used on the mixer LO port. The output from the synthesizer is +10 dBm, so the pad reduces this to the correct LO level of +7 dBm. There is significant loss in this part of the circuit. After going through the mixer, pad and matching network, the conversion gain from antenna to the input of the 45-MHz crystal filter (Y600) is approximately 0 dB.

The crystal filter is terminated in 2600 ohms at its input by the matching network and at its output by the bias resistor divider of the next stage. An 8-dB amplifier (Q601) follows the crystal filter to compensate for losses in the second mixer and filter. The conversion gain at the output of the Q601 amplifier circuit is 6 dB. The second mixer is terminated in the same fashion as the first.

Two more stages of gain (Q602, Q603) were added, but they are probably not required. Their total gain is adjusted by changing the value of R619, which is across the collector choke L607 on Q602. In the prototype, a value of 100  $\Omega$  for R619 yielded a total converter gain of 12 dB. This brings the atmospheric noise level just above the input noise floor of my trans-

ceiver. Higher resistances increase the gain and vice-versa.

All the amplifiers used in the converter have fairly high overload characteristics and do not require broad-band matching transformers. The receiver sensitivity averages 1  $\mu$ V for a 6-dB S/S + N ratio using a 5-kHz IF filter for a 100% modulated AM signal.

## PROGRAMMING

The receiver program consists of a basic program called DUAL1 and assembly language program SYN1. DUAL1 is approximately 200 lines and SYN1 is 55 lines long. SYN1 was written using the Apple's mini-assembler, which is described in reference 7. Listings for these programs are available from ARRL Hq. as part of the template package for this project.<sup>1</sup> Alternatively, a disk with all of the software needed to control this converter is available from the author.<sup>2</sup>

The primary function of DUAL1 is to calculate the values for the N and A counters once a frequency has been selected. The rest of the program formats the display, waits for command characters, and handles files. Lines 360 through 520 scan the keyboard, waiting for an entry that directs the program to change, save, recall a frequency or call a disk subroutine.

Once a frequency has been selected, lines 520 through 550 calculate the coarse-loop frequency. If the coarse-loop frequency is greater than 52 MHz, it sets the VCO range bit high. Lines 580 and 590 find the fine-tune loop frequency. Then, lines 610 through 640 calculate the proper N and A values for both loops.

Since the N values comprise 10 bits, they are broken into two bytes by lines 650 to 680. The A values are only 7 bits long so they can fit into one byte. The R value does not change. Its bit representation has been pre-calculated and is POKED directly into the binary program. RM(1) and RL(1) are POKED into locations 9 and 26 (decimal) respectively. RM(2) and RL(2) are POKED into locations 235 and 236 (decimal) respectively. Lines 690 to 780 multiply the appropriate bytes by powers of two to position the most significant bit next to the carry and then POKE all of the values into 10 vacant memory locations.

After all 10 bytes are POKED into memory, the basic program calls the binary program, SYN1, located at 38000 to 38135 (decimal) or 9470 to 94F7 (hex). This program has the job of turning on and off the data, clock, and latch enable output ports in the correct sequence. See Fig. 41 for a description of the game port pin-outs

and the address to toggle each port. The binary program has five bytes to look at for each synthesizer. Each byte is loaded into the accumulator and then rotated one bit to the left into the carry bit. The X register is loaded with the number of bits to be rotated and is decremented until all the bits are sent for each byte. At the end of each sequence, one more high bit is sent representing the control bit.

If the carry is high, a subroutine is called which sets the data line to a 1 and vice-versa. The line is set high by loading the accumulator (LDA) to \$C059 and low by loading to \$C058. (See Fig. 41.) A clock pulse is sent with each data bit by loading accumulator (LDA) to \$C040. The clock (strobe) goes low for one instruction cycle. The value in the accumulator is irrelevant when loading these addresses. After all 64 bits have been sent, 32 per synthesizer, the VCO range shift bit, stored at \$946F, is loaded into the accumulator. The data line is either set high or low if this byte is a 1 or 0. No clock pulse is sent with this bit, so it does not enter the synthesizer, but remains on the data line which is also connected to the VCO range flip-flop. The latch enable is now set high, by loading the accumulator to \$C059. It is high for a period determined by the wait subroutine at address \$FCA8. The length of the wait is determined by the value loaded into the accumulator, in our case \$3D. This gives us a wait of approximately 10 ms. The line is then turned off by loading the accumulator to \$C058. Data gets latched into the synthesizers on the positive edge of this pulse and its duration determines how long the adaptive filter stays in its wide-band mode.

The binary program then returns control to DUAL1 which then starts the process over again by scanning the keyboard, waiting for another command.

The other part of the program requiring comment is the method of creating files of frequencies on disk. File names are stored as text files. The Apple catalog command won't work to display only the text-file names in the right hand corner of the screen. In this program, a separate file (FMEN\$) contains the filenames. By using this technique, the filenames can be pulled out and placed anywhere on the screen. After initializing a new disk, you must run FCREATE to open the FMEN file.

## CONSTRUCTION

Fig. 33 shows the completed receiving converter. Although the author's unit relies heavily on surface-mounted devices, regular axial components can be used as well. All of the components mount on a single 4.25-  $\times$  7.5-inch PC board. The board material is double-sided, 0.062-inch glass-epoxy stock. Circuit traces are etched on both sides, and the holes are plated through. Unetched circuit board material is soldered directly to the PC board to form shielded compartments. The sides are 1.75

<sup>1</sup>A template package, including program listings, etching patterns and parts placement guide is available from the ARRL Technical Department Secretary for \$5.00.

<sup>2</sup>Program disks and etched PC boards are available from the author. Contact Lee Snook, W1DN, RR 1, Box 126, Janesville, MN 56048 for details.

inches high. Etched PC boards are available from the author. See note 2. A template package with top and bottom etching patterns, drilling information and a parts-placement guide is available from ARRL Hq. See note 1.

Surface-mounted components are available from a growing number of suppliers. If you have trouble finding specific components, the author may be able to assist. The surface-mounted ICs, transistors and diodes are available from Motorola. For information on the nearest distributor, write Motorola Semiconductors, Box 20912, Phoenix, AZ 85036. The chip resistors used here were made by Dale Electronics, 2064 12th Ave., Columbus, NE 68601. The Kemet chip capacitors are from Union Carbide, Electronics Div., P.O. Box 5928, Greenville, SC 29606. The inductors are made by CoilCraft, 1102 Silver Lake, Cary, IL 60013. Other good sources of chip resistors and capacitors are Mouser Electronics and Newark Electronics.

A minimum of construction details will be given since the PC board reduces assembly to soldering parts in the right location. Once you overcome the fear of handling and soldering SMDs, they offer several advantages over conventional construction. Most of the circuitry and printed-circuit traces are on one side of the board, leaving the other for a good ground plane. The board can be laid flat in the work area, and you won't be continually turning it over to solder and clip component leads. Another advantage is time saved by not having to form the leads on conventional components before stuffing the board.

The key to SMD construction is soldering technique. It's mandatory to have the right tools for the job. Use small-gauge silver solder (available from standard suppliers such as Kester). Regular tin/lead solder will eventually leach or bridge across component terminals, resulting in a short across the component over time. Invest in a low-temperature, fine-tipped soldering

iron. You'll also need a higher wattage iron for soldering to ground planes and shields.

The surface-mounted resistors and capacitors used for this project measure  $0.06 \times 0.12$  inches and can be held in place with fine-tipped tweezers. Place a dab of solder on the iron and temporarily tack one end of the component to its trace. This will hold the component in place. Now you can have both hands free to heat the other end of the component and feed it solder for a good connection. Then, return to the first end and resolder it to make a good connection. Don't overdo the amount of solder. A small magnifying glass is helpful for checking the connection.

Although no standard coding scheme has been adopted for chip capacitors and resistors, the two most common schemes are given in Table 1. Avoid buying surface-mounted components that don't have identifying markings. Such components do exist, but use of them can make troubleshooting difficult.

The small surface-mounted ICs are probably the hardest parts to solder. A fine-tipped iron is mandatory, and the leads should be carefully checked for solder bridges. Pin number one is in the lower left corner when the IC is positioned so you can read the part number.

The axial RF chokes are mounted on the bottom side of the PC board. The exception to this is L605, which should be mounted on the top side for better isolation between the input and output of the crystal filter.

Good shielding around each compartment and around the whole board is required in the noisy environment of the computer and the four oscillators. Double-sided unetched PC board was soldered directly to the main PC board making compartments around the reference oscillator, synthesizers, and the converter. Nickel-plated brass nuts were soldered in each corner for attaching a top and bottom lid.

### Tune-Up Procedure

Probably the most difficult part of building a synthesizer is getting the voltage-controlled oscillator to operate properly. For testing high-quality VCOs, a spectrum analyzer and a means of measuring phase noise are essential. A good VCO has phase-noise components a few kilohertz away from the carrier which are far below the

noise floor of an RF spectrum analyzer. These phase-noise components ultimately determine the receiver's selectivity with regard to strong adjacent signals. One way this phase noise can be measured is to phaselock to the source and mix the signal down to an audio level where it can be viewed with a high-dynamic-range audio spectrum analyzer.

Since most hams don't have these instruments, we will have to be content with the signal purity we get. As a minimum, a frequency counter and an oscilloscope will be required to tune up this project. If your frequency counter reading seems to be unstable while making a measurement, it could indicate high spurious signal, reference signal, or harmonic levels.

Refer to the OPERATION section of this article. Start the Apple II computer control program and enter any starting frequency. Set the increment step size to 10 Hz. Remember, the starting frequency is in MHz and the increments are in Hz. Press the up-arrow or down-arrow key and look at the waveforms on pins 11, 12, 13 of U300 and U400 with your scope. These are the CLOCK, DATA, and LATCH ENABLE signals sent from the computer through buffer U100. They should resemble the waveforms in Fig 36. The CLOCK and DATA pulses are very short, so a sweep rate of 0.2 ms/div is required.

Measure the voltage on pin 1 of U303 and U507. It should be 0 V when frequencies greater than 8 MHz are entered into the computer and about 8 V when frequencies less than 8 MHz are entered. The 10-ms LATCH ENABLE pulse should appear on pins 5 and 13 of U302, U402 and U502 during frequency changes. This pulse is used to turn on the transmission gates that bypass the loop filters during frequency acquisition.

Be sure to remove power from the circuit when removing and replacing ICs and components in the following steps. First, tune up the coarse-tune loop. Remove U506 (to disable the lock-detect feature) and U300. Connect a variable voltage source to pin 17 of the socket for U300. This can be accomplished by using a small multi-turn trimmer potentiometer with one leg in pin 19, the other in pin 16 and the slider leg in pin 17 as the variable voltage source. Adjust this voltage source until 1 V appears on pin 17. Connect your frequency counter to the output of the coarse-tune loop at C329. Enter a frequency of greater than 8 MHz (increment step size can be any value) and adjust L305 until the counter reads approximately 52 MHz with 1 V on pin 17. Now adjust the voltage source for 7 V on pin 17. You should measure about 67 MHz on the counter. If you don't get this frequency span, the VCO does not have the required gain, probably caused by a misplaced part in the oscillator circuit.

Enter a frequency of less than 8 MHz and repeat the procedure. This time, use

C333 to adjust the frequency to 45 MHz with 1 V on pin 17. Increase to 7 V on pin 17; this should increase the frequency to approximately 57 MHz. Don't retune L305 while making this second adjustment. The value of padder capacitor C325 can be changed if C333 doesn't have enough range.

To test U301, the dual modulus prescaler, connect U300, pin 8 to +8 V and measure the frequency at U300, pin 10. It should be 1/64 the VCO output frequency. When U300, pin 8 is grounded, the frequency at pin 10 should be 1/65 the VCO frequency. Replace U300 and remove U400.

Now test the fine-tune loop. Enter a 5-MHz starting frequency and any increment step size into the computer. Connect a variable voltage source to the C410-R408 junction and adjust for 1 V. Attach the counter to C425 and adjust L403 for a reading of 48 MHz. Set the voltage source to 7 V. The frequency should now be about 53 MHz. Check U401, the dual modulus prescaler, in the same manner as U301. Replace U400. This completes the initial VCO tune-up.

Tune the reference oscillator. The frequency should be measured at pin 3 of U300 and U400. This pin is a buffered output that will not load the reference oscillator during the measurement. Adjust C200 until the counter reads 16.3800 MHz.

Check the coarse-tune loop. With U300 and U400 back in their sockets, set the starting frequency to 8 MHz with a step size of 1 MHz. With the up-arrow key, increment the frequency to 20 MHz while using your scope to observe the voltage at the C310-R304 junction. The voltage should start at about 1 V and jump in 0.3 V steps to about 6 V. If this is not the case, retune L305 as described previously.

Set the starting frequency to 1 MHz and repeat the procedure while incrementing from 1 to 7 MHz. This time, the voltage should start at about 1 V and jump in 0.5 V steps to 5 V. If this is not the case, retune C333 as described previously. Remember to tune only L305 when the frequency of operation is above 8 MHz and to tune only C333 when the frequency is below 8 MHz.

The fine-tune loop can be checked in a similar fashion. Set the starting frequency to 5 MHz and the step size to 1000 Hz. The voltage at the C410-R408 junction should start at approximately 3.6 V and increase to 5 V. Then it should drop back to 3.6 V and again increase to 5 V. This pattern should repeat every 10 kHz.

Adjustment of the output loop is probably the most critical and important step in the procedure. This is because the output VCO must track the coarse-tune VCO fairly closely, and its frequency should be greater than the coarse VCO - 500 kHz. The output of the phase/frequency detector in U500 will compensate for about

0.5 MHz of tracking error. It will, however, produce an error voltage to compensate in the wrong direction if the output VCO frequency is less than the coarse-tune VCO - 500 kHz.

Check the divide-by-100 counter. The frequency at pin 2 of U501 should be 1/100 of the fine-tune synthesizer loop output (U501, pin 7).

Remove U500. Connect a 4-V source to pin 13 of the U500 socket. This can be done by inserting a resistive voltage divider between pins 16 and 7, with the center at pin 13. Enter a starting frequency of 8 MHz and a step size of 1 MHz into the computer. Adjust L504 so that the frequency at the C522-L507 junction is 53 MHz (500 kHz above the coarse loop).

Enter a 1-MHz starting frequency and a 1-MHz step size. Adjust C534 so the frequency at C522-L507 is 46 MHz. Now, step to 20 MHz and record the frequencies. The frequencies should never exceed 500 kHz less than or 1 MHz greater than the coarse-tune VCO frequency. Variations in varactor characteristics and differences between the parallel capacitances across the varactors can cause differences in tracking. If the output VCO changes frequency faster the coarse-tune VCO (that is, if the output VCO frequency is higher than the coarse-tune VCO frequency by more than 1 MHz), decrease the value of C316 by 1 or 2 pF and repeat the alignment and test procedure. Increase the value of C316 if the output VCO frequency is lower than the coarse-tune VCO frequency by more than 500 kHz. Note that the coarse loop will not cover 20 MHz if the value of C316 is increased too much.

Replace U500. Set the starting frequency to 1 MHz and step from 1 to 20 MHz in 1 MHz steps while observing the voltage at the C501-R502 junction. The voltage should remain between 3 and 7 V. If it does not, the VCOs are not tracking or the correction VCO does not have enough gain. If the tracking cannot keep the oscillators within acceptable limits, as a last resort, the compensation loop gain can be increased by increasing C504 by a small amount. Increasing C504 too much will cause degradation of the tracking characteristics.

Monitor the synthesizer output frequency at the R605-R606 junction. Step through various frequencies. The output should follow the computer display, plus 45 MHz.

Tune the 45-MHz crystal filter, Y600. This can be done by sweeping a signal generator across the passband or by tuning the receiver across a strong constant signal; check the converter output for a flat passband. If more conversion gain is desired, decrease the value of R619. For less conversion gain, increase the value of R619. In the prototype, 100  $\Omega$  for R619 set the conversion gain to about 12 dB.

The lock detector output from the converter is in parallel with the computer's open-apple key. If the converter does not

lock (the display will indicate LOCKED or UNLOCKED) when applying power, depress the open-apple key to force load the synthesizers.

Note that the sidebands will be reversed because of the relationship of the RF and LO signals during the conversions. Tune the receiver to 28.62 MHz and have fun!

## OPERATION

You'll need to make up an interface ribbon cable to go between the receiving converter's I/O DIP socket and the Apple II computer's internal game port. Note that only six lines are used. You'll also need to connect the converter to an antenna and make a cable to go between the converter output and the receiver antenna input. The last step is to connect a 12-V dc, 250-mA supply to the converter.

Turn on the supply voltage to the receiving converter and tune the station receiver to 28.62 MHz. Make up a disk for your Apple II that has the operating system and the receiving converter control program files. These files are HELLO, DUAL1, SYN1, FCREATE, FMEN\$ and B.TIME BY INTERRUPT. Turn on the computer with the program disk inserted. The Apple's disk operating system will run the start-up program called HELLO. This program does the following: loads a date/clock program, sets the maximum high memory address (HIMEM) to make room for the binary loader program (SYN1), loads the binary loader program, turns on the 80-column display and runs the BASIC receiver program (DUAL1). If you do not have a date/time card in your computer, the top two lines will be blank.

Remember that the core of the program DUAL1 is the synthesizer loader routine located at lines 520 to 840. It does most of the work to calculate and load the serial data stream to the synthesizers. The rest of the program just performs the frills for incrementing the frequencies, selecting options, and saving and recalling files from disk. What you would like your receiver display to look like and do is probably different than mine, so don't be afraid to start with the core program and change it to suit your needs. (Don't forget to make a copy of the master disk first!)

After booting from the disk, the screen will go to the 80-column display mode. You'll be prompted "Create a File Y/N." At this point, you can either create a file or go right into the converter control screen. You can create up to 20 files; each file can hold up to 40 station frequencies. Each station frequency can have an eight-letter comment. For instance, you can create a file called "HAMSSB" which contains your favorite frequencies in the 160 through 20-meter voice segments. Or you could create files of all the international broadcast segments with each segment containing BBC, Radio Moscow, HCJB and so on. Note that files and frequencies can also be entered while the

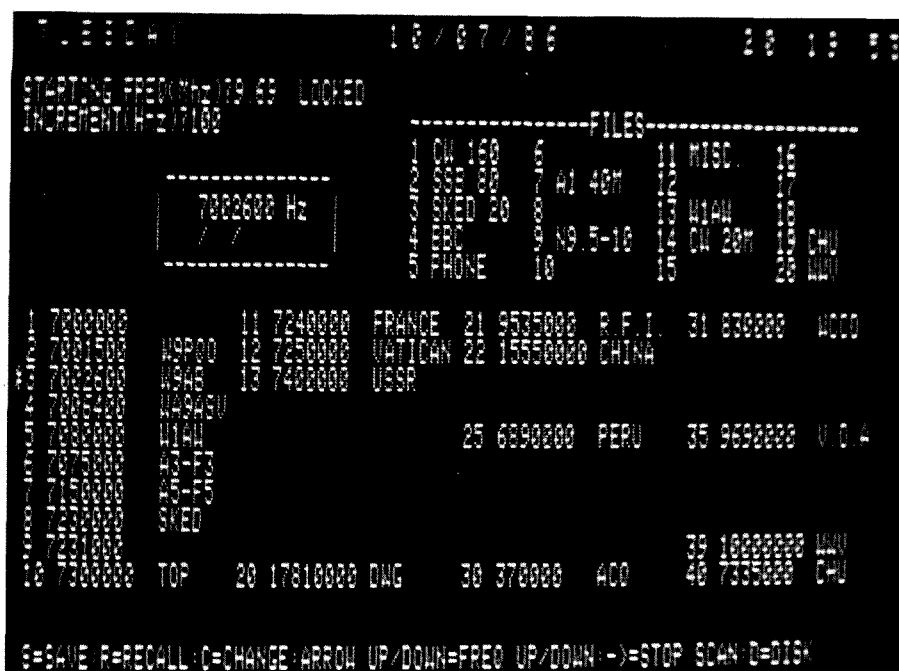

Fig. 42 — The computer receiver display.

program is in the listening mode.

If you want to create a file, enter Y for yes. You will now be asked how many stations you want to enter in the file, with a maximum of 40. For example, let's create a file with the 5, 10 and 15-MHz WWV frequencies. Enter 3 for the number of stations. You will now be prompted for the frequency (in MHz) of the first station. For this example, enter 5.0. Next, you will be prompted for comments. Enter WWV. Now you will be prompted for the frequency of the second station, then for comments. When you have entered the information on the last station, you will be prompted for a file number for this information to be stored under. For example, enter 1. Next, you will be prompted for a file name. In this case, WWV is appropriate. Now the file information will be stored on disk.

After you are done entering file information (or if you answer N(o) to the "Create a file" prompt), the receiver frequency display will be loaded to the screen. See Fig. 42. This screen contains important information. A box with the current operating frequency appears at the left center of the screen. On the upper right-hand side of the screen is a list of FILES. There are file numbers (1 to 20) and names. If you created the example file described previously, the file name WWV would be displayed for file 1. The words LOCKED or UNLOCKED are displayed in the upper center of the screen to indicate the condition of all three synthesizer loops. UNLOCKED will be displayed if one or more of the loops loses lock.

A prompt will ask you to enter the starting frequency in MHz. Then you will be prompted to enter the frequency increment step size in Hz. Increments as small as

10 Hz can be entered. When you have entered the frequency and step size, the selected frequency (displayed down to the 1 Hz) will be shown in the frequency display box. The converter will automatically be set to that frequency.

At the bottom of the screen is a menu of commands to help you tune the converter. Three commands make use of the cursor-control arrow keys. Pressing up-arrow causes the converter to scan higher in frequency; down-arrow makes it scan lower in frequency; and right-arrow stops the scanning. Other commands are called by entering the first letter of each command. These are Save, Recall, Change and Disk.

To begin scanning from the starting frequency, press the up-arrow or down-arrow keys. The default scanning rate is approximately two increment steps per second. To increase the scan rate, press the greater than (>) key; to decrease the scan rate, press the less than (<) key. To stop scanning, press the right-arrow key. The scan rate could be sped up by compiling the BASIC program or writing it in assembly language.

Putting a frequency into memory and then into a disk file can easily be accomplished directly from the receiver display screen. Simply enter the desired frequency into the display box or scan to it, and then press S for save. The computer will ask for a memory location (1-40) and for a comment (call sign or whatever). After entering the memory number, frequency and comment, this information will be displayed about halfway down the screen. Up to 40 of these station frequencies can be stored in a disk file under one file name.

To access files on disk, press D. The program will ask you if you want to Save,

Recall or Delete a file. The file name must begin with a letter and be no longer than 8 characters. To retrieve a file, simply press D, R (for recall) and the file number (from the file menu). For example, you could recall file 1 (WWV) from the previous example by pressing D, R and 1. All of the frequencies in the file, along with numbers and names, will be displayed in four columns across the lower part of the screen. In this case, the frequency list would read

```
1 5000000 WWV
2 10000000 WWV
3 15000000 WWV
```

Any of these frequencies can be loaded by pressing R and the corresponding frequency number. For example, press R 2 to load the 10.0 MHz WWV frequency. An asterisk appears next to the selected memory number and the frequency is placed in the dial box. You can scan up or down from this frequency at the current step increment by pressing the appropriate arrow key.

If at any time you want to change the frequency or increment, press C (for change) and the cursor will move to the starting frequency location. Then enter the new starting frequency and step size information.

As written, the BASIC program (DUAL1) does not have error handling routines or elaborate schemes for coping with keyboard entry errors. Outside of the synthesizer control part of the program, there is nothing special here. The BASIC code is relatively straightforward and can

be refined if you wish. If the program bombs, it is best to re-boot the disk and start over. Hopefully, you will have saved your files on disk before this happens.

## FUTURE PROJECTS

Fig. 41 shows the Apple II I/O game port. Two digital outputs AN(2)-AN(3), three analog inputs PDL(0)-PDL(1)-PDL(2), and two digital inputs PB(1)-PB(2) are not used on the game port. These lines could be used for extra features not implemented in the existing configuration.

The output line could switch in an attenuator, turn the power on and off, provide a blanking pulse to quiet the receiver during the time the synthesizer changes frequency, or control a TR switch. It should be noted that precautions should be taken not to transmit into the converter if it is connected to a transceiver.

An AGC voltage could be used to feed the analog input line for carrier detection in the scan mode. The scan could be programmed to stop or pause if a carrier above a fixed level is detected. Multiple listening frequencies for a foreign broadcast could be programmed, and when the carrier drops below a level, the computer could search for a stronger carrier at another frequency. This same method might be used to plot the spectrum while scanning.

A joystick can be used to scan up or down at various rates as a function of the stick displacement. Also, the two unused

inputs might be connected to a digital shaft encoder for tuning the receiver.

If you have a time of day clock in your computer, a short program could tune the bands at a particular time of day for recording. Another future project is to design an RS-232-D interface that could accept the inputs from any computer.

With the flexible computer controller, the tasks you can make this receiver do are only limited by your imagination.

# A Modified Cubic-Incher

This transmitter is a modified version of the 40-m Cubic Incher by Dennis Monticelli, AE6C, which appeared in July 1982 *QST*. This version, shown in Figs. 43 through 46, can be built for the 80- or 40-meter band and features improved harmonic rejection. It was developed in the ARRL lab by Greg Bonaguide, WA1VUG.

### Circuit Description

T1 keeps the design simple by taking the place of several separate inductors and transformers. C1 and C2 form a capacitive voltage divider to limit the amount of feedback in the oscillator loop. C3, the transmitter tuning control, is adjusted to obtain the cleanest CW note. D1 serves to reduce harmonics in the output waveform. C4 bypasses RF on the dc line, and C7 helps to eliminate any residual power supply ripple which might otherwise become superimposed on the output signal. Start-

up resistor R1 delivers about 1 mA to the base of Q1, a 4-watt NPN transistor that can handle infinite SWR when operated at 12 volts or less. Half-wave filter components C5, L1 and C6 are used to clean up the RF before it reaches antenna jack J1. Design values for C1, C2, C3, C5 and C6, plus winding information for L1, can be found in Table 1. Crystal Y1 is a fun-

damental cut type chosen for the desired operating frequency.

### Construction

As can be seen in Fig. 44, the transmitter uses point-to-point wiring on double-sided epoxy circuit board material. Layout is not critical, except that component lead lengths should be kept short (1 inch or less). Since

**Table 1**

toroids are self-shielding devices, they can be located close together.

It is a good idea to first construct the transmitter on a piece of unetched circuit board to check operation before installing all the parts into a tight space. In this way, component changes and circuit voltage checks can easily be made.

### Alignment

Alignment requires a dummy load (two 2-watt, 100-ohm resistors in parallel will work fine), a 0-1 A meter, and a monitoring receiver. Connect the ammeter in the + 12-volt line, being sure to observe polarity markings. Next, attach the dummy load, insert a crystal, turn the transmitter power supply on and tune the monitoring receiver around the crystal frequency. If nothing is

heard, and 250- to 450-mA of current is being drawn, adjust C3 until the crystal begins to oscillate. Next, attach a straight key in series with the 12-volt line, send a string of dits and dahs, and adjust C3 for the best sounding CW note. It should be stable and chirp free. Finally, attach an antenna and readjust C3 slightly. The frequency of the transmitter will shift whenever anything connected to the oscillator varies. This includes not only C3, but environmental changes affecting the antenna, such as wind and rain, as well!

This circuit is an easy way to get a homebrew QRP signal on the air. Provided the operator takes care in adjusting the oscillator/transmitter for a pure-sounding CW note, he or she should get miles of enjoyment from this tiny 2-watter.

Fig. 46 — Spectral photograph of the Modified Cubic-Incher, tuned for 1.6-W output. Each horizontal division represents 5 MHz. Vertical divisions represent 10 dB. The second harmonic is 32 dB below the carrier. This transmitter meets FCC spectral purity requirements.

# A VXO-Controlled CW Transmitter for 3.5 to 21 MHz

The 6-W CW transmitter shown in Figs. 47 to 50 can be built in a few evenings and will provide hours of on-the-air enjoyment. It features a variable-crystal oscillator (VXO) to generate a highly stable, adjustable-frequency signal. With the circuit shown here, frequency spans of 5 kHz or more can be realized. See Table 1. Only a few crystals are necessary for coverage of the popular CW frequencies. This single-band transmitter may be built for any one band from 80 through 15 meters. Since most crystals for frequencies above 25 MHz are overtone types, and this transmitter requires fundamental-type crystals, there is no provision for 10-meter operation.

## Circuit Description

The schematic diagram of the transmitter is shown in Fig. 48. Q1 and associated

components form a Colpitts variable-frequency crystal oscillator. C1 is used to adjust the frequency of the oscillator, and C2 is used to limit the span of the oscillator. If no limit is provided, the oscillator can operate "on its own" and no longer be under the control of the crystal. This is undesirable. On the 30-, 40- and 80-meter bands, C2 is not necessary and is omitted from the circuit. Supply voltage is fed to the oscillator only during transmit and spot periods. This prevents the oscillator from interfering with received stations operating on the same frequency.

Output energy from the oscillator is routed to Q2, a grounded-base amplifier. This stage provides some gain, but more important, it offers a high degree of isolation between the oscillator and the driver stage. Oscillator pulling and chirp are virtually nonexistent.

The driver stage uses a broadband amplifier that operates class A. This stage is keyed by grounding the base and emitter resistors. C10 is used to shape the keying waveform. Although the keying is rather hard, there is no evidence of clicks.

Two MRF476 transistors are used in parallel for the power amplifier. These transistors were designed for the Citizens Band service and work nicely at HF frequencies. Each transistor is rated for 3 W output. The original transmitter design used MRF472 output transistors, but Motorola no longer manufactures these devices. They are still available from many surplus outlets, however. L2 is used as a dc ground for the bases, making the transistors operate class C.

The low output impedance at the collectors of the output transistors is stepped up to 50 ohms by broadband transformer T3. A five-element Chebyshev low-pass filter is used to assure a clean output signal. This transmitter exceeds current FCC spectral purity specifications (see Fig. 49). D2 is used to clamp the collector voltage waveform to protect the output transistors if the transmitter is operated into an open circuit or high-SWR antenna system. The transmitter is designed to operate into a load that is close to 50 ohms resistive. S1 is used as the transmit/receive switch. One section transfers the antenna to an accompanying receiver or to the output of the transmitter. Another section is used to activate the VXO during transmit and the third section is provided for receiver muting purposes.

D3 and the associated components form an RF output driver for M1. This circuitry

**Table 1**

Fig. 47 — The completed 6-W VXO controlled transmitter is housed in a small aluminum enclosure. RG-174 is used for all interconnections carrying RF. This version uses the older MRF472 output transistors, which are mounted flat on the board.

Fig. 48 — Schematic diagram of the VXO-controlled transmitter. All resistors are ¼-watt carbon types unless noted otherwise. All capacitors are mylar or disc ceramic unless otherwise noted. Polarized capacitors are electrolytic or tantalum.

C1, C2, C3, C4, C6, C17 and C18 — See Table 1.

D1 — Zener diode, 9.1 V, 1 W.

D2 — Zener diode, 36 V, 1 W.

J1, J2 — Binding post.

J3 — Key jack.

L1, L3, L4, L5 — See Table 1. Wind with no. 24 or 26 enamel wire.

L2 — 8 turns no. 26 enameled wire on FB73-801 ferrite bead.

M1 — 0-1 mA meter, Calctro DI-91Z or equiv.

Q1, Q2 — NPN transistor, 2N2222A or equiv.

Q3 — NPN transistor, 2N3866 or equiv.

Q4, Q5 — Transistor, MRF476 or equiv. (see text).

R14-R17, incl. — Fixed resistor, 1.8 ohms, ½ W.

R18 — Meter shunt, 13½ inches no. 26 enamel wire wound on a high-value 1-watt resistor.

S1 — Toggle switch, 3PDT.

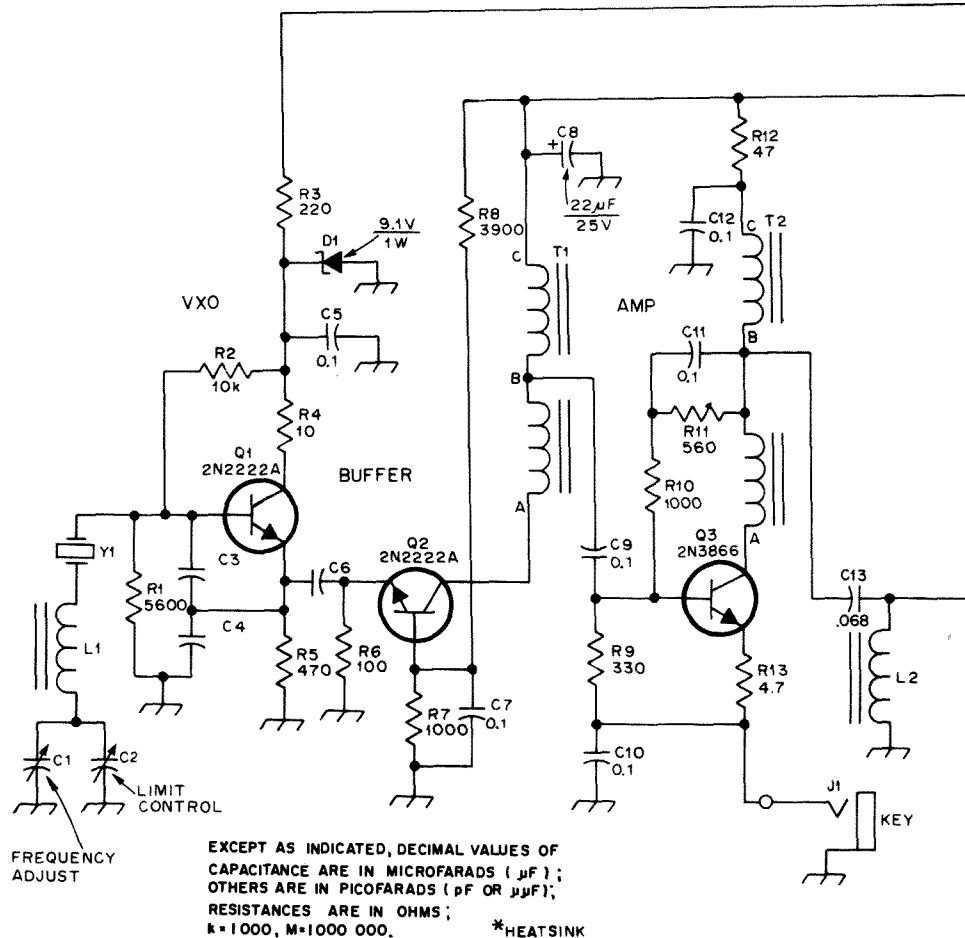

S2 — Push-button switch, SPST normally open.

S3 — Toggle switch, DPDT.

T1, T2 — Broadband transformer, 10 turns no. 24 enameled wire, bifilar wound on an FT37-43 core.

T3 — Broadband transformer, 10 bifilar turns no. 24 enameled wire on an FT50-43 core.

Y1 — Fundamental crystal for frequency range desired.

is optional as there are no power-output tuning adjustments. M1 is also used to monitor transmitter current consumption.

### Construction

The majority of the circuit components are mounted on a double-sided PC board. One side of the board is etched with the circuit pattern, and the other side is left unetched as a ground plane. A small amount of copper is removed from around each hole on the ground-plane side of the board to prevent leads from shorting to it. A test transmitter was built in the ARRL lab using single-sided board and the transmitter seemed to function normally with no instability. No long-term testing was performed, however. A parts-layout guide and photo of the finished board appear in Fig. 50.

Affixed to the front panel are the transmit/receive switch, spot switch and the tuning capacitor. The rear apron supports

the antenna and mute jacks, key jack and binding posts.

A homemade cabinet measuring 3 × 6 × 8¼ inches was used in the construction of this transmitter. The builder may elect to build a cabinet from sheet aluminum or circuit-board material. The layout is not critical except that the lead from the circuit board to C1 should be kept as short as possible — an inch or two is fine.

A bent aluminum heat sink was attached to the output transistors. Commercial TO-220 heat sinks could also be used. If MRF472 transistors are available, they can be mounted flat on the circuit board and screws passed through the center of the transistors to hold them down. The ground plane will act as a heat sink sufficient for short key-down periods.

The only adjustment needed is that of setting the VXO limit capacitor (C2), and even this adjustment is not needed for the 80-, 40- and 30-meter transmitters. This

adjustment can be done with the aid of a receiver. With a fundamental crystal in the circuit, adjust C2 for a maximum frequency spread that approximates the value shown in Table 1. If too much frequency spread is available, increase the amount of capacitance. Make a final check with the receiver by listening to the keyed signal from the transmitter. It should be steady and chirp free.

To provide wider frequency coverage, several crystals may be used. A crystal socket may be mounted on the front panel, or several sockets can be mounted on a separate circuit board and a simple rotary switch used to connect the desired crystal into the circuit. This option is shown in Fig. 48. Any number of crystals may be used, depending on the number of positions on the rotary switch. With crystals spaced 10-kHz apart, the circuit can provide continuous coverage of 50-60 kHz of the 20-meter band.

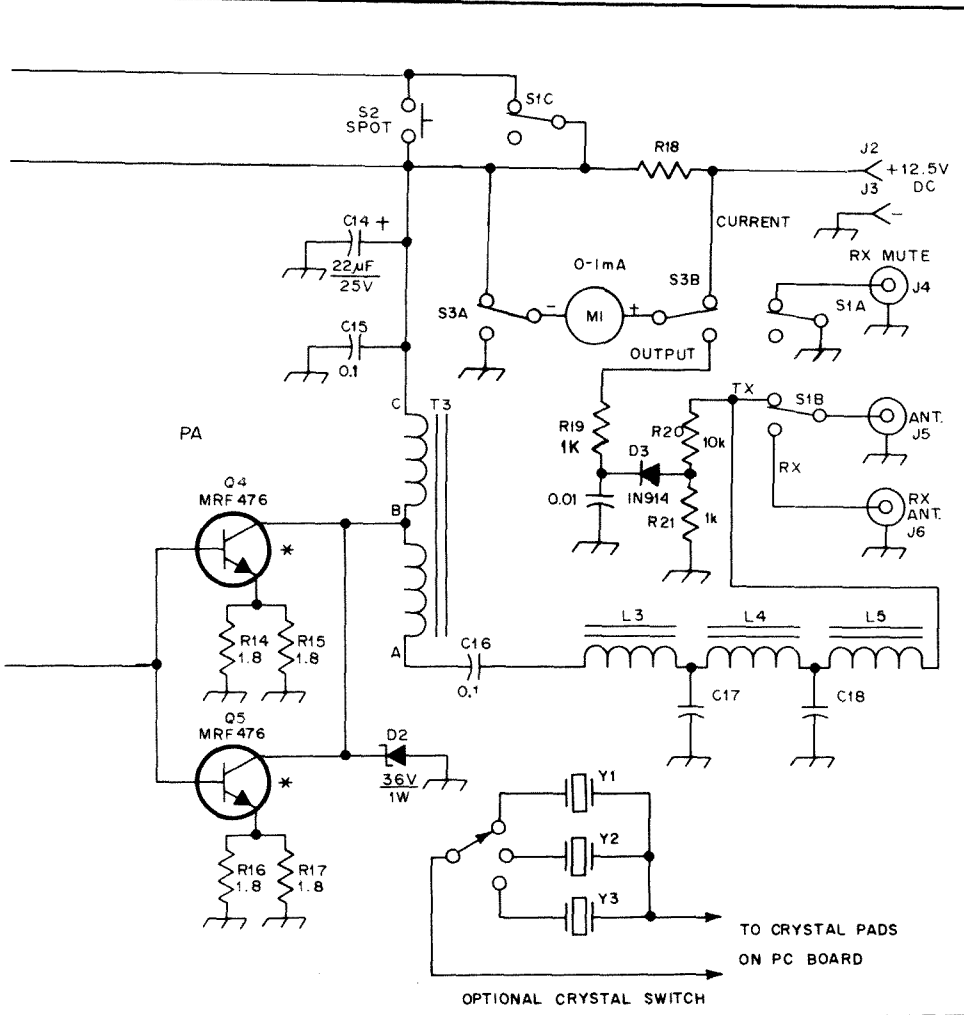

Fig. 49 — Spectral display of the VXO-controlled transmitter. Here the transmitter is operated in the 20-meter band. The second harmonic is down 56 dB relative to the fundamental output. Similar presentations were obtained on each of the other bands. This transmitter complies with the current FCC specifications regarding spectral purity.

Fig. 50 — The component-placement diagram for the 6-W transmitter PC board is shown at A. The component side of the board is shown, with an X-ray view of the circuit foil. A full-size etching pattern appears at the back of this book. At B is a photo of the transmitter circuit board built using MRF476 transistors. The devices are mounted upright on the board with a heat sink attached to the metal tabs on the transistors.

# A 1500-W-Output Amplifier for 160 Meters

Until a few years ago, most commercially available power amplifiers included no provision for top-band operation. With low sunspot numbers, 160 meters has become a great DX band. Sometimes a barefoot transceiver just isn't enough, and an amplifier is needed to make the QSO. The project described here and shown in Figs. 51 through 57 can enhance DX possibilities for those amateurs with an older five-band HF amplifier. It uses an EIMAC 3CX1500A7/8877 in grounded-grid configuration and will develop 1500 watts PEP output with 2500 volts on the plate. The amplifier is easy to drive, 50 to 60 W for full output, so any of the 100-W transceivers will do the job. Dick Stevens, W1QWJ, designed and built this project.

## Circuit Details

The schematic diagram is shown in Fig. 52. The RF deck includes everything except the high-voltage power supply. Several suitable supplies are described elsewhere in this book. See Chapters 27 and 31, and the six-band 8877 HF amplifier described later in this chapter for ideas on building a high-voltage supply.

The input circuit (C7, L1, C8) is a low-Q pi network. No filament choke is needed with the 8877, which further simplifies the circuit.

The plate circuit is a pi network designed for a Q of 12. The tuning capacitor consists of a 300-pF fixed value (C17) in parallel with a 241-pF variable (C18). L2 is a section of standard Barker and Williamson coil stock. The loading capacitor consists of a 1600-pF fixed value (C20) in parallel with a 1000-pF variable (C19).

C13 bypasses the B+ line. Although an 8-kV unit was used here, any value above 4 kV should work fine. RFC2 is a Millen 1-mH, 1-A transmitter plate choke. RFC3 is included for safety to ground the high voltage that would appear at the antenna connector if dc blocking capacitor C16 fails.

Filament inrush current protection is provided by R1 and K1 in the T1 primary. After the initial current surge, K1A shorts out R1, applying full filament voltage. Power is applied to DS2, indicating that the filaments are on. T1 is a 5.0-V, 10.5-A transformer made by Avatar Magnetics. The primary is tapped to allow for precise adjustment of the filament voltage at the tube pins.

A grid overcurrent trip circuit is included to protect the 8877 from damage. The cost of an 8877 makes protection circuitry a must! Grid current is sensed across R5. If the grid current exceeds a preset value, Q1 conducts and actuates K2. Contact K2A, in the K3 coil supply line, opens and removes power from K3, placing the ampli-

Fig. 51 — The 160-meter amplifier is built behind a 19- × 7-inch rack panel. Meters with bezels add to the clean appearance of the unit.

fier in STANDBY. To restore normal circuit operation, turn S3 to the off position; this will reset K2. S3 is "on" for normal operation. This switch provides an additional function: It controls the VOX circuit and antenna bypass relay circuit, so the amplifier can be switched in and out of the line between antenna and transceiver.

Zener diode D5 provides operating bias for the 8877. During receive periods, R6 is in the circuit, and the tube is cut off. For transmit, K3A shorts out R6.

All metering is done in the negative return lead for safety. C5, C6, D3 and D4 protect the meters. The antenna bypass relay (K4) is located externally but is powered from the amplifier.

## Construction

The amplifier uses parts that are not too hard to find and are often available at flea markets at a very reasonable price. All components are, however, available commercially if the builder chooses that route. Most of the parts used in this project were purchased from Radio Shack, Electronic Emporium and RadioKit. See Chapter 35 for addresses.

Although an EIMAC SK-2200 series socket could be used, the socket used for this amplifier was homemade. It is built around a Johnson type 247 and an aluminum plate. Complete details of this plate, along with a full-size template, are shown in Fig. 53. This socket assembly can be made with hand tools — there is no fancy

or complex metal work required.

Figs. 54 and 55 show the top and bottom of the chassis of the completed amplifier. Construction of a single-band amplifier is significantly easier than that of a multiband unit. Layout is not critical, and there is plenty of room to spare.

The amplifier is built on a 2 × 17 × 13-inch (HWD) aluminum chassis (Bud AC-419). This chassis is bolted to a standard 19 × 7-inch rack panel (Hammond PBPA 19007). The top and side panels are formed from a single piece of perforated sheet metal often found at hardware stores.

Fig. 54 shows the top of the chassis. The 8877 is located along the back edge, near the center. C18 is mounted along the left-hand edge of the chassis, and the fixed capacitors that make up C17 mount directly behind C18. Details of the mounting plate for C17 are given in Fig. 56. C19 is mounted to the right of C18, and the capacitors that make up C20 mount to the chassis behind C19. L2 is mounted on an acrylic strip that is supported above the chassis by two ceramic standoff insulators. J3 and J5 mount to an aluminum bracket that bolts to the rear of the chassis.

The blower and filament transformer may be seen along the right-hand edge of the chassis. M1 and M2 mount to the front panel near the filament transformer. K1 and K3 mount in sockets between the filament transformer and the front panel.

Fig. 55 shows the underside of the chassis.

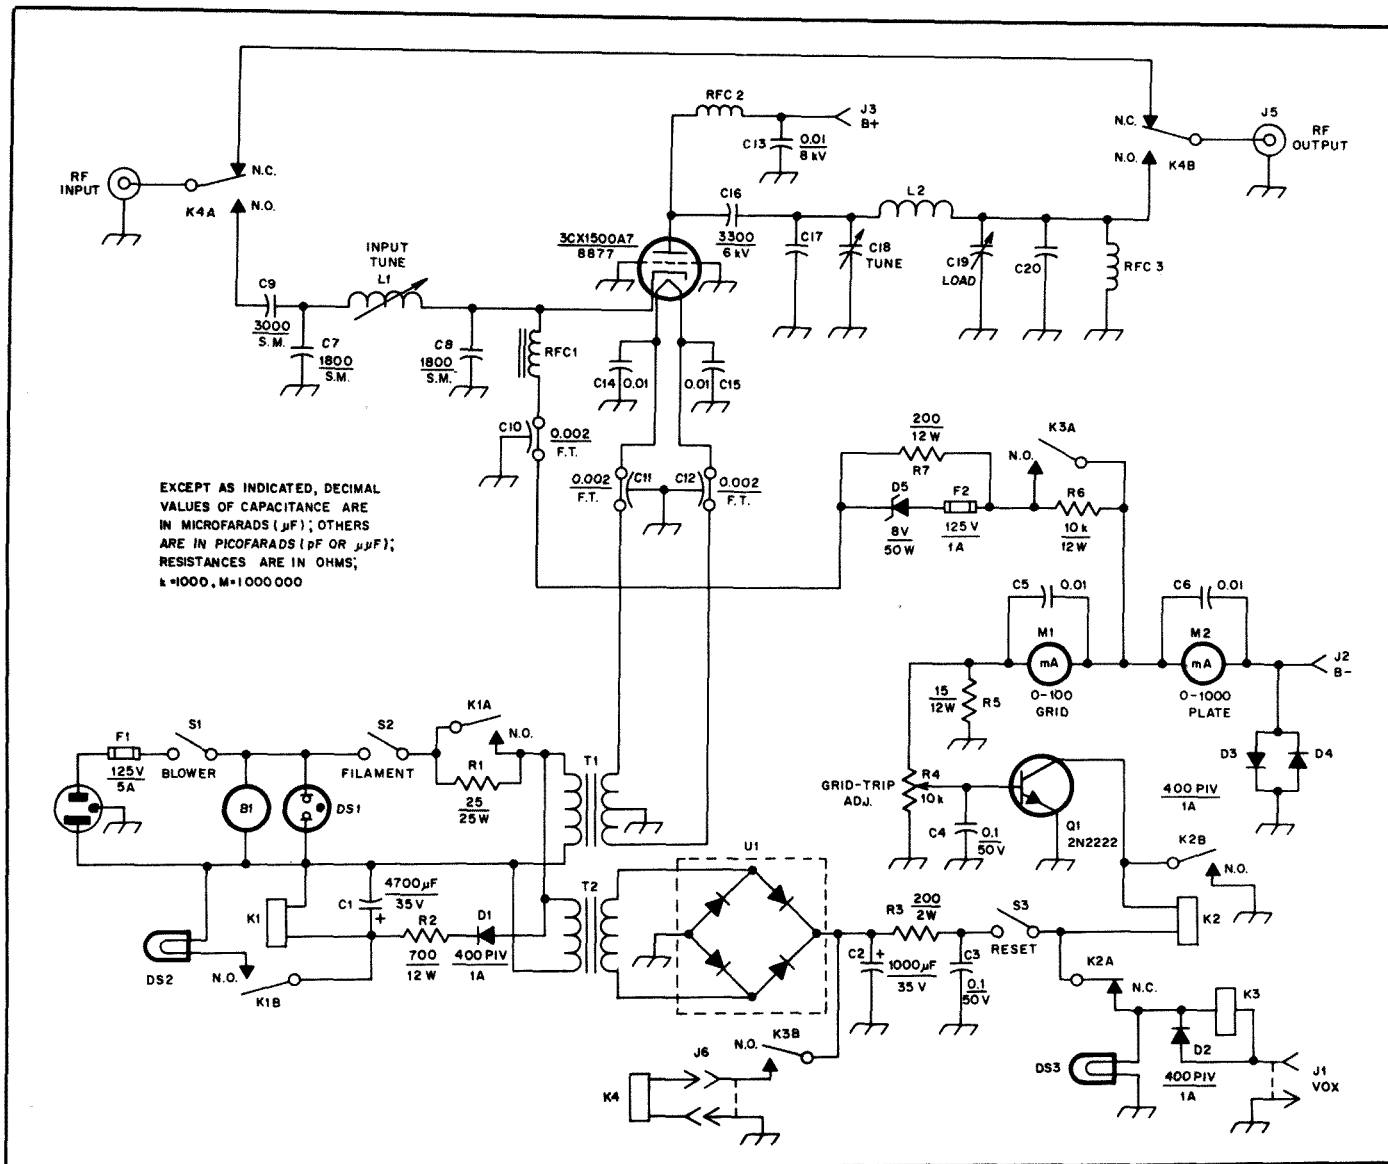

Fig. 52 — Schematic diagram of the 160-meter amplifier. Capacitors are disc ceramic unless otherwise noted. S.M. means silver-mica. Capacitors marked with polarity are electrolytic.

B1 — Dayton 4C012A 54-CFM blower.  
 C7, C8 — 1800-pF silver-mica capacitor; made from a 1500-pF unit in parallel with a 300-pF unit.  
 C9 — 3000-pF, 400-V silver-mica capacitor.  
 C10, C11, C12 — 0.002- $\mu$ F, 8-kV feedthrough capacitor (Erie 1202-005 or equiv.).  
 C13 — 0.01- $\mu$ F, 8-kV ceramic capacitor.  
 C16 — 3300-pF, 6-kV ceramic doorknob capacitor.  
 C17 — Three 100-pF, 5-kV ceramic doorknob capacitors in parallel.  
 C18 — 241-pF, 4.5-kV air variable capacitor (Cardwell 154-16 or equiv.).  
 C19 — 1000-pF, 1.5-kV air variable capacitor (Cardwell 154-30 or equiv.).

C20 — Two 800-pF, 5-kV ceramic doorknob capacitors in parallel.  
 DS1 — 117-V ac pilot light.  
 DS2, DS3 — 12-V dc pilot light.  
 J1 — Female chassis-mount phono jack.  
 J2, J3 — Millen 37001 high-voltage connector.  
 J4, J5 — Chassis-mount SO-239 connector.  
 J6 — Two-pin chassis-mount Cinch-Jones connector.  
 K1 — DPDT relay, 12-V dc coil, 10-A contacts, socket-mount.  
 K2 — Subminiature DPDT relay, 12-V dc coil.  
 K3 — DPDT relay, 12-V dc coil, 3-A contacts.  
 L1 — 4.4  $\mu$ H; 25t no. 24 enam. on a  $\frac{1}{2}$ -inch-OD, slug-tuned ceramic coil form.  
 L2 — 20  $\mu$ H; 17t no. 12 tinned, 3-inch ID, 6 turns per inch (B&W 3033 miniductor stock

or equiv.).  
 M1 — 0-100 mA meter.  
 M2 — 0-1000 mA meter.  
 RFC1 — 100- $\mu$ H RF choke.  
 RFC2 — 1-mH, 1000-mA transmitting type RF choke (Miller 4534 or equiv.).  
 RFC — 2.5 mH, 200-mA RF choke (Miller 4537 or equiv.).  
 T1 — Filament transformer. 117-V ac primary; 5-V, 10.5-A center-tapped secondary (Avatar AV-434 or equiv.). Available from Avatar Magnetics, 1147 N. Emerson St., Indianapolis, IN 46219.  
 T2 — Power transformer. 117-V ac primary; 12.6-V, 1.2-A secondary.  
 U1 — 50-PIV, 4-A bridge rectifier.

An enclosure is fashioned around the input circuit for shielding and to direct the air flow up through the socket. The blower draws air from behind the amplifier and blows it into the input compartment. A homemade chimney, fashioned from

Teflon sheet, directs air through the tube cooler. A suitable chimney, part number SK-2216, is available from EIMAC.

L1 mounts to the rear chassis wall so the input match can be adjusted with the covers on. Filament and bias voltage enter the in-

put compartment through feedthrough capacitors. D5 mounts to a chunk of scrap aluminum bar for heat sinking. The grid overcurrent components (Q1, K2) are arranged on a small piece of perforated board. R4 is mounted to the chassis near

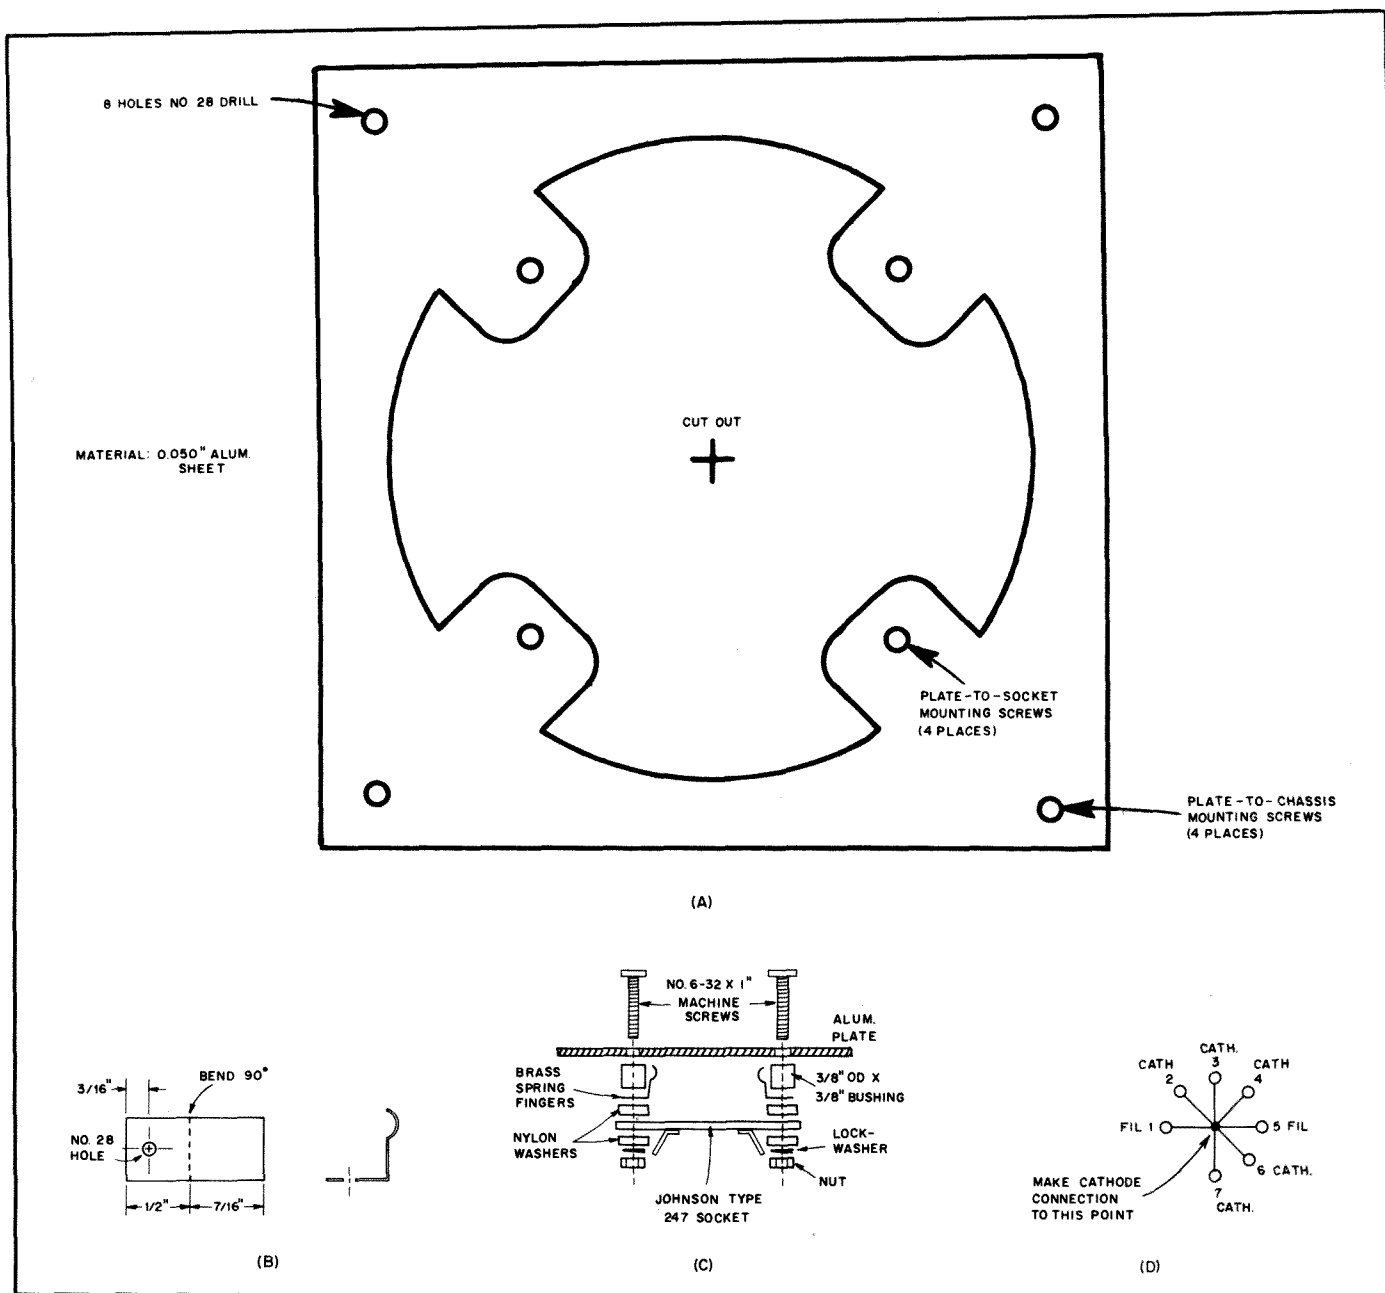

Fig. 53 — Details of the homemade socket for the 8877 tube. All hardware is no. 6-32. A full-size template for the aluminum plate is shown at A. Connection to the grid is made through four spring fingers made from spring brass or copper. Details of these clips are shown at B. Assembly of the socket is shown at C. Assemble as follows. Insert four 1-inch no. 6-32 machine screws through the plate. Slip a 3/8-inch by 3/8-inch-OD aluminum bushing over each screw. Place a spring finger on each screw, followed by a nylon washer. Slide the Johnson 247 socket onto the screws, and secure each screw with a nylon washer, metal lock washer and nut. Align the spring fingers for good contact with the grid ring and tighten. Connections to the bottom of the socket are shown at D.

the meters and is adjustable from the top. Liberal use of terminal strips simplifies wiring. There is plenty of room, and wiring is not critical at all, except that the input network should be mounted near the tube socket.

#### Testing and Tune Up

Connect the amplifier output to a dummy load through a wattmeter capable of reading 1500 W. Connect an HF transmitter capable of supplying at least 60 W to the amplifier input through an SWR/watt-

meter. Connect a high-voltage supply, preferably with a variable autotransformer on the ac line to make the B+ continuously variable, to J2 and J3. The power supply should be able to deliver approximately 2500 V at 1 A. Be careful: The high voltage in this amplifier can be lethal!

Apply 117-V ac to the RF deck and operate the blower switch. The blower should come on, and the blower indicator lamp will light. You should feel air exhausting through the tube cooler.

Operate the filament switch. After a

short delay, the filament indicator will light showing that the inrush protection circuit has cycled. Operate the reset switch, and the indicator lamp will light showing the amplifier is in the "go" condition. EIMAC recommends that the 8877 filaments be on for three minutes before high voltage is applied. No delay circuit for plate voltage control has been provided here, so wait three minutes before turning on the plate supply.

Apply plate voltage gradually. Do not apply drive yet. Watch and listen for any

Fig. 54 — Top-side view of the 160-meter amplifier chassis.

Fig. 55 — View of the underside of the 160-meter amplifier chassis.

signs of arcing as you bring the plate voltage up to full operating potential. There should be no indication on M1 or M2. If all appears to be okay, lower the plate voltage to about 1000 V and apply about

10-W drive. Adjust L1 for lowest input SWR.

Increase drive and adjust the pi network for maximum output. Most likely the grid overcurrent trip circuit will operate, placing

Fig. 56 — Full-size template of the plate used to connect the three doorknob capacitors that make up C17 to C18.

Fig. 57 — Spectral output of the 160-meter amplifier. Power output is 1500 W on 1.8 MHz. Each vertical division is 10 dB and each horizontal division is 2 MHz. All harmonics and spurious emissions are greater than 44 dB down. This amplifier complies with current FCC spectral-purity requirements.

the amplifier in STANDBY. Decrease the sensitivity by adjusting R4. This control is near high-voltage points, so take care and use an insulated screwdriver. Adjust this potentiometer so the grid protection circuit trips at 60 to 70 mA.

Apply full plate voltage and gradually increase drive. Adjust C18 and C19 for maximum output. These controls are somewhat interactive. Do not exceed 1 ampere of plate current. Recheck the input SWR when you reach full output power. Some additional adjustment of L1 may be necessary. Output power should be 1500 W with a plate voltage of approximately 2600 at 1 ampere and 60-W drive. Fig. 57 shows the amplifier spectral output.

# A Legal-Limit Amplifier for 160 through 10 Meters

The amplifier described here is an update of the 1500-W output legal-limit amplifier described in the 1985 and 1986 *ARRL Handbooks*. It uses the EIMAC 8877 (3CX1500A7) high-mu triode in grounded-grid service. The 8877 will easily deliver 1500-W RF output with the drive levels afforded by most 100-W-class transceivers. Operating at 1500-W output, tube dissipation is well within the manufacturer's specification.

Shown in Figs. 58 through 68, this amplifier covers 160 through 10 meters, not including the WARC bands. Operation on the 24-MHz WARC band is possible with the band switch in the 28-MHz position, but the input SWR will be a little higher than on the other bands. Many of the components used were purchased at flea markets and from mail-order dealers. The names and addresses of the parts suppliers are detailed at the end of Chapter 35. Amplifier parts are expensive. The builder is encouraged to substitute components from surplus dealers or flea markets where possible if cost is a problem. Be sure, however, to use only components with adequate ratings. The dc and RF power levels found in this project are capable of destroying parts with insufficient ratings.

Dick Stevens, W1QWJ, designed and built this project. The power supply and RF deck are built on separate chassis because of the size and weight of the power supply. Standard 19-inch rack panels are used for the front panels, so both pieces may be rack mounted if desired.

## Power Supply

The high-voltage power supply delivers 1 A continuously at user-selectable voltages of 2.5, 3 or 3.5 kV. During normal operation, only the 3-kV position is used, but a lower level is available for tuneup, and a higher level is available if line sag is a problem. Circuits are provided for protection, automatic start and PTT line control. Fig. 59 is the power-supply schematic diagram, and the unit is pictured in Figs. 60 and 61.

## Circuit Details

The secondary side of the power supply is conventional. T1 is a Hipersil transformer with a 234-V primary and secondary taps at 1770, 2125 and 2475 V. S3 is a high-voltage switch with large contacts and ceramic insulation used to select among the taps. The 234-V primary and full-value secondary contribute to good voltage regulation. D2 through D5 are 14-kV, 1-A rectifiers connected in a full-wave bridge. C2 is a surplus 53- $\mu$ F, 3.5-kV oil-filled capacitor. If the builder cannot locate one of these units, a suitable replacement should be at least 25  $\mu$ F at a similar voltage rating. R4, the 200-k $\Omega$  bleeder resistor, is made up of eight 25-k $\Omega$ , 25-W units connected in series.

Fig. 58 — The 8877 HF amplifier uses a standard rack-type front panel. The tuning and loading capacitors are controlled by vernier drives with turns counters. Once the settings for each band are determined, they can be recorded for quick band changes.

A high-voltage meter (M1) is included in the supply. The value of  $R_M$ , the multiplier resistor, will depend on the value of the basic meter movement. See Chapter 25 for information on meter multipliers and shunts. The B- lead floats above chassis ground. R3 is included to keep the B- near ground potential. The floating B- allows plate current to be metered in the negative lead for safety. C4 and C5 are bypass capacitors.

Power enters the supply from the 234-V line through a 20-A, 2-pole circuit breaker. DS1 will light when the circuit breaker is closed. With S1 in AUTOMATIC and S2 in START, a 24-V signal at J4 from the amplifier control circuitry will energize K1. K1A closes, energizing K2. DS2 lights. K2A and K2B apply reduced primary voltage to T1 through R2. After a second or so, C1 charges and energizes K3. K3A closes, shorting across R2, to apply full primary voltage to T1. This circuit protects D2-D5 from damage by effectively limiting inrush current through the rectifiers while C2 charges. R1 adjusts the charging time for C1. DS3 lights, signaling that the power supply is ready for service. An additional protective feature is that K1B is in the exciter PTT line to prevent keying the amplifier without high voltage present. Note that the supply can be activated manually (not by the amplifier control circuit) by placing S1 in the OFF position and using S2 to turn the supply on and off. PTT line protection is lost in the manual

mode, however.

J1 is a grounded, polarized 117-V ac receptacle used to provide power to the RF deck. Correct 117-V ac wiring must be used here. The ground (green) wire is connected to the chassis ground. The neutral (white) wire is connected to the 234-V line neutral. The hot side (black) is connected to one side of the 234-V line. Likewise, standard wiring must be used in the RF deck.

J1 and J2 are Millen connectors rated at 7 kV. Test prod wire (5-kV insulation) is used for the B+ and B- runs to the RF deck. A braid ground strap bonds the power supply and RF deck chassis together for added protection.

## Construction

The power supply is built behind a standard 12½-inch-high, 19-inch-wide rack panel. It is designed to fit inside a Bud Prestige series cabinet. T1 needs a good base to support the weight, so the bottom plate is made from a piece of ¼-inch-thick aluminum plate that is approximately 14 inches square. The size and shape of the power supply enclosure will depend on the actual components used. Be sure that it is sturdy, and allow sufficient room for air to circulate.

T1 and C2 are bolted to the bottom plate. The rectifiers, control relays and other parts mount on a shelf above C2. The eight 25-W resistors that make up the bleeder are mounted to two vertical strips of phenolic stock.

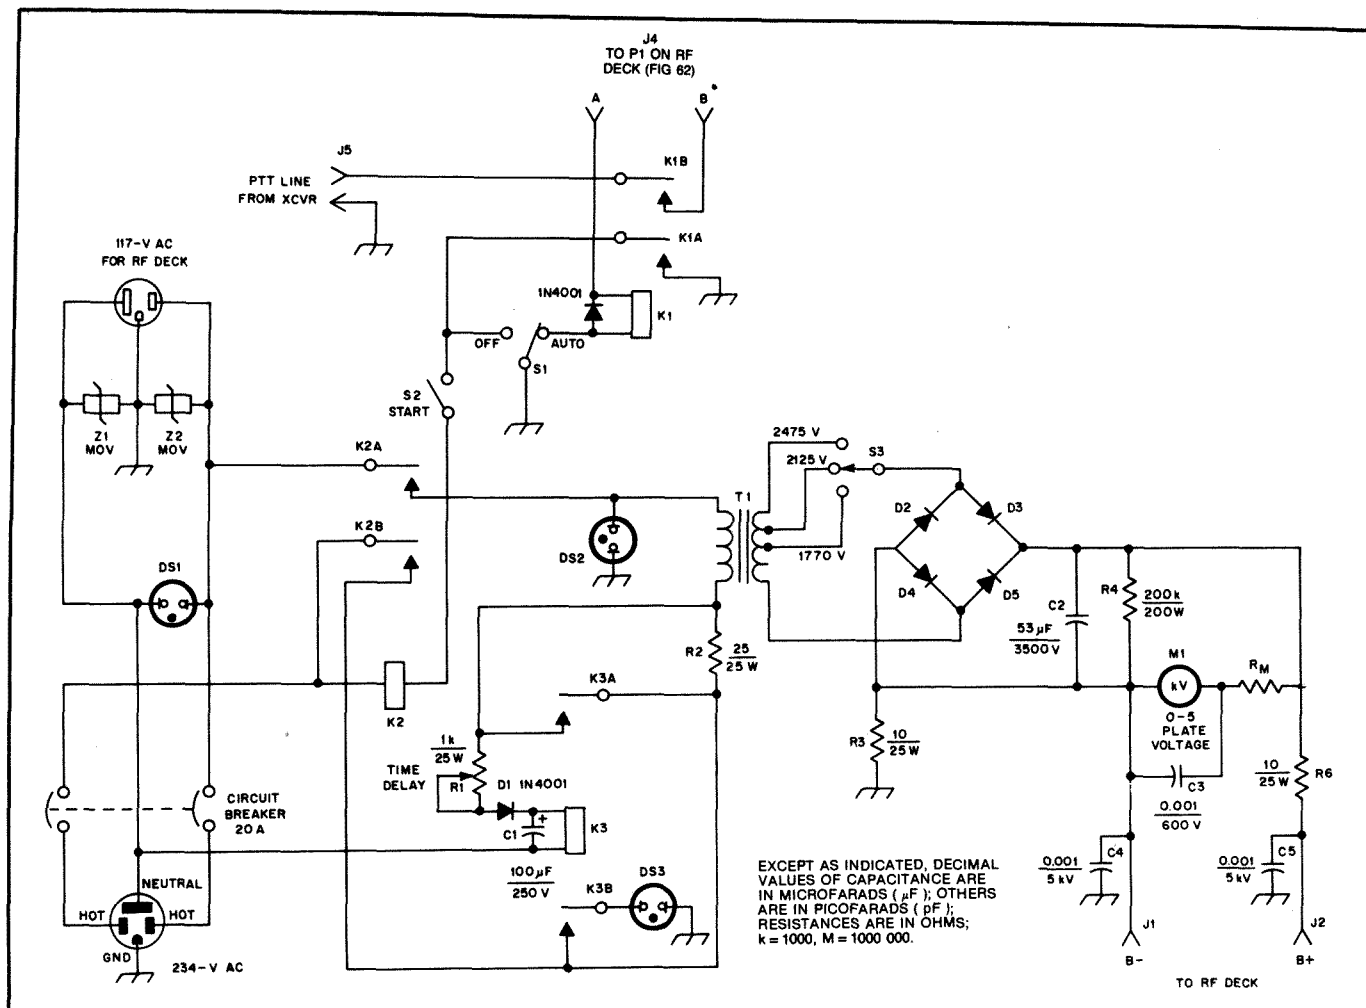

Fig. 59 — Schematic diagram of the high-voltage power supply. Capacitors are disc ceramic unless noted. Possible parts sources are listed in parentheses. See Chapter 35 for the addresses of the parts suppliers.

C2 — Oil-filled capacitor, 53  $\mu\text{F}$ , 3.5 kV (Electronic Emporium cat. no. 4W308T or equiv.).  
 D2-D5 — Rectifier, 14 kV, 1 A (K2AW's Silicon Alley HV-14 or equiv.).  
 DS1-DS5 — Neon pilot lamp, 120 V, with built-in dropping resistor (Radio Shack).  
 J1, J2 — High-voltage connector (Millen 37001 or equiv.).  
 J3 — Chassis-mount three-wire 117-V ac socket.  
 J4 — Two-conductor Jones socket.  
 J5 — Chassis-mount phono jack.

K1 — 4PDT relay, 24-V dc coil, 2-A contacts. (Potter & Brumfield KH4703-1 or equiv.).  
 K2, K3 — DPST relay, 120-V ac coil, 20-A contacts. (Potter & Brumfield PRD7AYO or equiv.).  
 M1 — 0 to 50  $\mu\text{A}$  meter with suitable multiplier resistor ( $R_M$ ). See text.  
 $R_M$  — Meter multiplier resistor. Exact value will depend on meter movement used. See text and Chapter 35 for information on meter multipliers.

R1 — Adjustable resistor, slider type, 1-k $\Omega$ , 25 W.  
 R4 — 200-k $\Omega$ , 200-W bleeder made from eight 25-k $\Omega$ , 25-W resistors in series (see text).  
 S1 — SPDT switch, 117-V, 3-A contacts.  
 S2 — SPST switch, 117-V, 3-A contacts.  
 S3 — High-voltage switch (see text).  
 T1 — Power transformer; 234-V primary, secondary taps at 1770, 2125 and 2575 V (Peter W. Dahl Co. no. PT-2475 or equiv.).  
 Z1, Z2 — 130-V metal-oxide varistor (Radio Shack).

### RF Deck

The RF deck houses the 8877 and associated RF circuitry as well as the

Fig. 60 — Front panel view of the 8877 amplifier high-voltage supply. It is built on a 12 1/2-inch high rack panel and mounted in a Bud Prestige cabinet. Output voltages of 2.5, 3 and 3.5 kV are switch-selectable from the front panel.

amplifier-control circuit board. This amplifier uses a tuned input circuit and a pi-L output circuit. The filament transformer (T1) and antenna relay (K6) are built in. Cooling is provided by blower B1. Fig. 62 is a schematic diagram of the control circuitry, and Fig. 63 shows the RF circuitry.

### Control Circuits and Metering

The control circuits are somewhat involved and are designed to protect the expensive 8877 tube from excessive fila-

Fig. 61 — Interior of the high-voltage power supply cabinet.

ment inrush current, excessive grid current, and application of drive in the absence of plate voltage. A three-minute delay circuit prevents keying the amplifier until the tube gets up to operating temperature, and another time-delay circuit keeps the blower running for a short while after power is removed.

When S1 of Fig. 62 (POWER) is closed, several things happen. First, 117-V ac is applied through R2 to the primary of filament transformer T1. R2 limits inrush current and is in the line until C2 charges, energizing K2. K2A shorts across R2, applying full primary voltage to T1. K2B lights the FILS LED. Note that T1 has several primary taps to allow adjustment of the filament voltage (measured at the socket) to 5.0 V,  $\pm 0.25$  V, as specified by the tube manufacturer. At the same time filament power is applied, blower B1 starts and time-delay relay K1 starts to heat. K1A does nothing at this time. When power is turned off, however, K1A will stay closed for several minutes to run the blower and cool the tube after filament voltage is removed. K1 does not control the blower

directly, but rather does so through K8, a relay with contacts heavy enough to handle the current needed by the blower motor.

S1 also starts K3, a three-minute time-delay relay. When K3 energizes, the OPERATE LED lights. Finally, S1 applies primary voltage to T2 of the 24-V dc control-relay supply. When S2, RESET, is closed, 24 V is applied to various points in the control circuit. A 24-V signal is sent through relay contacts K4B and K3A to energize K1 in the high-voltage power supply. K3A also allows 24 V to reach K5, the PTT relay, so that the amplifier may be keyed from the PTT line. Note that since K3A is in the line to the HV-supply control relay and the PTT relay, the HV supply cannot be turned on and the PTT line cannot be keyed until after the three-minute warmup period.

The transceiver PTT control connects to the HV power supply, and K1B in the power supply activates K5 in the RF deck to prevent keying the amplifier in the absence of B+. K5A applies operating bias to the 8877, and K5B operates the antenna TR re-

lays (K6, K7). K6 has a slight time delay, provided by C5. This feature assures that K7 will close before K6 to prevent hot switching.

Protection from excessive grid current is provided by Q1 and associated components. When the grid current exceeds a certain amount (set to approximately 70 mA by R5), Q1 fires and operates K4. K4C lights the TRIP LED. K4B opens, shutting off the HV supply and opening the PTT circuitry to protect the tube. To reset the amplifier, switch S2 off and then on again and everything will restart automatically. S2 can also be used to place the amplifier in standby if operation with the transceiver only is desired.

M1 and M2 of Fig. 63 monitor grid current and plate current. Plate current is monitored in the B- lead, rather than in the B+ lead, for safety. A pair of back-to-back diodes and 0.01- $\mu$ F capacitors protect the meters from transients and RF voltages.

#### Input Circuitry

The RF input appears at J1 of Fig. 63. If the amplifier is turned off or bypassed by S2 of the control circuit, the input signal is routed directly to the output connector, J2. When the amplifier is in operation, the input signal goes to the tuned input circuitry and then to the 8877 cathode. Although the 8877 input impedance is close to 50 ohms and RF drive could be connected directly to the 8877 cathode, the tuned input is used for improved linearity and lower drive requirements.

There is a separate pi network (C1, L1, C2) for each band. S1 selects the appropriate network for the band in use. The input networks were designed with a Q of approximately 2 to be broadly resonant on each band. For clarity, only one pi network is shown in Fig. 63. Table 1 presents the complete input network data.

The coil (L1) for each band is wound on a 3/8-inch slug-tuned form. The slugs were purchased from a surplus dealer, but any 3/8-inch slug-tuned form with a red core should work. Table 1 gives both calculated capacitor values and the real-world values used in this amplifier.

#### Output Circuitry

B+ enters the RF deck through J3 and is routed through RFC2 and RFC3. The B+ line is bypassed by C8 and C9. C7 is a dc blocking capacitor that keeps dc voltages out of the tank circuit and off the feed

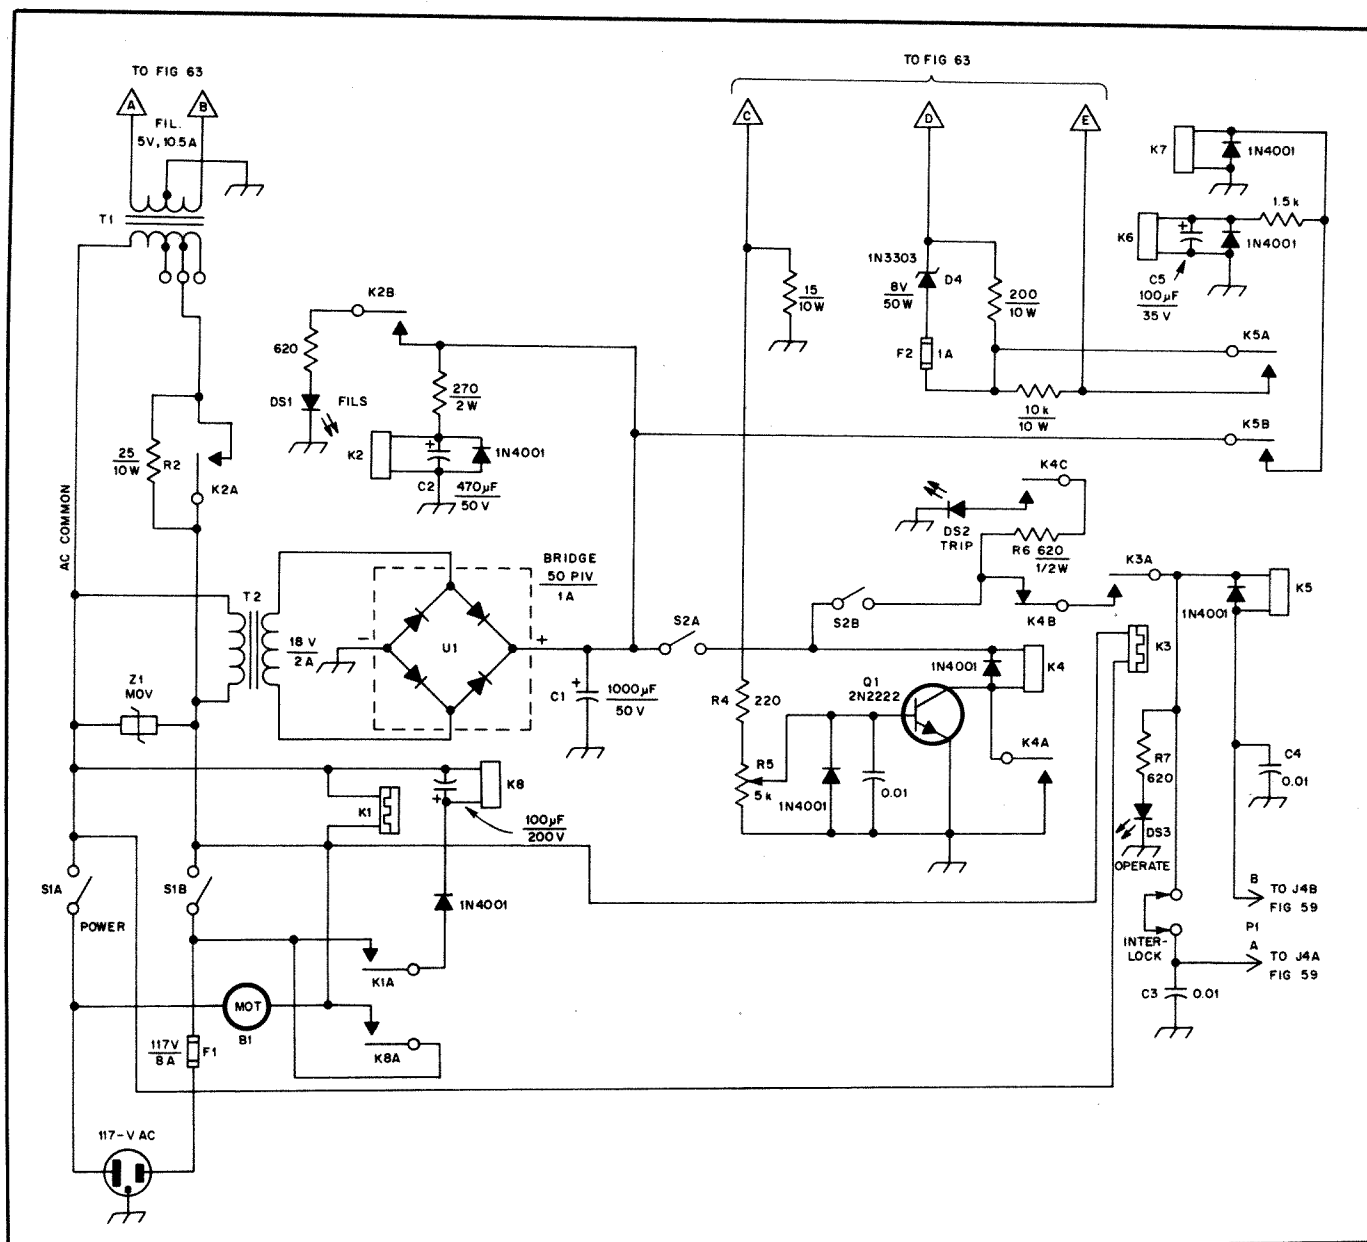

Fig. 62 — Schematic diagram of the 8877 amplifier control circuitry. Resistors are  $\frac{1}{4}$ -W types unless noted. Capacitors are disc-ceramic types unless noted. Capacitors marked with polarity are electrolytic. See Chapter 35 for the addresses of the parts suppliers.

B1—Blower, 54 CFM (Dayton 4C012A or equiv.).

DS1-DS3—LED.

D4—Stud-mount Zener diode, 8 V, 50 W (1N3303 or equiv.).

K1—Time-delay relay with a 2-3 minute delay on release, 115-V ac coil (Amperite 115NO69 or equiv.).

K2—DPDT relay, 12-V dc coil with 120-V, 10-A contacts (Radio Shack).

K3—Time-delay relay with a 3-minute delay on operate, 115-V ac coil (Amperite 115NO180 or equiv.).

K4, K5—4PDT relay, 24-V dc coil with 2-A contacts (Potter & Brumfield KH4703-1 or equiv.).

K6, K7—Dow Key Model 60 coaxial antenna relays with 24-V dc coils.

K8—DPDT relay, 120-V ac coil with 125-V ac, 10-A contacts (Radio Shack).

T1—Filament transformer. Primary: 120-V with taps for  $\pm 4\%$  and  $\pm 8\%$ ; secondary: 5 V, 10.5 A (Avatar Magnetics AV-454 or equiv.).

P1—Two-conductor Jones plug to match J4 in the HV power supply (Fig. 59).

T2—Power transformer. Primary: 117-V; secondary: 18 V, 2 A.

U1—Bridge rectifier module, 50 PIV, 1 A (Radio Shack).

Z1—130-V metal-oxide varistor (Radio Shack).

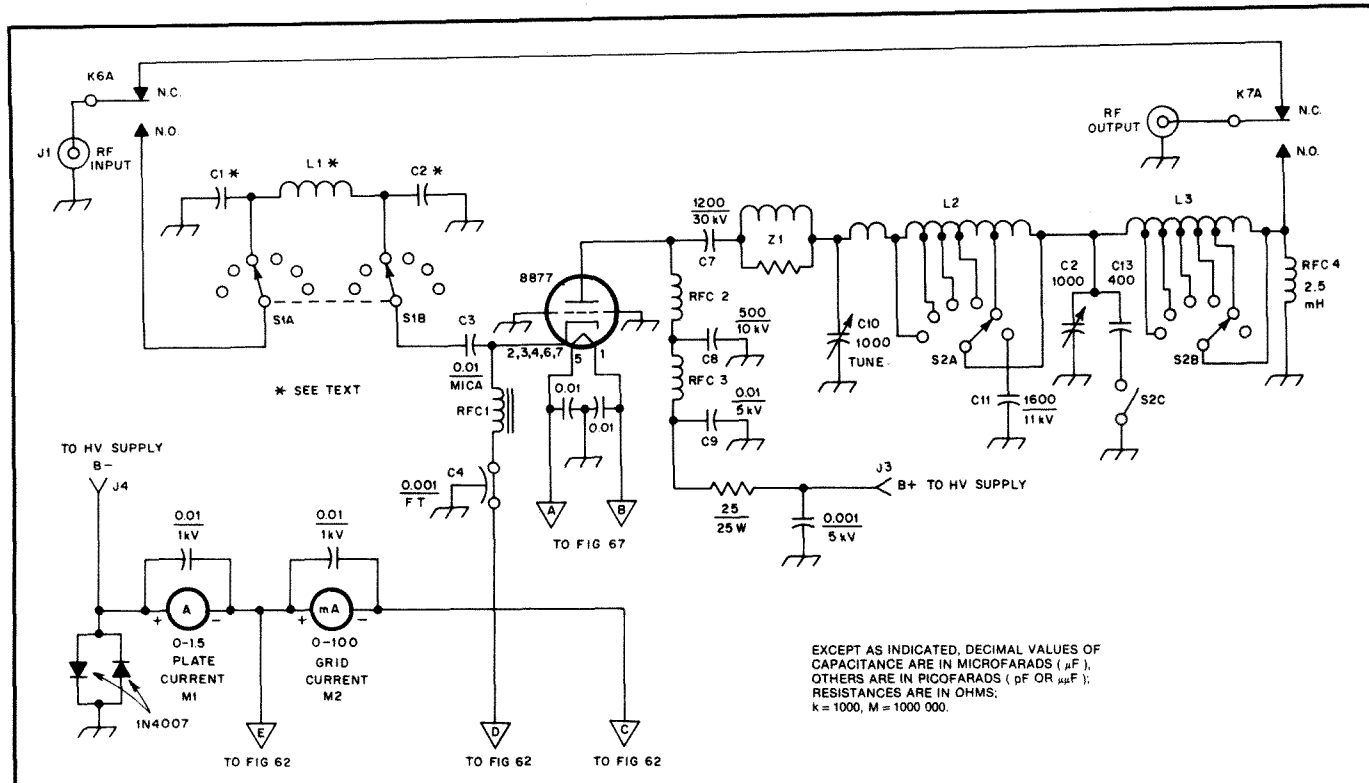

Fig. 63 — Schematic diagram of the 8877 amplifier RF deck. Resistors are  $\frac{1}{4}$ -W types unless noted. Capacitors are disc-ceramic types unless noted. Capacitors marked with polarity are electrolytic. See Chapter 35 for the addresses of the parts suppliers.

- C1, C2—See Table 1.  
 C7—1200-pF, 30-kV RF-type doorknob capacitor (Electronic Emporium).  
 C10—1000-pF, 5-kV vacuum variable capacitor (Jennings UCSL 1000-5 or equiv.).  
 C11—Two 800-pF, 5-kV doorknob capacitors in parallel.  
 C12—1000-pF, 1.5-kV air variable (Cardwell 154-30 or equiv., avail. from RadioKit).  
 C13—400-pF, 5-kV doorknob capacitor.  
 J1, J2—Female UHF connector (in this case, part of K6 and K7).

- J3, J4—High-voltage connector (Millen 37001 or equiv.).  
 K6, K7—See Fig. 62.  
 L1—See Table 1.  
 L2, L3—See Fig. 64.  
 RFC1—50  $\mu$ H; 39T no. 24 enam. wire close wound on a  $\frac{1}{4}$ -inch powdered iron core.  
 RFC2—No. 24 enam. close wound on a 1-inch Teflon form. The form is 5 inches long; the winding is 4 inches long. Measured inductance is 195  $\mu$ H.  
 RFC3—8.2  $\mu$ H (Ohmite Z50 or equiv.).  
 RFC4—2.5 mH (Millen 4537 or equiv.).

- S1—Single wafer, 2-pole, 6-position ceramic rotary switch with indexing to match S2.  
 S2—Six position, two section, high-power ceramic RF switch with non-shorting contacts and 60-degree indexing (Model 86, avail. from Radio Switch Corp., Rt. 79, Marlboro, NJ 07746). Section S2C is a homemade addition. See Fig. 68.  
 Z1—Parasitic suppressor. Made from 2T of  $\frac{1}{2}$ -inch wide copper strap,  $\frac{1}{2}$ -inch ID. Shunt the strap with two 100- $\Omega$ , 2-W carbon-composition resistors in parallel.

Table 1  
Input Coil Data

Band	L1 ( $\mu$ H) (Calculated)	L1 Winding Information <sup>†</sup>	C14, C15 (pF) (Calculated)	C14, C15 (pF) (Values Used)

10	0.30	4T no. 20	100	100

<sup>†</sup>All coils wound on 3/8-in-diameter form; slug-tuned with red core. Available from Electronic Emporium, part number PLS5-B-2.

C12 (LOAD), a 1000-pF air variable, does not have enough capacitance for operation on 160 and 80 meters. A spare contact on S2A switches C11 into the circuit for 160-meter operation, while S2C switches C13 into the circuit for 80-meter operation.

L2 is made from a section of  $\frac{1}{4}$ -inch copper tubing for 10 meters and a section of B&W Pi Dux stock for the other bands. The L coil, L3, is also made from a small section of Pi Dux stock. S2 switches the taps for use on the various bands. Fig. 64 is a detailed diagram of the tank coil connections.

### Construction

The completed RF deck is shown in Figs. 65 and 66. The main support for the components is a standard 4- $\times$ 17- $\times$ 10-inch (HWD) chassis (Bud AC-427). Like the power supply, the chassis is mounted

line and antenna. Should C22 short, placing dangerous voltage on the output connector, RFC4 will short the B+ line to ground and blow the power-supply circuit breaker.

This amplifier uses a pi-L tank circuit for better suppression of harmonic energy. To get a better Q and improved efficiency on 10 and 160 meters, a 1000-pF vacuum-variable capacitor was chosen for C10 (TUNE).

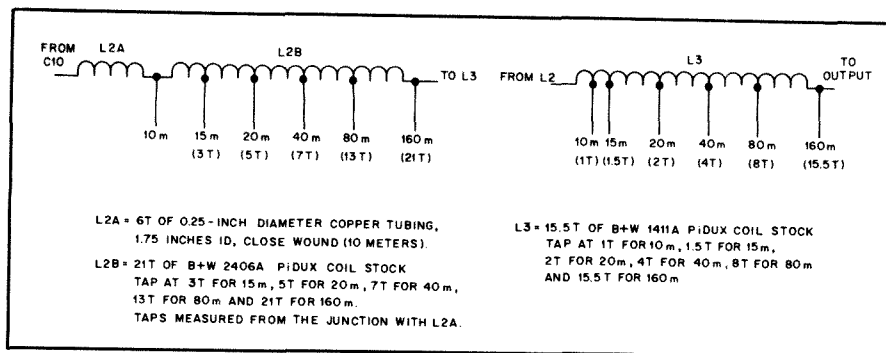

Fig. 64 — Details of the pi-L coils, L2 and L3 of Fig. 63.

Fig. 65 — Underside of the 8877 amplifier chassis.

to a 19-inch-wide, 12½-inch-high rack panel. For RF shielding, sidewalls 4¾ inches high are mounted to the chassis with aluminum angle stock. A top cover bolts to aluminum angle stock that is connected to the sidewalls. Similar aluminum-sheet-and-angle-stock construction is used to enclose the tube socket underneath the chassis.

A separate enclosure that is bolted to the amplifier top cover houses the input circuitry. This enclosure is positioned so that its band switch is directly above the main band switch in the output network. A simple chain drive from the main band switch makes both input and output switches turn in unison from a single front-panel control. The sprockets (part no. RCS-12) and chain

(RCX-25) are available from Small Parts, Inc. See the parts suppliers list in Chapter 35. Align the chain drive with both switches in the 10-meter position. Leave some slack in the chain to allow the detents in both switches to function effectively.

The underside of the chassis is shown in Fig. 65. A single circuit board in the lower half of the photo contains the bias and control circuitry. The antenna relays are mounted to the rear chassis wall, to the right of the control circuitry. The filament and control circuit transformers are mounted at the top left of the photo, near the front panel, and the tube socket is to the right of the transformers. A Dayton blower pressurizes the enclosed cathode compartment, and air exits through the tube anode cooler. A Teflon chimney directs the exhaust air.

The tube socket is homemade from a Johnson 247 ceramic socket and miscellaneous hardware. Complete details for fabrication of this socket are shown earlier in this chapter, associated with a 160-meter 8877 amplifier. The recommended EIMAC socket is part number SK-2200.

The relative positions of the output-network components is shown in Fig. 66. The tuning capacitor is mounted close to the tube, and the loading capacitor is on the other side of the chassis. Both of these capacitors use Groth turns-counter dials with vernier drives for smooth tuning. These drives were purchased from Robert H. Bauman Sales, P.O. Box 122, Itasca, IL 60143.

The band switch is in the center of the chassis. S2C, to switch in additional loading capacitance for 80 meters, is a home-made addition to the band switch. It consists of two Barker and Williamson high-power switch contacts (available from B&W or RadioKit — see Chapter 35) and a wafer made from a piece of double-sided PC-board material. See Fig. 68. S2C is attached to the main band switch shaft.

The pi coil, L2, may be seen to the left of the 8877. The two coil pieces are supported by a rectangular piece of glass-epoxy circuit board material with all copper removed. The coil assembly is mounted above the chassis with ceramic standoffs. The L coil is mounted with a similar arrangement to the left of the band switch and perpendicular to the pi coil. The two coils must be mounted at right angles to prevent undesired coupling. All plate circuit connections are made with copper straps.

In this amplifier, it was necessary to provide a ½-inch wide ground strap between the tuning and loading capacitors to prevent ground-loop currents. Connect the frame of the loading capacitor to the lead-screw mechanism of the vacuum variable. Do not ground this strap to the chassis.

Fig. 66 — Interior of the 8877 amplifier RF deck. The input compartment, which was attached to the top cover, has been removed. The chain-drive sprocket on the main band-switch shaft is visible between the chassis and the front panel.

### Tuneup and Operation

Check the high-voltage power supply for proper operation before connecting it to the RF deck. Check all circuit paths in the B +

supply and RF deck for possible short circuits. Verify the operation of all control circuitry with the high-voltage off and with the tube removed from the socket. If every-

thing works, apply power to the filament transformer, blower and control circuitry, and measure the filament voltage at the tube socket. If all is well, remove power from the RF deck and install the covers. Connect the high-voltage supply. Connect an exciter capable of delivering about 100 W to the input through a wattmeter and connect the amplifier output to a suitable dummy load through a second wattmeter.

Place the power-supply switches in AUTOMATIC and START. Close the RESET switch on the RF deck and turn the POWER switch on. The blower will start and filament power will be applied. The FILS lamp will light. After three minutes, K3 will close and the high-voltage supply will turn on. Press the transceiver PTT switch. M2 should indicate about 150 mA resting plate current.

Apply about 10 to 20 W of drive and adjust the TUNE and LOAD controls until the grid-current meter reads about 70 mA. Adjust R5 until the grid-trip circuit functions. Reset the circuit and verify that the grid-trip circuit functions at about 70 to 80 mA.

Apply about 10-W drive and adjust the slugs of the coils in the input pi networks for lowest SWR at the center of each band. Adjust the TUNE and LOAD controls for maximum output. Tuning of a pi-L circuit is similar to that for a conventional pi circuit, except that the setting of the LOAD capacitor is much more critical. Gradually increase drive until the power output reaches 1500 W. Recheck the input SWR on each band with the amplifier running at full output.

Table 2 shows the operating parameters for this amplifier as measured in the ARRL lab. Fig. 67 shows the exceptionally clean spectral output from the pi-L network.

Table 2

### 8877 Amplifier Operating Characteristics

Band	Power Output (W)	Plate Voltage (V)	Plate Current (mA)	Grid Current (mA)	Drive Power (W)	Input SWR
160	1500	2700	1000	30	65	1.1:1
80	1500	2800	900	35	65	1.2:1
40	1500	2800	900	40	65	1.1:1
20	1500	2800	1000	40	65	1.2:1
15	1500	2800	1000	45	65	1.2:1
12	1500	2800	1000	50	65	1.5:1
10	1500	2800	980	50	65	1.4:1

Fig. 67 — Worst-case spectral photograph of the 8877 amplifier. Power output is 1500 W on 3.5 MHz. Each vertical division is 10 dB, and each horizontal division is 1 MHz. All harmonics and spurious emissions are at least 54 dB down. This amplifier complies with current FCC spectral-purity requirements.

The aluminum piece that mates the switch wafer to the band-switch shaft is shown at B. At C, the entire switch is assembled on a Plexiglas sheet.

# A 160- to 10-Meter Amplifier Using the 3CX1200A7

Billed as a replacement for the glass 3-1000Z, the EIMAC 3CX1200A7 metal/-ceramic triode is the basis of the 160- to 10-meter amplifier described here and shown in Figs 69 through 78. The amplifier will produce 1500 W output for about 100 W drive, making it a natural companion for today's solid-state transceivers. Dick Stevens, W1QWJ, designed and built this project.

The 3CX1200A7 requires a higher plate voltage than other ceramic transmitting tubes. In this case, the design is for 3500 V at full load. The amplifier will, however, still produce 1000 W output with 2500 V on the plate. A high-voltage power supply design is not included with this writeup. This amplifier was used with the power supply described earlier in this chapter along with a 160- to 10-meter 8877 amplifier. The high-voltage supply was modified slightly for use with this amplifier: C1 is increased to 200  $\mu$ F, and R1 is changed to 1.5 k $\Omega$  to allow a longer charging time for C2. Another suitable high-voltage power supply design appears in Chapter 27.

A large volume of air is required to adequately cool the 3CX1200A7. Use of

Fig 69—The 3CX1200A7 160- to 10-meter amplifier is built behind a standard 19 x 10½-inch rack panel. Vernier drives are used to control the loading and tuning capacitors. The top meter can be switched to read plate voltage, grid current, forward power and reflected power. (The meter switch is above the LOAD and PLATE dial drives.) The bottom meter is dedicated to plate current. An external low-pass filter is mounted on the left side of the chassis.

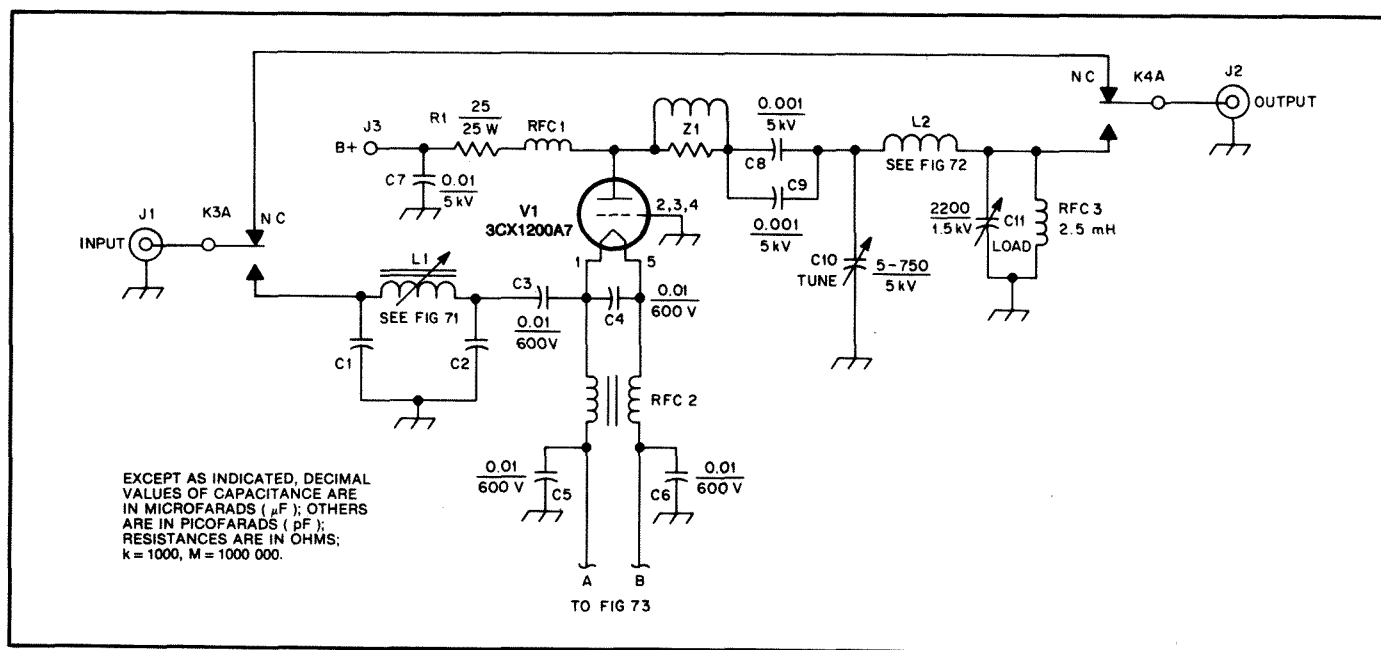

Fig 70—Schematic diagram of the 3CX1200A7 amplifier RF deck. Details of the input and plate-tank circuits are shown in Figs 71 and 72.

- L1—Input pi-network tunable coil. See Fig 71 for details.
- L2—Plate-tank coil. See Fig 72 for details.
- RFC1—90- $\mu$ H, 1-A RF choke (Hammond 1521 or equiv).

- RFC2—Bifilar wound 30-A filament choke, 28 bifilar turns no. 10 enam wire on a ½-in. diam x 7½-in. long ferrite core (Peter W. Dahl Co.).
- RFC3—2.5 mH RF choke (Millen 4537 or equiv).
- Z1—Parasitic suppressor, four 220- $\Omega$ , 2-W metal-film resistors in parallel, mounted on a 5-inch long, ½-inch wide copper strap bent in a U shape.

Fig 71—Details of the 3CX1200A7 amplifier input circuit. Component values are shown for  $Q = 4$  and  $Q = 2$ . The amplifier was built using the values for  $Q = 4$  (see text).

C1, C2—500-V silver-mica capacitors. See table for values.

L1—The coils for each band are wound on JW Miller 42A000CBI tunable ceramic coil forms (3/8-inch diam with red core). The number of turns required for each band:

10 meters—4 turns no. 22 wire spaced to occupy 3/8 in.

15 meters—6 turns no. 22 wire spaced to occupy 1/2 in.

20 meters—7 turns no. 22 wire spaced to occupy 1/2 in.

40 meters—9 turns no. 22 wire spaced to occupy 1/2 in.

80 meters—11 turns no. 22 wire close wound.

160 meters—20 turns no. 24 wire close wound.

S1—Double wafer, 6-position ceramic rotary switch with 60° indexing to match plate-tank bandswitch S2 (Centralab 2551 or equiv).

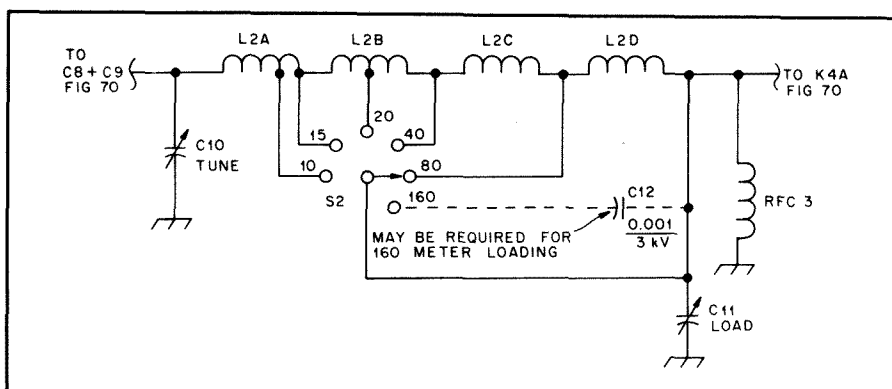

Fig 72—Details of the plate-tank circuit for the 3CX1200A7 amplifier. See Fig 70 for the rest of the circuit.

C10, C11—See Fig 70.

L2A—5 turns of 1/4-inch diam copper tubing, 2 1/4 inches ID, 2 1/2 inches long. See text. Tap at 4 turns for 10 meters. Tap at junction of L2A and L2B for 15 meters.

L2B—6 1/4 turns of B&W 2404T coil stock. Tap at 3 turns for 20 meters. Tap at junction of L2B and L2C for 40 meters.

L2C—6 1/2 turns of B&W 2406T coil stock. Tap at junction of L2C and L2D for 80 meters.

L2D—10 turns of B&W 2408T coil stock. For 160 meters, use L2A, L2B, L2C and L2D.

RFC3—See Fig 70.

S2—Six position, one section, high-power ceramic RF rotary switch with nonshorting contacts and 60° indexing (Radio Switch Corp Model 86 or equiv).

the proper EIMAC air system socket (part no. SK410) and chimney (part no. SK436) is essential. The blower is a Dayton 4C440, rated at 60 CFM.

This project makes extensive use of parts purchased at flea markets and from surplus dealers. Although most components could be purchased new (at considerable expense), there are many good parts available surplus. The builder is encouraged to modify the design shown here when possible to make use of whatever surplus parts are available.

### RF Circuits

Fig 70 is a schematic of the amplifier RF circuitry. For clarity, some details of the input and output circuits are omitted—these details are shown in Figs 71 and 72.

Details of the tuned input circuit are shown in Fig 71. Individual pi networks are used for each band. A tunable coil and two fixed capacitors are used for each band.

These circuits are designed for a  $Q$  of 4, based on EIMAC's recommendation. Tubes requiring high values of grid drive require a higher  $Q$  than the usual 2 to prevent flattopping. Tuning of the input circuits is sharp, but if they are adjusted for an SWR of 1:1 at the center of each band, the SWR at the band edges is less than 1.5:1.

Unfortunately, you won't be able to "fudge" the 10-meter input circuit to reach 12 meters—the  $Q$  is too high. Component values are given for input networks with a  $Q$  of 2 for those builders wishing to reach 12 meters.

The amplifier plate tank circuit is a standard pi network with a calculated  $Q$  of 10. Details are shown in Fig 72. Use of a vacuum variable (C10) for the tuning capacitor makes it easy to get a reasonable  $Q$  at 160 and 10 meters. The 3CX1200A7 has a high internal capacitance: tube capacitance and stray circuit capacitance

are almost enough to resonate the plate circuit at 10 meters. The minimum capacitance of an air variable suitable for tuning on 160 meters is too great to allow a reasonable  $Q$  on 10 meters. So, the vacuum variable, with its low minimum capacitance, is ideal for this application. An air-variable capacitor (C11) is used for loading. As shown in Fig 72, an additional 1000-pF fixed capacitor (C12) may be switched in if more loading range is needed for 160 meters.

The location of RFC1 differs from many other designs. Normally, the plate RF choke is connected to the junction of the parasitic suppressor (Z1) and plate blocking capacitor (C8 and C9). In this case, a low-frequency parasitic was noticed during testing, and moving RFC1 to the position shown corrected this problem.

Switches for the input (S1) and output (S2) circuits are connected by a chain drive so only one front-panel bandswitch control is needed. S1 and S2 *must* have the same indexing. All of the parts necessary for making the chain drive arrangement are available from Small Parts, Inc (see Chapter 35).

### Metering and Control Circuits

Control and metering circuits are shown in Figs 73 through 75. Circuitry is included to prevent amplifier operation without plate voltage, and filament inrush protection is also provided. No ALC arrangement is used because modern transceivers will not overdrive the amplifier. Metering includes grid current, plate current, plate voltage and forward and reverse power.

Refer to Fig 73. Closing S1 starts the blower and lights DS1. Closing S2 applies 120 V to T2 through R3, the inrush-current-limiting resistor. Simultaneously, C1 charges through R2, and after a second or so K1 operates and contacts K1A short out R3, applying full primary voltage to T2. K1B contacts cause DS2 to light, showing that the filament inrush protection has functioned. Closing S2 also applies 120 V

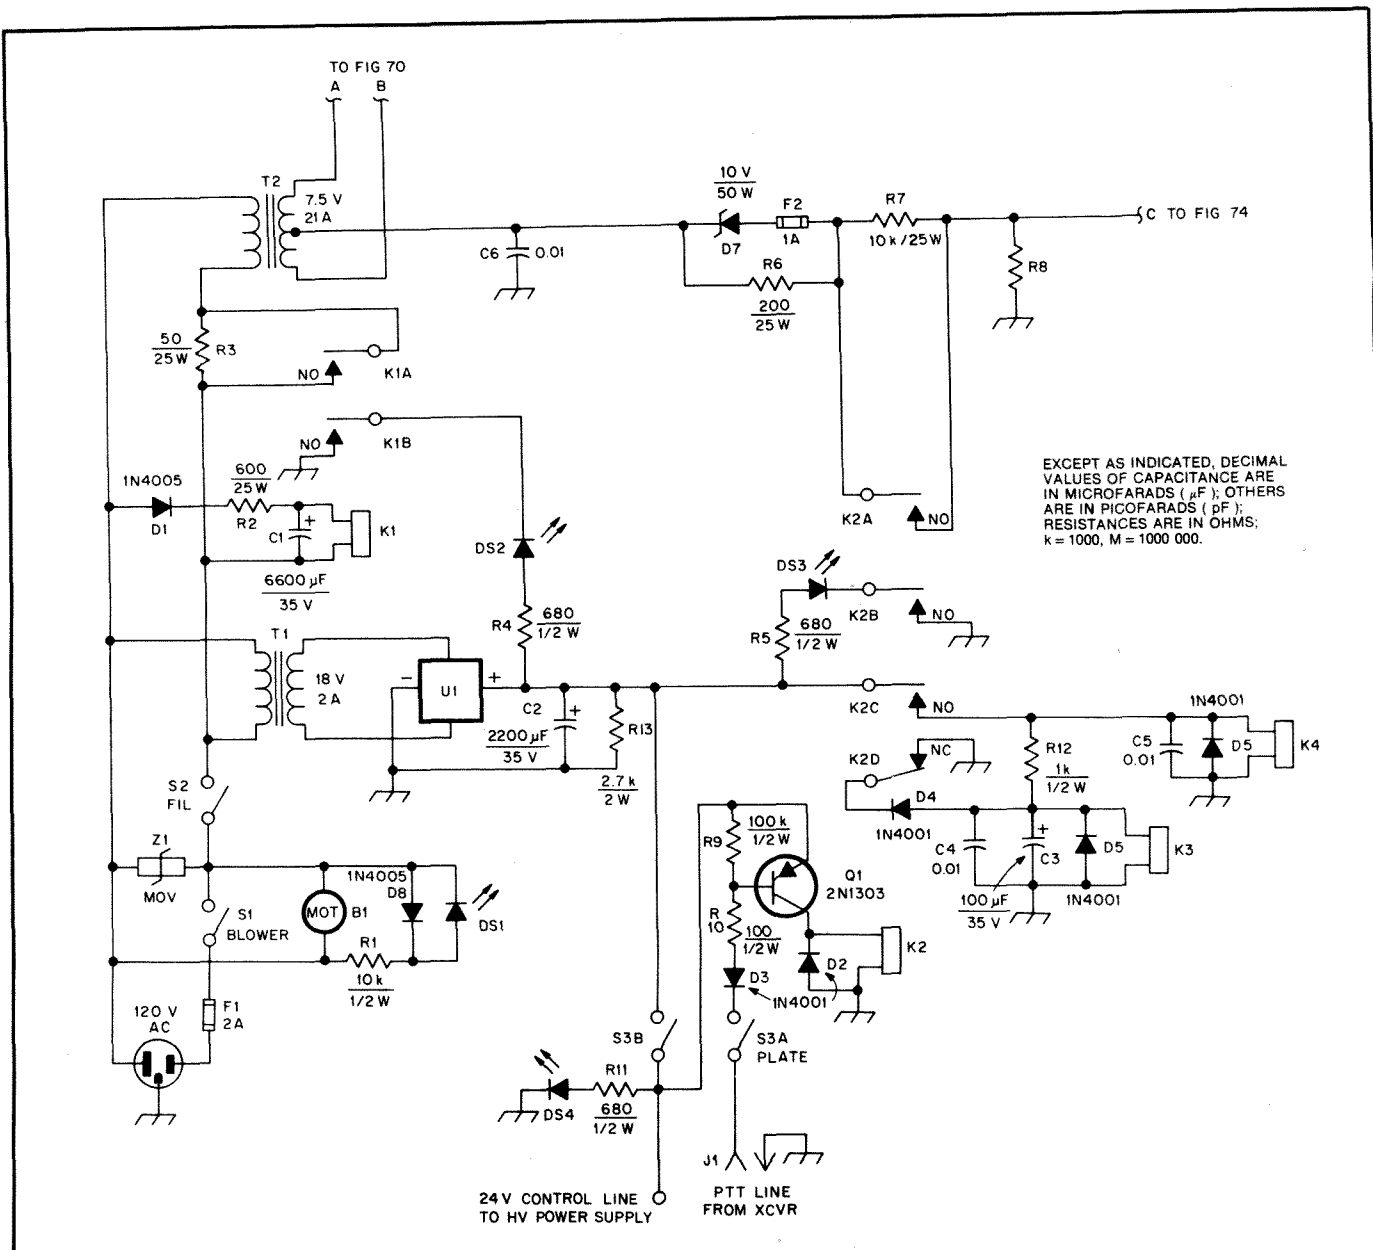

Fig 73—Details of the control circuitry for the 3CX1200A7 amplifier. Capacitors are disc-ceramic, 50-V types unless noted. Capacitors marked with polarity are electrolytic.

B1—60 CFM blower (Dayton 4C440 or equiv).  
C1—6600-μF, 35-V electrolytic made from two 3300-μF, 35-V capacitors in parallel.

D2-D6—50-PIV, 1-A diode (1N4001).  
D7—10-V, 50-W Zener diode (1N2808 or equiv).  
DS1-DS4—LED.  
J1—Phono jack.  
K1—DPDT relay with 10-A contacts and 12-V

dc coil.  
K2—4PDT relay with 3-A contacts and 24-V dc coil.  
K3—RF input relay (see Fig 70). SPST relay with 3-A contacts and 24-V dc coil.  
K4—Antenna relay (see Fig 70). SPST relay with 10-A contacts and 24-V dc coil. Dow-Key antenna relay preferred; must be able to handle 1.5 kW of RF.  
R8—Grid-current meter shunt. Value depends

on meter movement used. See text.  
S1, S2—SPST switch.  
S3—DPDT switch.  
T1—Control circuit transformer. Primary, 120 V; secondary, 18 V at 2 A.  
T2—Filament transformer. Primary, 120 V; secondary, 7.5 V at 21 A (Peter W. Dahl Co).  
U1—100-PIV, 1.5-A bridge rectifier.  
Z1—130-V metal-oxide varistor.

to T1. T1 and related components supply 24 V dc for other control circuits.

Closing S3 sends 24 V dc to the high-voltage power supply. The high-voltage supply is activated by a 24-V dc relay in the primary. DS3 lights when S3 is closed. You may choose a different method of activating the high-voltage supply, depending on your individual needs.

Q1 is the amplifier keying transistor. Many modern transceivers have amplifier keying circuits with insufficient current

and/or voltage ratings to close a relay coil. They can, however, key Q1 which in turn keys the relays in the amplifier. When Q1 conducts, K2 operates and completes several functions. K2A shorts out R7, which changes the tube bias from cutoff to operating bias. DS3 lights to show that the tube is ready to operate. K2C activates K3 and K4, the antenna relays. K4, the output relay, closes immediately. There is a slight delay in the closure of K3, caused by R12 and C3, to prevent hot switching K4.

When the amplifier is unkeyed to return to receive, K2D discharges C3 so that there is no additional delay as K3 returns to the receive position.

Operating bias is provided by D7. F2 protects the grid from excessive current. R8 is a grid milliammeter shunt. Its exact value depends on the meter used.

This amplifier includes metering for plate current, grid current, plate voltage, forward power and reverse power. See Fig 74. M2 is a dedicated plate-current meter. M1

Fig 76—Top view of the 3CX1200A7 amplifier with the cover removed. The blower, at the right rear, is bolted to the input chassis that runs along the rear of the amplifier assembly. The filament transformer is mounted in front of the blower, on the chassis that holds the control circuits. K1 and K2 are mounted in sockets to the right of the filament transformer. The wattmeter adjustment potentiometers (R5 and R6, Fig 75) are mounted on a bracket on the side of the plate-circuit enclosure near the filament transformer. The plate-current meter and multimeter are mounted on the front panel (lower right corner of photo), and the multimeter rotary switch is mounted to the front panel in front of the plate-circuit enclosure. The 3CX1200A7 is mounted on the input-circuit chassis at the right rear of the plate circuit enclosure. High-voltage wiring and bypass capacitors, and the RF choke, are to the left of the tube. The Minibox in the left rear corner of the plate-circuit compartment houses K4, the output relay. The vacuum-variable tuning capacitor is mounted at the right front of the plate compartment, and the loading capacitor is at the left front. The plate-coil assembly and plate-circuit bandswitch (under the plate coil) are mounted between the two capacitors.

Fig 77—Bottom view of the 3CX1200A7 amplifier with the covers removed. The amplifier chassis assembly consists of three parts: (1) the input chassis (left side of photo) runs the entire width of the amplifier; (2) the control circuit chassis (lower right); and (3) the plate compartment (upper right) built on an aluminum sheet. The tuned input circuits are visible in the input chassis, above the tube socket. The pi networks are built on an unetched piece of circuit board material, with the coil adjustment shafts protruding through the rear panel. The input bandswitch is mounted to the opposite chassis wall, with its shaft protruding into the plate-circuit compartment. Below the tube socket is the filament choke. A small circuit board bolted to the rear wall to the left of the tube socket holds the input relay and associated components. In the control-circuit chassis, most components are mounted on terminal strips. K1 and K2 are mounted in sockets in the lower center of the chassis. Q1 and associated parts are mounted on a small circuit board in the lower right corner.

the coil. The finished coil is 5 turns, spaced 2½ inches.

A 2-7/8 × 8¼-inch piece of ¼-inch-thick Plexiglas® serves as the main plate-tank coil support. Drill a mounting hole in each corner of the Plexiglas sheet, ¼ inch in from the ends. Drill two holes for the 10-meter coil 1-5/8 inch in from one end. Mount the 10-meter coil above the Plexiglas sheet on 3/8-inch spacers.

Next, cut three pieces of B&W coil stock. You'll need 6¼ turns of 2404T, 6½ turns of 2406T and 10 turns of 2408T. Slide the 2404T onto the Plexiglas support, followed by the 2406T and then the 2408T. Using a thin piece of brass shim stock, connect one end of the 2404T to one of the mounting screws for the 10-meter coil. Using more shim stock to make a good mechanical bond, splice the other end of the 2404T to the 2406T, and the 2406T to the 2408T. Solder all connections. The free end of the 2408T goes to the loading capacitor.

The output-circuit shield is made of sheet aluminum and angle stock. The top has a screened hole for hot air exhaust.

K4, the output antenna relay, is in the Minibox mounted to the inside rear wall of the output compartment, directly behind the loading capacitor. The wattmeter RF-sensing circuitry is inside the Minibox mounted on the outside of the back panel, near the tube.

#### Problem Areas

During original tests, the amplifier operated very poorly above 20 meters. It had severe LF and VHF parasitics, and none of the common cures worked. By accident, it was found that the case of the filament transformer was hot with RF energy, and in fact an arc could be drawn from the transformer mounting bolts. An NE2 neon lamp, mounted on an insulated rod and placed near the tube or filament transformer, glowed bright purple. (Normally,

Table 1

#### Typical Operating Conditions for the 3CX1200A7 Amplifier

Plate Voltage	3500 V
Plate Current	800 mA
Grid Current	180 mA
Power Output	1500 W
Drive Power	100 W
Input SWR	<1.5:1

the neon lamp glows orange in the presence of HF energy. If it glows purple, VHF energy is present.) Removing the filament transformer from the shielded plate compartment cured the VHF parasitic problem, but there was still a trace of a low-frequency parasitic. Moving the plate RF choke (RFC1) to the position shown in Fig 70 cured this problem.

#### Tune-Up

Check the high-voltage supply for proper operation before connecting it to the RF deck. Check all circuit paths in the power supply and RF deck for possible short circuits. Verify the operation of all control circuits with the high-voltage off and with the tube removed from the socket. When everything works, place the tube in the circuit and apply power to the blower, filament transformer and control circuitry. Measure the filament voltage at the tube socket; it should be 7.5 V. If all is well, remove power from the RF deck and install the covers. Connect the high-voltage supply. Connect an exciter capable of delivering about 100 W to the input through a wattmeter and connect the amplifier output to a suitable dummy load through a second wattmeter.

Close the the BLOWER and FILS switches. The blower will start and filament power will be applied. The BLOWER and FILS lamps will light. Close the PLATE switch,

Fig 78—Spectral photograph of the 3CX1200A7 amplifier operating through the low-pass filter. Power output is 1500 W at 14 MHz. Each horizontal division is 10 MHz; each vertical division is 10 dB. All harmonics and spurious emissions are at least 56 dB below peak output.

and the high-voltage will come on. Plate voltage should register with M1 in the E<sub>p</sub> position. Press the transceiver PTT switch. M2 should indicate about 150 mA resting plate current.

Apply about 10-W drive and adjust the slugs of the coils in the input pi networks for lowest SWR at the center of each band. Adjust the TUNE and LOAD controls for maximum output. Gradually increase drive until the power output reaches 1500 W. With 3500 V on the plate, grid current should be about 200 mA, and plate current should be about 800 mA. Recheck the input SWR on each band with the amplifier running at full output.

Table 1 shows the operating parameters for this amplifier. Although it has no problem meeting FCC specifications for spectral purity, a B&W low-pass filter is bolted to the side of the plate-tank compartment for added harmonic suppression. Fig 78 shows the spectral output of the amplifier with the low-pass filter.

## Chapter 31

# VHF Radio Equipment

The bands at 50, 144 and 220 MHz each contain more spectrum space than the total of *all* bands below 50 MHz! Little wonder that the VHF bands are popular favorites with many hams.

This chapter contains projects for the VHFer. In it you will find preamplifiers and converters for receiving. You will also find transmitting converters and transverters (used for transmitting and receiving). Most hams will be interested in the

RF power amplifiers. Perhaps you will find what you are looking for.

For a discussion of RF amplifier theory see Chapter 15. Transmitter and receiver theory is covered in Chapters 11 and 12.

## Dual-Gate MOSFET Preamplifiers for 28, 50, 144 and 220 MHz

The performance of many older receivers can be improved with a simple preamplifier in the front end. The simple design shown in Figs. 1 through 5 uses a dual-gate MOSFET to provide about 20-dB gain with associated noise figures of 1 to 1.5 dB on 28, 50, 144 and 220 MHz. They can be used for weak-signal or satellite work, and they can help put some life into an older 144- or 220-MHz FM transceiver. This is a simple, stable design. When built with a 3SK48, 3SK51 or 3N204, it will hold its own with all but the best GaAsFET designs. Kent Britain, WA5VJB, designed and built these preamplifiers.

### Circuit Details

The basic circuit for the 28- and 50-MHz designs is shown in Fig. 1. Fig. 2 shows the 144- and 220-MHz versions. Q1 is a VHF dual-gate MOSFET. Many devices will work in this circuit. The author has successfully used the following devices (listed in order of preference): 3SK48, 3SK51, 3N204, 3SK40, 3N211. L1 and C1 tune the input. C6 and L2 tune the output of the 144- and 220-MHz versions. The 28- and 50-MHz preamplifiers use an untuned resistive output. R1 and R2 provide gate-2 bias.

### Construction

The preamps shown here were built

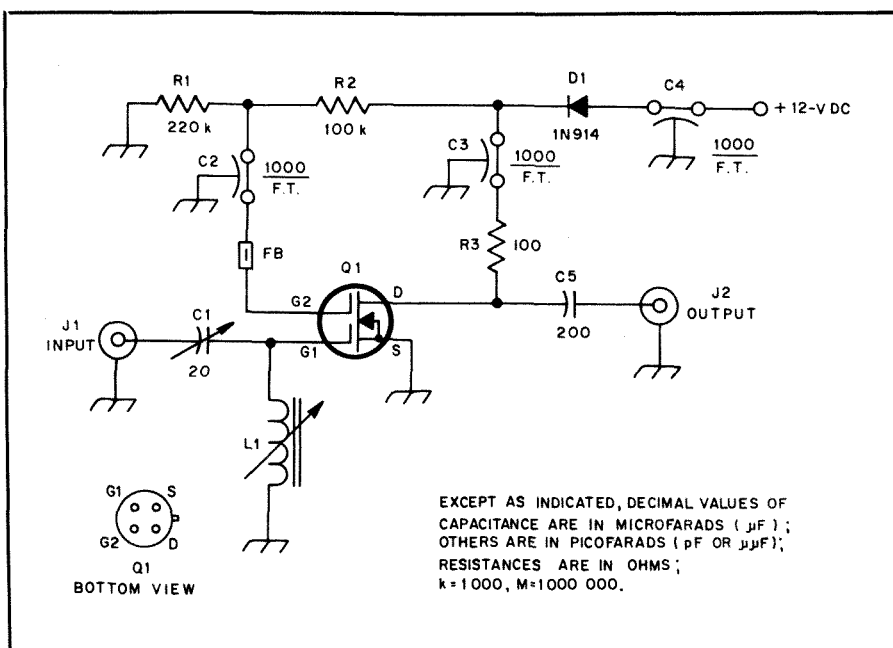

Fig. 1 — Schematic diagram of the 28- and 50-MHz dual-gate MOSFET preamplifiers. Resistors are  $\frac{1}{4}$ -W carbon types.

C1 — Ceramic or piston trimmer capacitor, 20- to 25-pF max.  
C2, C3 — 500- to 1000-pF feedthrough capacitor, solder-in type preferred.  
C4 — 500- to 1000-pF feedthrough capacitor.  
C5 — 100- to 200-pF silver-mica or ceramic capacitor.

J1, J2 — Female chassis-mount RF connectors, BNC preferred.

L1 — 28 MHz: 23t no. 24 enam. on  $\frac{1}{4}$ -inch slug-tuned coil form. 50 MHz: Same, but 10t.

Q1 — Dual-gate MOSFET such as 3SK51 or 3N204. See text.

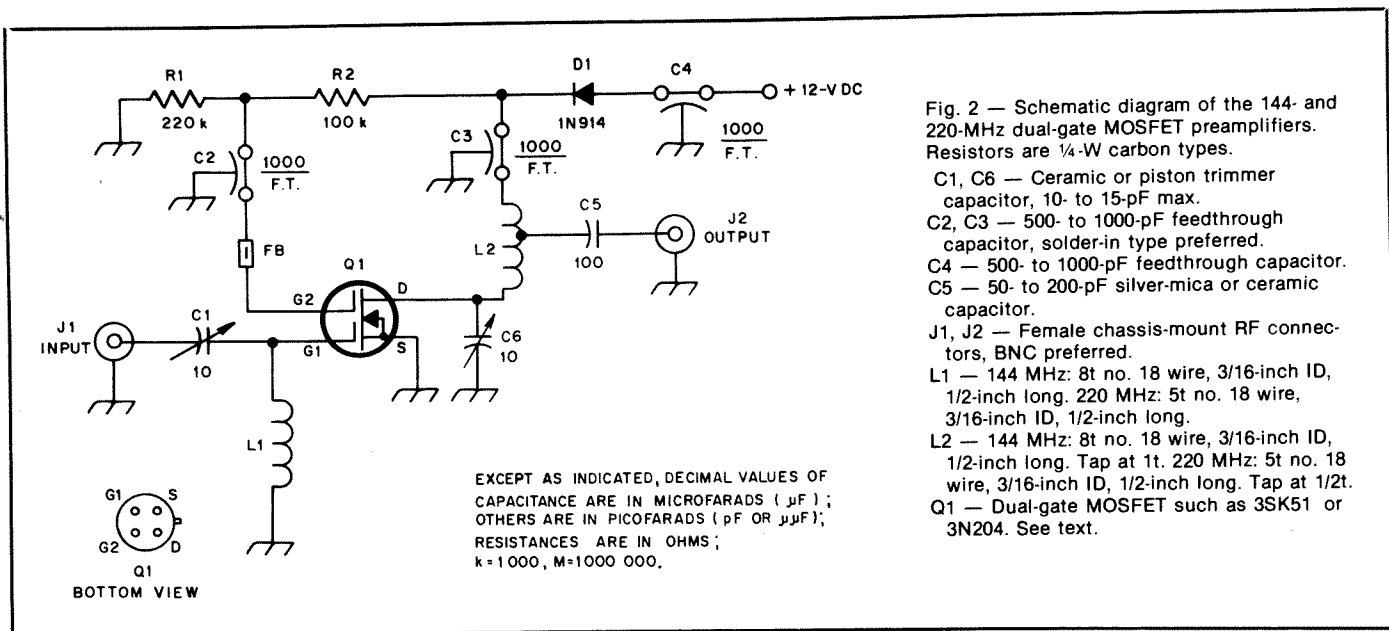

Fig. 3 — RF component side of the board of a 2-meter version of the dual-gate MOSFET preamplifier.

Fig. 4 — Another view of the 2-meter MOSFET preamp showing the dc components mounted on the other side of the board.

“dead bug” style on a piece of unetched double-sided circuit-board material. The foil acts as a ground plane, and all ground connections are made directly to it. The finished preamp fits inside a small Minibox. See Figs. 3 and 4. Fig. 5 shows the general layout. Dc components, including C4, D1, R1 and R2 mount on one side of the board. Voltage is fed to the transistor through C2 and C3. Parts placement is not at all critical. Solder the case of Q1 to the ground plane.

Parts for this project are available from many of the suppliers listed in Chapter 35. One source for 3SK51 transistors is Fuji-Svea, P.O. Box 3375, Torrance, CA 90510.

Adjustment is easy. Simply tune in a weak signal and adjust C1 and L1 (28- and 50-MHz models) or C1 and C6 (144- and 220-MHz models) for best signal-to-noise ratio.

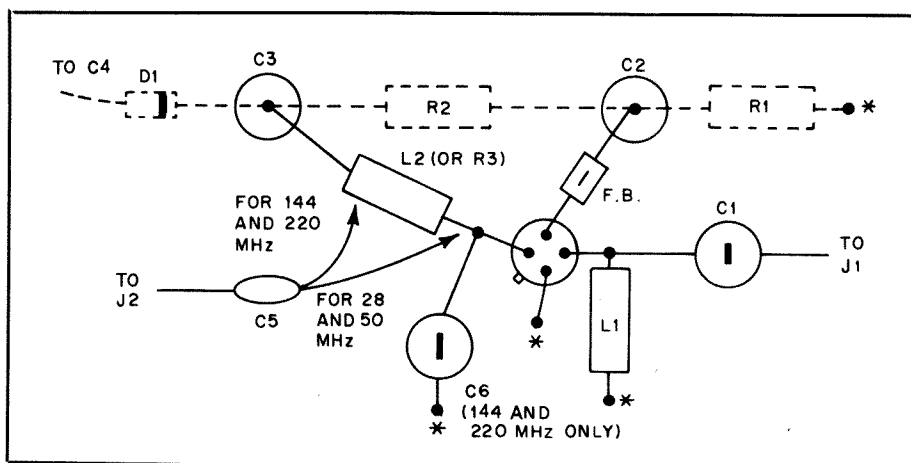

Fig. 5 — Suggested board layout for the MOSFET preamplifier. There are slight differences between the 28- and 50-MHz versions and the 144- and 220-MHz units. See text. Parts outlined with dashed lines are mounted on the back of the board. Component numbers refer to Figs. 1 and 2.

# Dual-Gate GaAsFET Preamplifiers for 28, 50, 144 and 220 MHz

Dual-gate GaAsFET devices offer builders the opportunity to experiment with the latest technology — low-noise GaAsFETs — for a modest investment. The preamplifiers described here use GaAsFETs that cost less than \$5 each, yet the preamplifiers offer noise figures well under 1 dB with gains ranging from 20 to 24 dB. Kent Britain, WA5VJB, designed and built the preamplifiers shown in Figs. 6 through 10.

## Circuit Details

The basic circuit for the 28- and 50-MHz designs is shown in Fig. 6. Fig. 7 shows the 144- and 220-MHz versions. Q1 is a dual-gate GaAsFET. Many devices will work in this circuit, including the NEC NE41137, Motorola MRF966/967 and Mitsubishi MGF1100. Parts values are given for all of these devices so the builder can use whatever transistor is easiest to find. L1, C1 and C2 tune the input. C5 and L2 tune the output of the 144- and 220-MHz versions. The 28- and 50-MHz preamplifiers use an untuned resistive output. R1 and R2 provide gate-2 bias.

Variable capacitors can be miniature ceramic trimmer capacitors or piston trimmers. The exact value is not critical; any trimmer with a maximum value around that specified will do. C7, the output coupling capacitor, can be any small silver-mica around the specified value. For

Table 1

L1 and L2 Values for 144- and 220-MHz Dual-Gate GaAsFET Preamplifiers

Device	L1		L2	
	144 MHz	220 MHz	144 MHz	220 MHz
NE41137	7t	5t	7t, tap at 2t	5t, tap at 1½t
3SK97 and MGF1100	5t	3½t	7t, tap at 2t	5t, tap at 1½t
MRF966/967	12t	8t	8t, tap at 2t	5t, tap at 1½t

Note: All coils are no. 20 to 24 wire, 3/16-inch ID, spaced one wire dia.

stability, it is important to use good-quality capacitors for the gate 2 and source bypasses. Ceramic chip or leadless disc-ceramic types are necessary to provide a low-impedance ground.

## Construction

The dual-gate GaAsFET preamplifiers are built "dead bug" style on a piece of double-sided PC board material. See Figs. 8 and 9. The circuit board acts as a low-impedance ground plane, and all ground connections are made directly to it. J1, J2 and C9 also secure the circuit board to the lid of the enclosure. The enclosure can be any aluminum diecast box (Bud CU-124; Hammond 1490B) or Mini-box (Bud CU-3002A) approximately 4 by 2 inches, or you can make one by soldering pieces of circuit board material together.

Q1 is supported above the ground plane

by its gate 2 and source leads, which are soldered directly to C3 and C4. The other ends of these capacitors are soldered to the ground plane. R4 should be soldered in place with essentially no lead length. Placement for the rest of the parts is not critical, but keep the leads short. A layout that has proven successful is shown in Fig. 10.

GaAsFETs are static-sensitive, so handle them accordingly. See Chapter 24 for information on working with static-sensitive devices. It's best to assemble the rest of the circuit and install Q1 last. Use a grounded iron if possible, and solder the leads quickly.

Parts for this project are available from Microwave Components of Michigan and Applied Invention, both listed in Chapter 35. NEC transistors are available from California Eastern Laboratories, 3260 Jay St., Santa Clara, CA 95050.

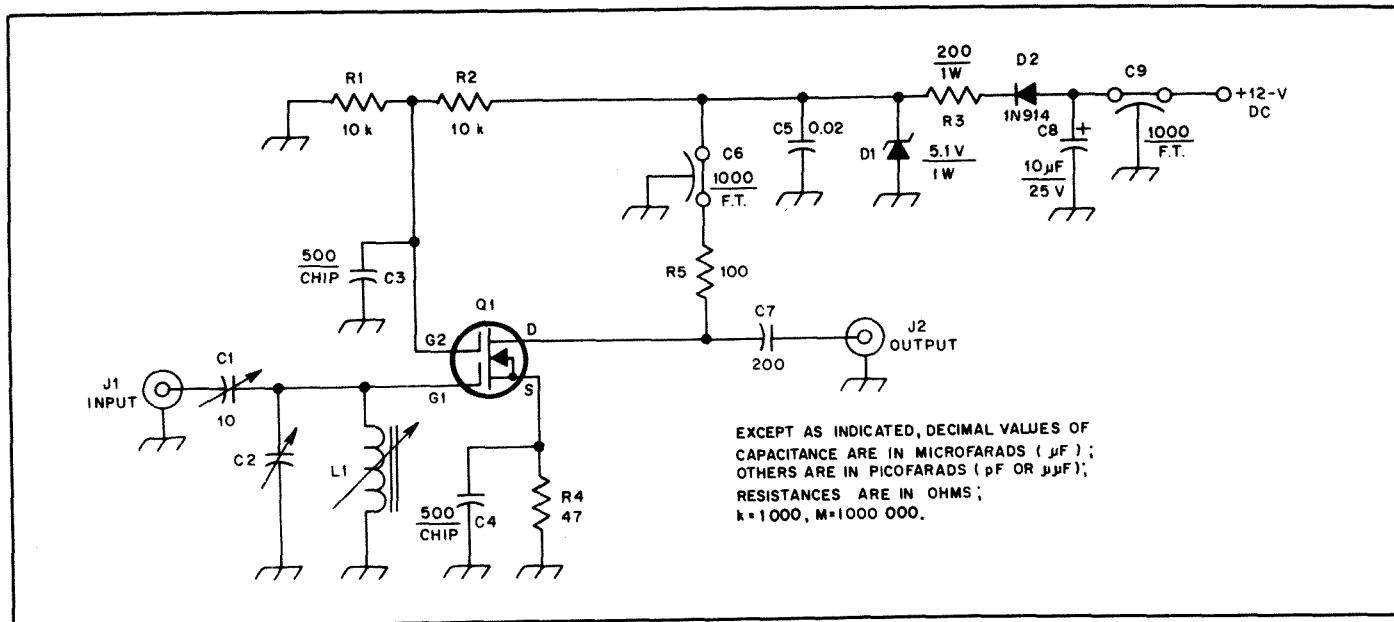

Fig. 6 — Schematic diagram of the 28- and 50-MHz dual-gate GaAsFET preamplifiers. Resistors are ¼-W carbon types unless noted.

C1 — Ceramic or piston trimmer capacitor, 10-pF max.

C2 — Ceramic or piston trimmer capacitor, 20- to 25-pF max.

C3, C4 — 200- to 1000-pF chip capacitor.

C6, C10 — 500- to 1000-pF feedthrough capacitor, solder-in type preferred.

C7 — 200- to 500-pF silver-mica or disc-ceramic capacitor.

C8 — 5- to 25-µF electrolytic capacitor.

C9 — 500- to 1000-pF feedthrough capacitor.

D1 — 5.1-V, 1-W Zener diode (1N4733 or equiv.).

D2 — 1N914, 1N4148 or any diode with ratings

of 25 PIV and 50 mA or greater.

J1, J2 — Female-chassis mount RF connectors, BNC preferred.

L1 — 28 MHz: 13t no. 24 enam. on ¼-inch slug-tuned coil form. 50 MHz: Same, but 9t.

Q1 — Dual-gate GaAsFET, NEC NE41137, Mitsubishi MGF1100 or 3SK97.

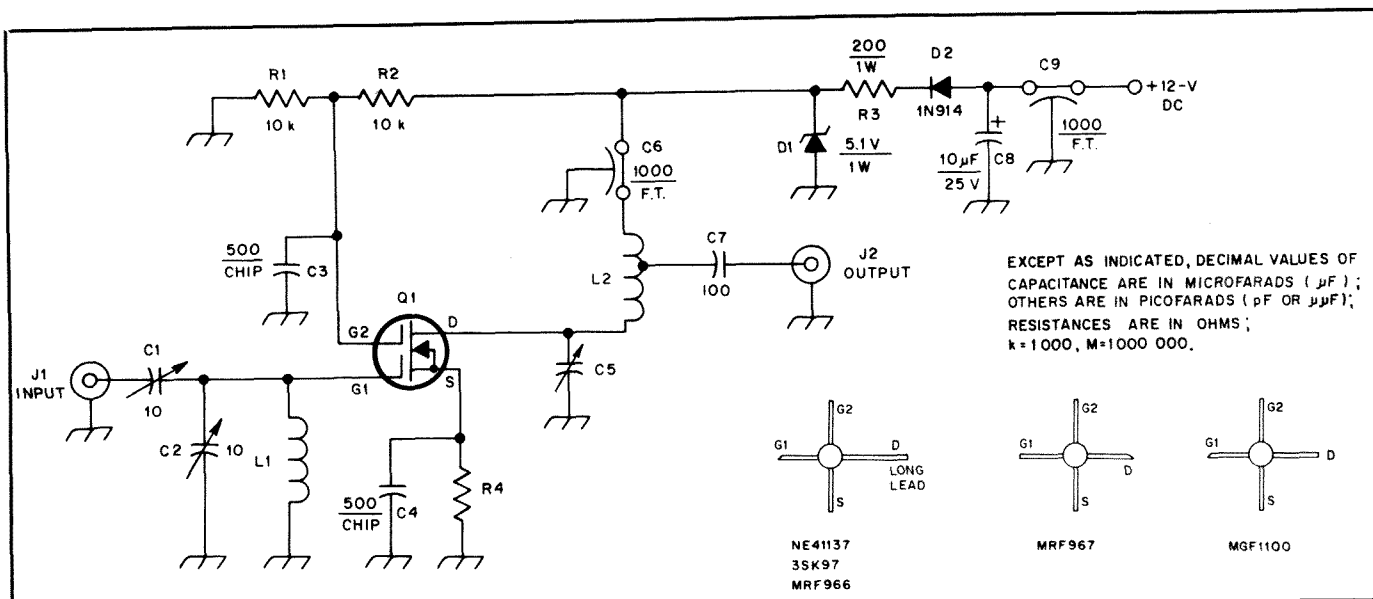

Fig. 7 — Schematic diagram of the 144- and 220-MHz dual-gate GaAsFET preamplifiers. The same circuit is used for all versions, but some parts values are different. See Table 1. Resistors are  $\frac{1}{4}$ -W carbon-composition types unless otherwise noted.

C1, C2 — 10-pF (max.) ceramic or piston trimmer capacitor.  
C3, C4 — 200- to 1000-pF ceramic chip capacitor or leadless disc-ceramic capacitor.  
C5 — For 144 MHz: 20 pF trimmer capacitor.  
For 220 MHz: 10-pF trimmer capacitor.  
C6, C9 — 400- to 1000-pF feedthrough capacitor.  
C7 — 50- to 100-pF silver-mica capacitor.

C8 — 1- to 25- $\mu\text{F}$ , 25-V electrolytic capacitor.  
D1 — 5.1-V, 1-W Zener diode (1N4733 or equiv.)  
D2 — 1N914, 1N4148 or any diode with ratings of 25 PIV and 50 mA or greater.  
J1, J2 — Female chassis-mount BNC or Type-N connector.  
L1 — See Table 1.  
L2 — See Table 1.

Q1 — NEC NE41137, Motorola MRF966/967, Mitsubishi MGF 1100 or 3SK97 dual-gate GaAsFET. See text.  
R1 — For NE41137, MGF1100, 3SK97: 10 k $\Omega$ ; for MRF966/967: 4.7 k $\Omega$ .  
R2 — 10 k $\Omega$  for all devices.  
R3 — 150- to 250-ohm, 1- or 2-W resistor.  
R4 — For NE41137, MGF1100, 3SK97: 47  $\Omega$ ; for MRF966/967: 100  $\Omega$ .

Fig. 8 — This version of the 50-MHz dual-gate GaAsFET preamplifier is built in a small diecast box. Construction of the 28-MHz preamp is identical. A suggested parts placement is shown in Fig. 10.

Fig. 9 — This 144-MHz dual-gate GaAsFET preamp uses an NE41137 and is built on the lid of an aluminum diecast box. The 220-MHz version is similar. See Fig. 10 for a suggested parts placement.

Fig. 10 — Suggested board layout for the dual-gate GaAsFET preamplifier. There are slight differences between the 28- and 50-MHz versions and the 144- and 220-MHz units. See text. Component numbers refer to Figs. 6 and 7.

# GaAsFET Preamplifiers for 144 and 220 MHz

GaAsFET devices enable amateurs to build preamplifiers with very low noise figures for terrestrial, satellite and EME work. In addition, GaAsFETs offer superior strong-signal IMD performance — a characteristic that is important on our crowded bands. Described here and shown in Figs. 11 through 13 are preamplifiers for 144 and 220 MHz that use readily available Mitsubishi MGF1402 or MGF1202 devices. Other single-gate GaAsFETs such as the

Dexcel 1500 and 2500 series, or the NEC 700 series, also work well. Gain is typically 20 to 24 dB with noise figures of about 0.5 dB. Kent Britain, WASVJB, designed and built these preamplifiers.

## Circuit Details

Fig. 11 is a schematic diagram of the preamplifier. The circuit is the same for both bands, although some component values are different. L1, C1 and C2 tune

the input. C5 and L2 tune the output. Variable capacitors can be miniature ceramic trimmer capacitors or piston trimmers; piston types are recommended. The exact value is not critical; any trimmer with a maximum value around that specified will do. C6, the output coupling capacitor, can be any small silver-mica around the specified value. For stability, it is important to use good-quality capacitors for the source bypasses. Note that there are two

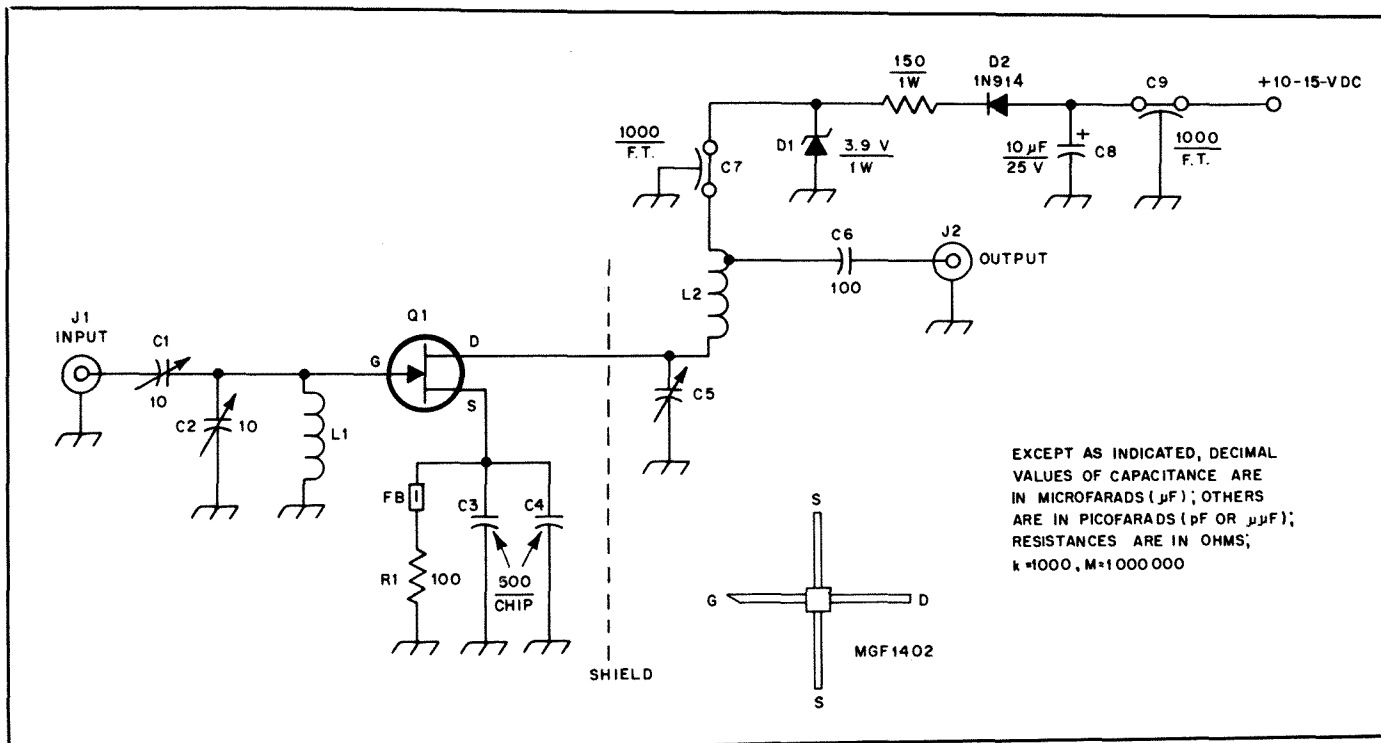

Fig. 11 — Schematic diagram of the 144- and 220-MHz MGF1402 GaAsFET preamplifiers.

C1, C2 — 10-pF (max.) ceramic or piston trimmer capacitor (piston trimmer preferred).  
C3, C4 — 200- to 1000-pF ceramic chip capacitor or leadless disc-ceramic capacitor.  
C5 — For 144 MHz: 20 pF trimmer capacitor. For 220 MHz: 10-pF trimmer capacitor (piston trimmer preferred).  
C6 — 100- to 200-pF silver-mica capacitor.  
C7, C9 — 400- to 1000-pF feedthrough capacitor.

C8 — 1- to 25- $\mu\text{F}$ , 25-V electrolytic capacitor.  
D1 — 3.9-V, 1-W Zener diode (1N4730 or equiv.).  
D2 — 1N914, 1N4148 or any diode with ratings of 25 PIV and 50 mA or greater.  
J1, J2 — Female chassis-mount BNC or Type-N connector.  
L1 — For 144 MHz: 9t no. 20 wire, 3/16-inch ID, spaced 1 wire dia. For 220 MHz: same as

144 MHz, but 6t.  
L2 — For 144 MHz: 6t no. 20 wire, 3/16-inch ID, spaced 1 wire dia. Tap at 1½t. For 220 MHz: 4t no. 20 wire, 3/16-inch ID, spaced 1 wire dia. Tap at 1t.  
Q1 — Mitsubishi MGF1402 GaAsFET. Others usable (see text).  
R1 — 100- $\Omega$ , 1/4- or 1/8-W resistor.  
R2 — 150- to 250-ohm, 1- or 2-W resistor.

(A)

(B)

Fig. 12 — This 220-MHz GaAsFET preamplifier is built in a Hammond 1590A diecast box. All ground connections are made to the circuit-board ground plane. A suggested parts placement is shown in Fig. 13.

source leads and that each has a bypass capacitor. Ceramic chip or leadless disc-ceramic types are necessary to provide a low-impedance ground.

### Construction

The GaAsFET preamplifiers are built "dead bug" style on a piece of double-sided PC board material. See Fig. 12. The circuit board acts as a low-impedance ground plane, and all ground connections are made directly to it. J1, J2 and C9 also secure the circuit board to the lid of the enclosure. The enclosure can be any aluminum diecast box (Bud CU-124; Hammond 1590B) or Minibox (Bud CU-3002A) approximately 4 by 2 inches, or you can make one by soldering pieces of circuit board material together.

Q1 is mounted to the shield by its source leads, which are soldered directly to C3 and C4. The other ends of these capacitors are soldered to the ground plane. R4 should be soldered in place with essentially no lead length. A layout that has proven successful is shown in Fig. 13. To help prevent L1 and L2 from coupling, wind one coil in the left-hand direction and the other in the right-hand direction.

GaAsFETs are static-sensitive, so handle

Fig. 13 — Suggested board layout for the MGF1402 144- and 220-MHz GaAsFET preamplifier. Component numbers refer to Fig. 11.

them accordingly. See Chapter 24 for information on working with static-sensitive devices. It's best to assemble the rest of the circuit and install Q1 last. Use a grounded iron if possible, and solder the leads quickly.

Parts for this project are available from Microwave Components of Michigan and Applied Invention, both listed in Chapter 35. MGF1402 transistors are available from Advanced Receiver Research, Box 1242, Burlington, CT 06013.

## Remote Preamplifier-Switching System

The preamplifier-switching system described here and shown in Figs. 14 through 16 is intended primarily for EME applications. Serious VHF and UHF operators may wish to consider similar systems for terrestrial work, as a tower-mounted preamplifier usually means a noticeable reduction in system noise figure.

### The Circuit

The relay-switching system is separated into two parts. One section is mounted at the tower, and the other, the control circuitry and power supply, is mounted at the station. A length of four-conductor, TV-type rotator cable can be used to inter-

connect the two units. The package mounted at the tower consists of two RF coaxial relays and a preamplifier. As shown in Fig. 15, K1 is used to switch the antenna between the transmit line and a line that connects K1 with K2. K2 switches the preamplifier to either the antenna or a 50-ohm termination. With the system shown, it is impossible to transmit accidentally into the preamplifier.

K1 must be able to handle the full transmitter power. Relays rated for high power at VHF and UHF include the Dow-Key DK-60 series and the Transco Y and D series. These relays are expensive when purchased new, but they often show up at

Fig. 14 — A preamplifier relay switching system suitable for EME work. The relay box is mounted at the antenna and the control box is located in the station. A length of four-conductor wire connects the two units.

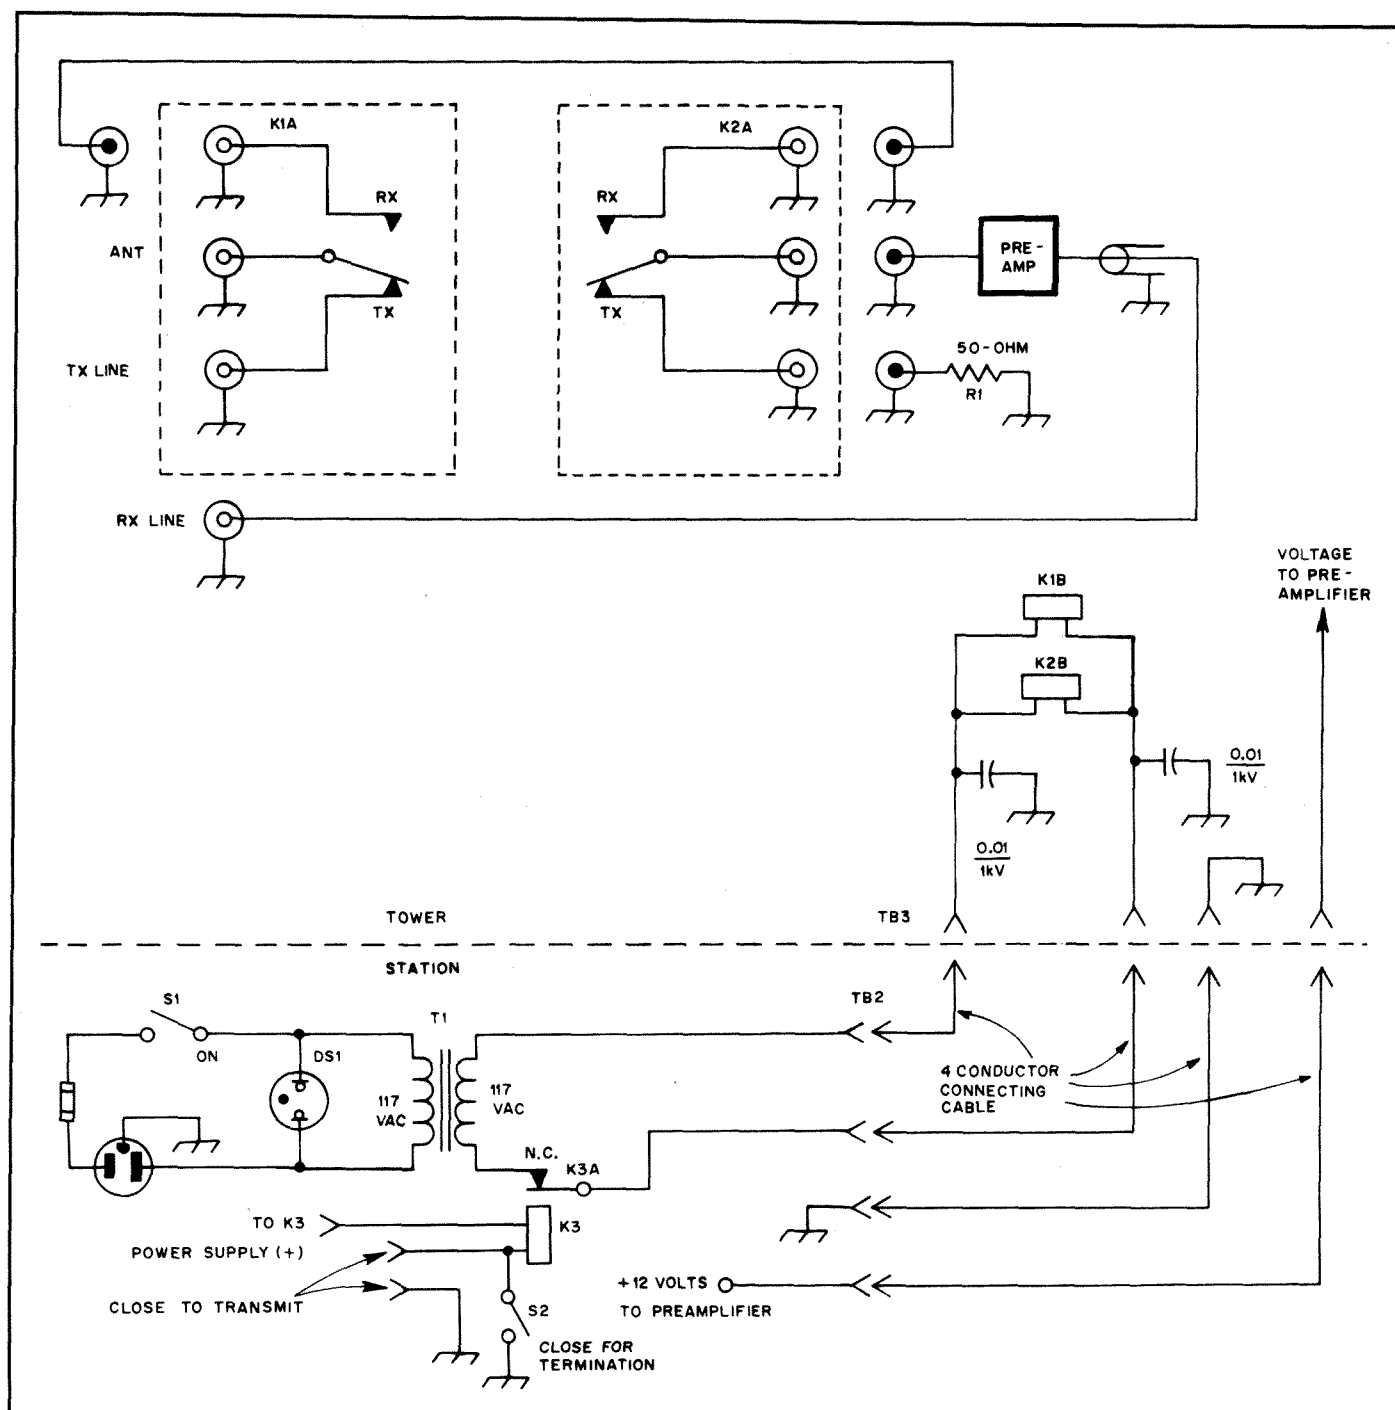

Fig. 15 — Schematic diagram of the preamplifier switching system. The diagram is divided into two parts; the top portion for the circuitry at the antenna and the bottom for use in the station.

DS1 — Neon indicator light with built-in dropping resistor.  
 K1, K2 — RF-coaxial relays suitable for the frequency range to be used.  
 K3 — SPDT relay with contacts to carry

voltage/current needed for coils of K1, K2.  
 R1 — Termination, 50 ohms, noninductive. Resistor built into a PL-259 connector.  
 S1, S2 — Toggle SPST.

T1 — Isolation transformer, 117-V ac primary, 117-V ac secondary, 15 VA, Stancor P-6411 or equiv.  
 TB1-TB3, incl. — Terminal block, screw connection, four terminals.

flea markets. K2 is used only to switch the receive line, so it may be a low-power relay. Typical surplus relays have BNC connectors. The project shown here uses two Dow-Key relays.

Relay isolation is an important consideration. High power levels can leak through the unused relay contacts and damage the receive preamplifier, so the use of two relays helps keep the level of RF that appears at the preamp to a minimum.

Generally, no more than 10 mW or RF should be allowed to reach the preamp input. Use of a 0.1- to 0.25-wavelength section of cable between K1 and K2, instead of the double-male connector shown here, would substantially increase isolation.

The control circuit is set up so that the relays must be energized to receive. This offers two advantages. When the station is not in use, the preamp is terminated in a 50-ohm load rather than the antenna. This

protects the preamp from static charges from nearby lightning strikes. Also, if the tower-mounted preamp or one of the relays should fail, the transmit line would be connected directly to the antenna. Another TR relay can be installed at the station end of the transmit line and operation could continue (although without the benefit of a tower-mounted preamp).

S2 allows the operator to switch the relays without putting the station into

transmit. The preamp input can be switched between the 50-ohm load and the antenna. This allows for sun-noise measurements.

A method of sequencing the relays and the other components is recommended so that the relays are not "hot switched" with RF power applied. A TR sequencer is described elsewhere in this chapter.

The portion of the system mounted at the station is essentially a power supply and control circuitry. A line-isolation transformer is used to power the 117-V relay coils. A pilot light, fuse and ON/OFF switch are provided in this design. Many surplus relays have 26-V dc coils, so a suitable dc power supply will be necessary in some cases.

### Construction

The items to be mounted at the tower are enclosed in an ordinary chassis and bottom plate assembly. Fig. 16 indicates the general layout. Short lead lengths are used throughout. Bulkhead UHF feed-through connectors are used to ensure an RF- and water-tight enclosure. The item shown at the bottom center of the enclosure is a commercial preamplifier. Power for the preamplifier (12-V dc) is fed through the fourth wire of the four-wire cable that connects the two modules (tower and station). When all components are mounted properly, the chassis is sealed with silicone rubber (RTV). A terminal block provides for connection to the four-conductor cable. Two 0.01- $\mu$ F capacitors are mounted across

Fig. 16 — Interior view of the package mounted at the antenna. The object at the bottom center of the chassis is a commercial preamplifier.

the relay coils at terminal block TB3.

The station circuitry is mounted in a small aluminum cabinet. A neon indicator, on/off power and termination switch are

mounted to the front panel. The fuse and interconnection terminal blocks TB1 and TB2 are mounted on the rear apron. Component layout is not at all critical.

# TR Time-Delay Generator

If you've ever blown up your new GaAsFET preamp or hard-to-find coaxial relay, or are just plain worried about it, this transmit/receive (TR) time-delay generator is for you. This little circuit makes it simple to put some reliability into your present station or to get that new VHF or UHF transverter on the air fast, safe and simple. Its primary application is for VHF/UHF transverter, amplifier and antenna switching, but it can be used in any amplifier-antenna scheme. An enable signal to the TR generator will produce sequential output commands to a receive relay, a TR relay, an amplifier and a transverter — automatically. All you do is sit back and work DX! This project, shown in Figs. 17 through 23, was designed and built by Chip Angle, N6CA.

## Why Sequence?

In stations using transverters, extra power amplifiers and external antenna-mounted TR relays, several problems may arise. The block diagram of a typical station is shown in Fig. 17. When the HF exciter is switched into transmit by the PTT or VOX line, it immediately puts out a ground (or in some cases a positive voltage) command for relay control and an RF signal.

If voltage is applied to the transverter, amplifier and antenna relays simultaneously, RF can be applied as the relay contacts bounce. In most cases, RF will be applied before a relay can make full closure. This can easily arc contacts on dc and RF relays and cause permanent damage. In addition, if the TR relay is not fully closed before RF from the power amplifier is applied, excessive RF may leak into the receive side of the relay. The likely result — preamplifier failure!

The TR time-delay generator supplies commands, one after another, going into transmit and going back to receive from transmit, to turn on all station relays in the right order, eliminating the problems just described.

## Circuit Details

Here's how it works. See the schematic diagram in Fig. 19. Assume we're in receive and are going to transmit. A ground command to Q2 (or a positive voltage command to Q1) turns Q2 off. This allows C1 to charge through R1 plus 1.5 kΩ. This rising voltage is applied to all positive (+) inputs of U1, a quad comparator. The ladder network on all negative (−) inputs of U1 sets the threshold point of each comparator at a successively higher level. As C1 charges up, each comparator, starting with U1A, will sequentially change output states.

The comparator outputs are fed into U2, a quad exclusive-OR gate. This was in-

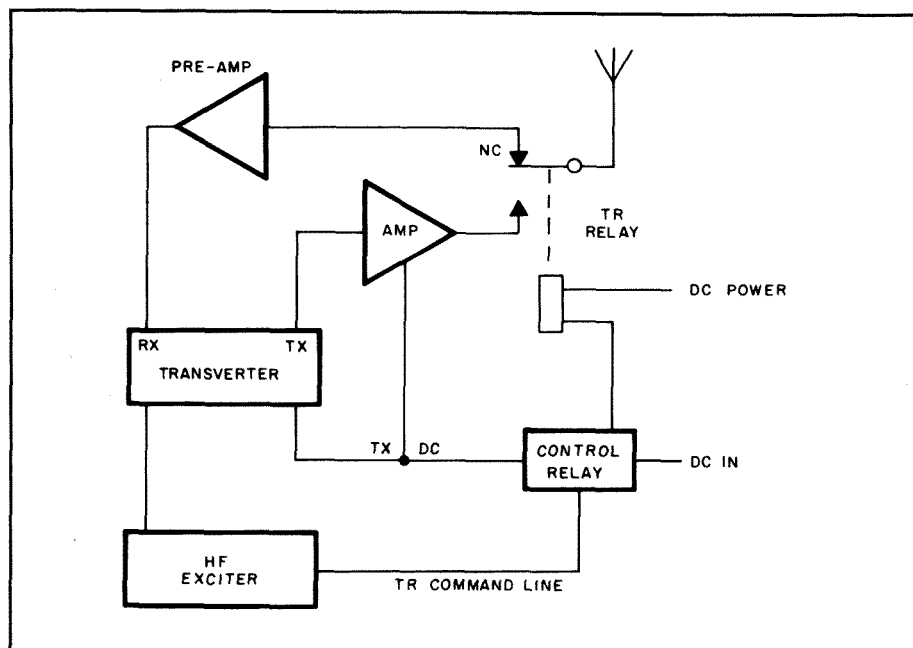

Fig. 17 — A typical VHF or UHF station arrangement with transverter, preamp and power amp. As shown, most TR relays change at the same time.

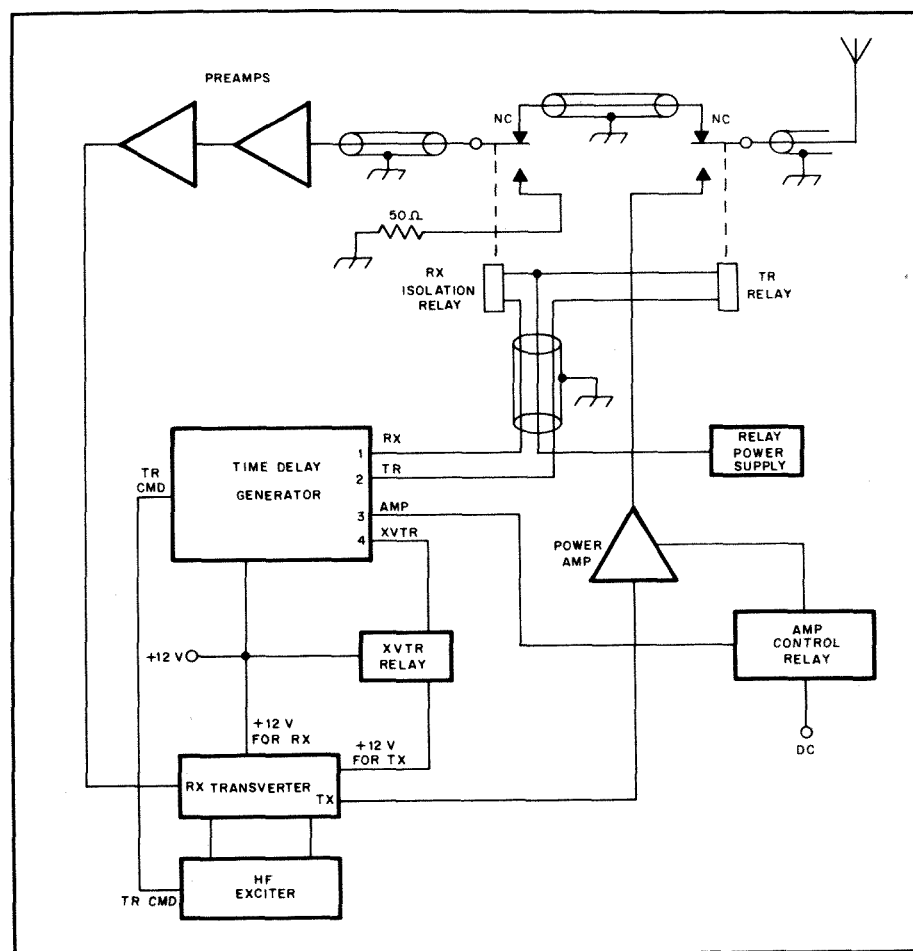

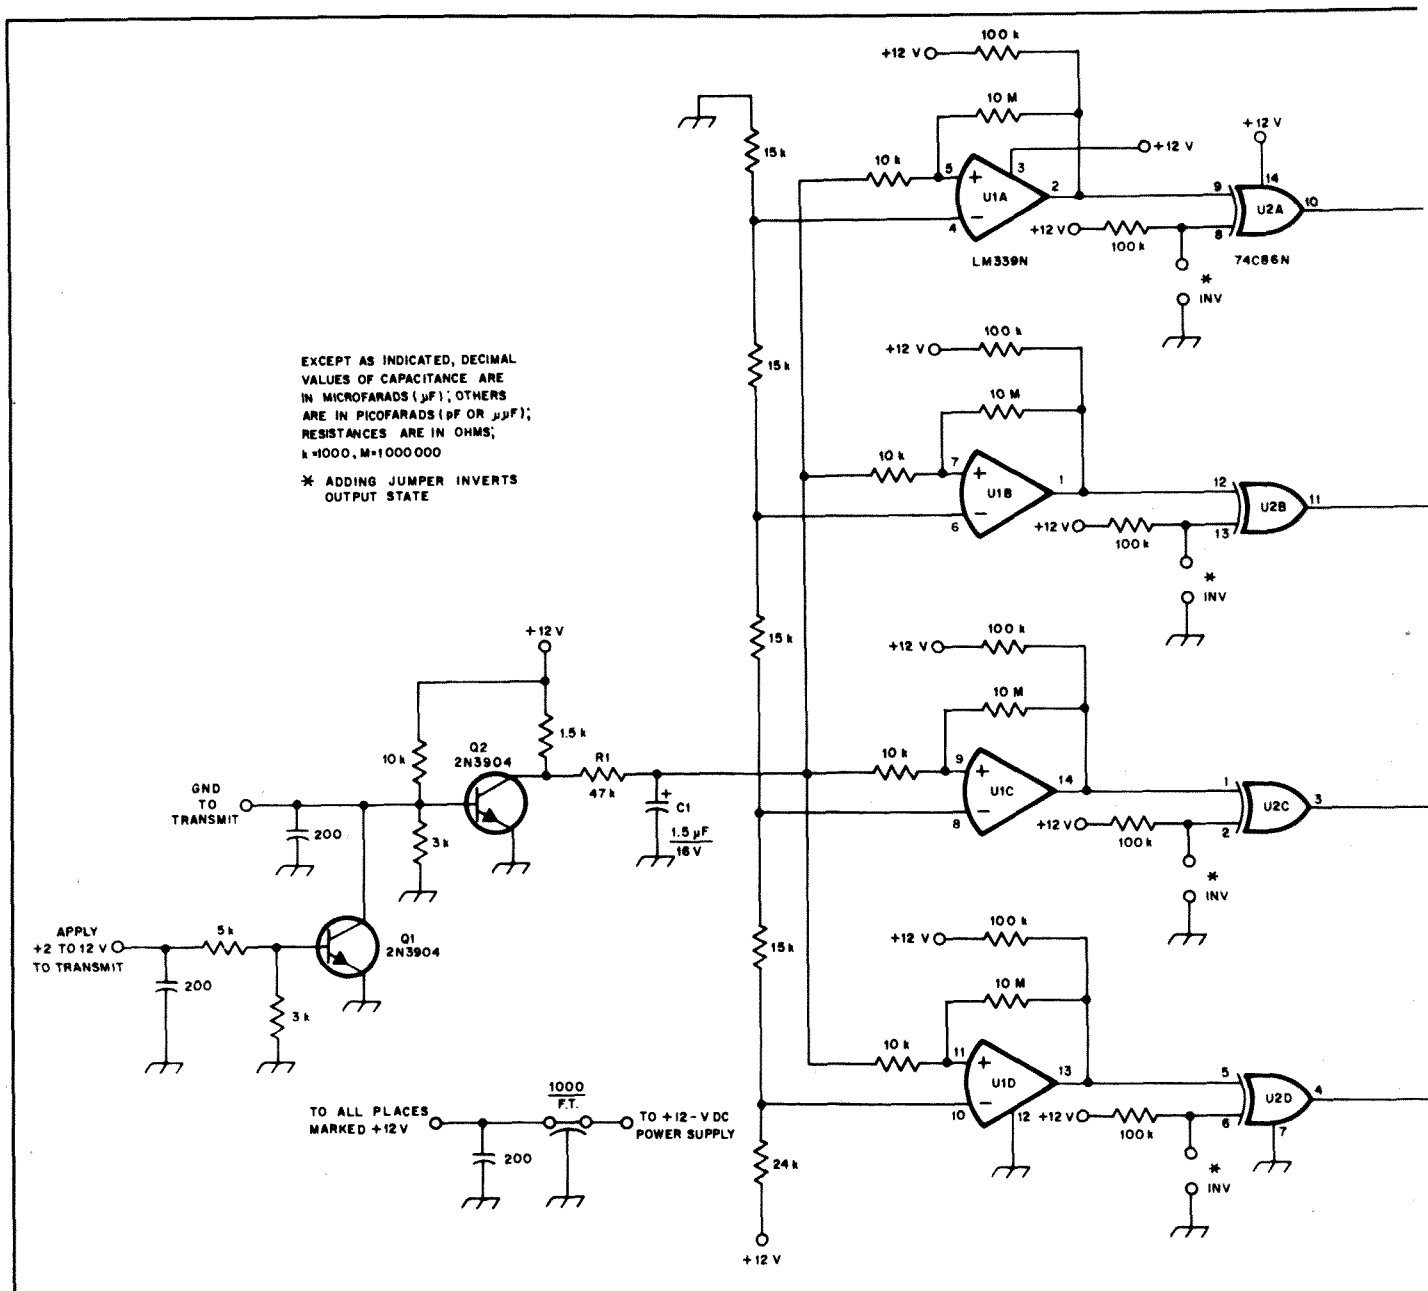

Fig. 18 — Block diagram of a VHF/UHF station with a remote-mounted preamp and antenna relays. The TR time-delay generator makes sure that everything turns on in the right order.

cluded in the design to allow "state programming" of the various relays throughout the system. Because of the wide variety of available relays, primarily coaxial, you may be stuck with a relay that's exactly what you need — except its contacts are open when it's energized! To use this relay, you merely invert the output state of the delay generator by inserting a jumper between the appropriate OR-gate input and ground. Now, the relay will be "on" during receive and "off" during transmit. This might seem kind of strange; however, high-quality coaxial relays are hard to come by and if "backwards" relays are all you have, you'd better use them.

The outputs of U2 drive transistors Q3-Q6, which are "on" in the receive mode. Drive from the OR gates turns these

transistors "off." This causes the collectors of Q3-Q6 to go high, allowing the base-to-emitter junctions of Q7-Q10 to be forward-biased through the LEDs to turn on the relays in sequential order. The LEDs serve as built-in indicators to check performance and sequencing of the generator. This is convenient if any state changes are made.

When the output transistors (Q7-Q10) are turned on, they pull the return side of the relay coils to ground. These output transistors were selected because of their high beta, very low saturation voltage ( $V_{CE}$ ) and low cost. They can switch (and have been tested at) 35 V at 600 mA for many days of continuous operation. If substitutions are planned, test one of the new transistors with the relays you plan to

use to be sure that the transistor will be able to power the relay for long periods.

To go from transmit to receive, the sequencing order is reversed. This gives additional protection to the various system components. C1 discharges through R1 and Q2 to ground.

Fig. 20 shows the relative states and duration of the four output commands when enabled. With the values specified for R1 and C1, there will be intervals of 30 to 50 milliseconds between the four output commands. Exact timing will vary because of component tolerances. Most likely everything will be okay with the values shown, but it's a good idea to check the timing with an oscilloscope just to be sure. Minor changes to the value of R1 may be necessary.

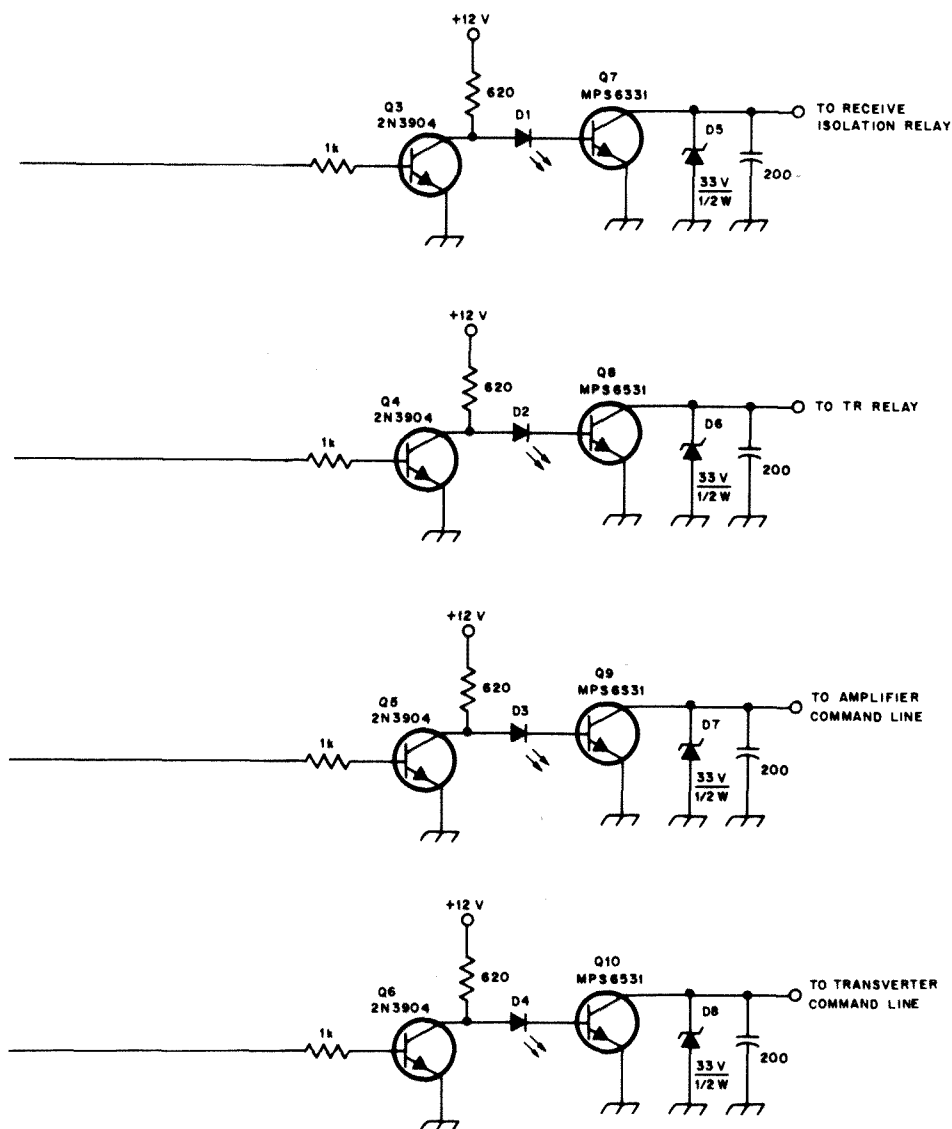

Fig. 19 — Schematic diagram of the TR time-delay generator. Resistors are  $\frac{1}{4}$  W. Capacitors are disc ceramic. Capacitors marked with polarity are electrolytic.

D1-D4 — Red LED (MV55, HP 5082-4482 or equiv.).

D5-D8 — 33-V, 500-mW Zener diode (1N973A or equiv.).

C1 —  $1.5\text{-}\mu\text{F}$ , 16-V or greater, axial-lead electrolytic capacitor. See text.

Q1-Q6 — General purpose NPN transistor (2N3904 or equiv.).

Q7-Q10 — Low-power NPN amplifier transistor, MPS6531 or equiv. Must be able to switch up to 35 V at 600 mA continuously. See text.

R1 —  $47\text{-k}\Omega$ ,  $\frac{1}{4}$ -W resistor. This resistor sets the TR delay time constant and may have to be varied slightly to achieve the desired delay. See text.

U1 — Quad comparator, LM339 or equiv.

U2 — Quad, 2-input exclusive or gate (74C86N, CD4030A or equiv.).

Most relays, especially coaxial, will require about 10 ms to change states and stop bouncing. The 30-ms delay will give adequate time for all closures to occur.

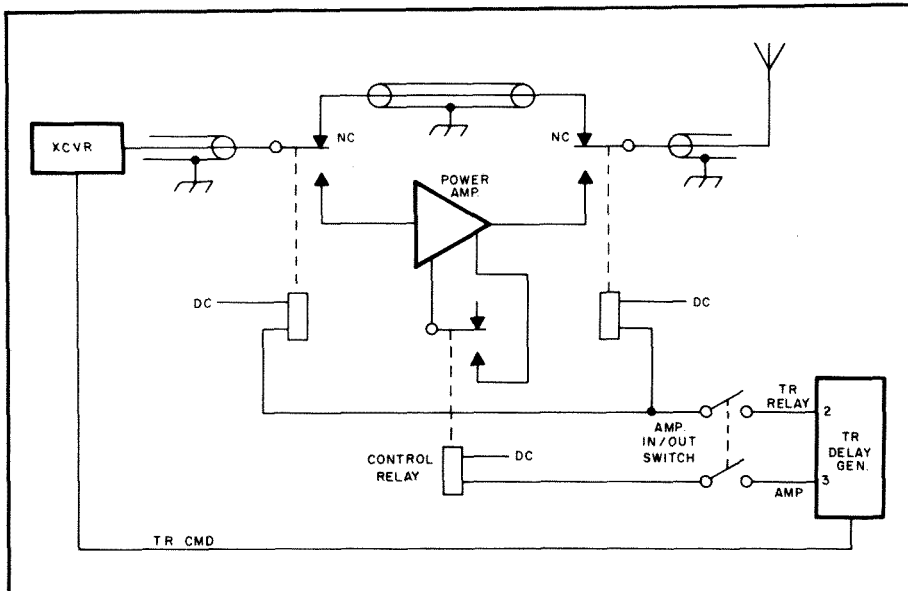

### Construction and Hookup

One of the more popular antenna changeover schemes uses two coaxial relays — one for actual TR switching and one for receiver/preamplifier protection. See

Fig. 20 — The relative states and durations of the four output commands when enabled. This diagram shows the sequence of events when going from receive to transmit and back to receive. The TR delay generator allows about 30 to 50 ms for each relay to close before activating the next one in line.

**Fig. 21 — The TR time-delay generator can also be used to sequence the relays in an HF power amplifier.**

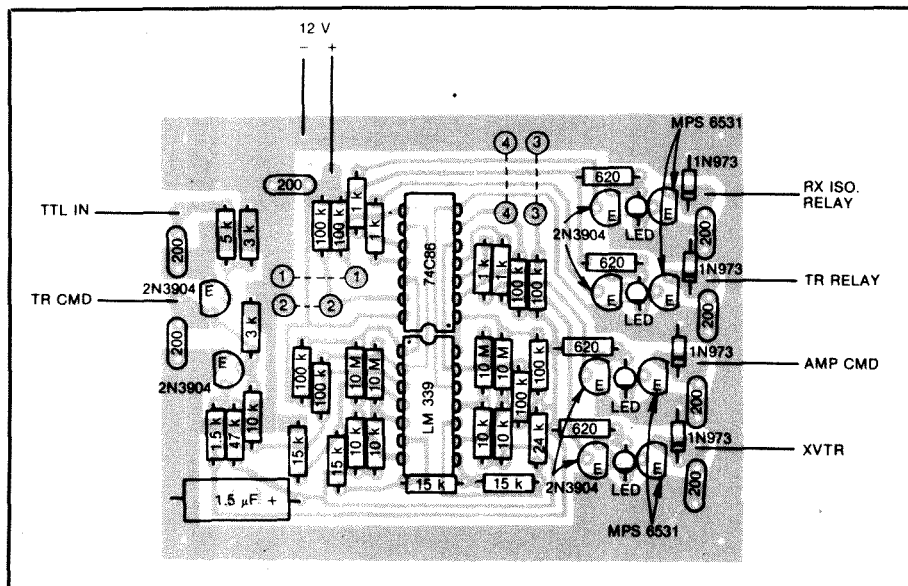

Fig. 22 — Parts placement diagram of the TR time-delay generator. A full-size etching pattern is given at the back of this book.

**Fig. 18.** A project using this scheme is presented elsewhere in this chapter.

Many RF relays have very poor isolation, especially at VHF and UHF frequencies. Some of the more popular surplus relays have only 40 dB isolation at 144 MHz or higher. If you are running high power, say 1000 W (+60 dBm) at the relay, the receive side of the relay will see +20 dBm (100 mW) when the station is transmitting. This power level is enough to inflict fatal

damage on your favorite preamplifier.

Adding a second relay, called the RX isolation relay here, terminates the preamp in a 50-ohm load during transmission and increases the isolation significantly. Also, in the event of TR relay failure, this extra relay will protect the receive preamplifier.

As shown in Fig. 18, both relays can be controlled with three wires. This scheme provides maximum protection for the receiver. If high-quality relays are used and

**Fig. 23 — The completed time-delay generator fits in a small aluminum box.**

verified to be in working order, relay losses can be kept well below 0.1 dB, even at 1296 MHz. The three-conductor cable to the remote relays should be shielded to eliminate transients or other interference.

By reversing the RX-TX state of the TR relays (that is, connecting the transmitter hardline and 50-ohm preamp termination to the normally open relay ports instead of the normally closed side), receiver protection can be provided. When the station is not in use and the system is turned off, the receiver preamplifier will be terminated in 50  $\Omega$  instead of being connected to the antenna. The relays must be energized to receive. This might seem a little backward; however, if you are having static-charge-induced preamplifier failures, this may solve your problem.

Most coaxial relays aren't designed to be energized continuously. Therefore, adequate heat sinking of coaxial relays must be considered. A pair of Transco Y relays can be energized for several hours when mounted to an aluminum plate 12 inches square and ¼ inch thick. Thermal paste will give better heat transfer to the plate. For long-winded operators, it is a good idea to heat sink the relays even when they are energized only in transmit.

Fig. 21 shows typical HF power amplifier interconnections. In this application, amplifier in/out and sequencing are all provided. The amplifier will always have an antenna connected to its output before drive is applied.

Many TR change-over schemes are possible depending on system requirements. Most are easily satisfied with this TR delay generator.

The TR delay generator is built on a  $2\frac{1}{2} \times 3\frac{1}{4}$  inch PC board. See Fig. 22. The board can be mounted in a small aluminum case, as shown in Fig. 23. Connections to the rest of the system are made through feedthrough capacitors. Do not use feedthrough capacitors larger than 2000 pF because peak current through the output switching transistors may be excessive.

# Three-Watt Transmitting Converter for 6 Meters

The linear transmitting converter shown in Figs. 36 through 39 is a simple, low-cost way to extend the coverage of any 28-MHz transmitter to the 6-meter band. Output power is 3 watts PEP and the 28-MHz drive requirement is 1 mW. This drive level is compatible with the transverter outputs found on many current HF transceivers. By selecting the appropriate resistor values, the input attenuator can easily be adjusted for drive levels as high as 100 mW.

Particular care was taken during the design stage to ensure that spurious emissions are at a minimum. The IMD performance is such that this unit can be used to drive a high-power linear amplifier without generating excessive adjacent-channel interference.

## Circuit Description

LO injection is supplied to the mixer by a crystal oscillator operating at 22 MHz. The output of the oscillator is filtered to reduce harmonics to approximately -40 dBc and is then applied to a power splitter, T2. One port of the splitter feeds the mixer, and the other output is connected to J1. This output can be used to supply LO to a receiving converter for transceiver operation. A 3-dB attenuator between the splitter and the mixer provides a wideband termination for the mixer LO port. The power delivered to the mixer is +7 dBm.

A commercial diode-ring module is used for the mixer. The excellent balance of this type of mixer reduces the band-pass filter requirements following the mixer. The IMD performance is also very good; the third-order products are 40 dB below each tone of the two-tone output signal when the input signal is at the recommended level of -10 dBm (each tone). The attenuator at the IF port prevents overdriving the mixer. The 20-dB pad shown in Fig. 37 allows a driving signal of 30 to 40 mW (PEP) to be used. This attenuator should be adjusted if other drive levels are desired.

The mixer is followed by a broadband amplifier, 6-dB pad and a 3-pole band-pass filter. The amplifier has a gain of nearly 20 dB at 50 MHz and provides a good termination for the mixer. Signal level at the filter output is about -10 dBm. Two more stages of class-A amplification follow the band-pass filter, bringing the signal level up to the +16 dBm necessary to drive the power-amplifier stage.

The power amplifier uses a Motorola MRF476 transistor operating class AB. The MRF476, a low-cost device in a plastic TO-220 package, will deliver a minimum of 3 watts PEP with good linearity at 50 MHz. A CW output of up to 4 watts can be obtained from this converter, but the key-down time should be limited to 60 seconds. This is because of the relatively small heat sink used in this unit. The power-amplifier input and output networks

Fig. 36 — Six-meter transmitting converter and 3-W PEP amplifier.

are both designed to match the transistor to 50 ohms. Their design was based on data supplied in the *Motorola RF Data Manual* (2nd edition). The amplifier output is filtered by a 7-pole low-pass filter designed for a cutoff frequency of 56 MHz and a ripple factor of 0.17 dB.

## Construction

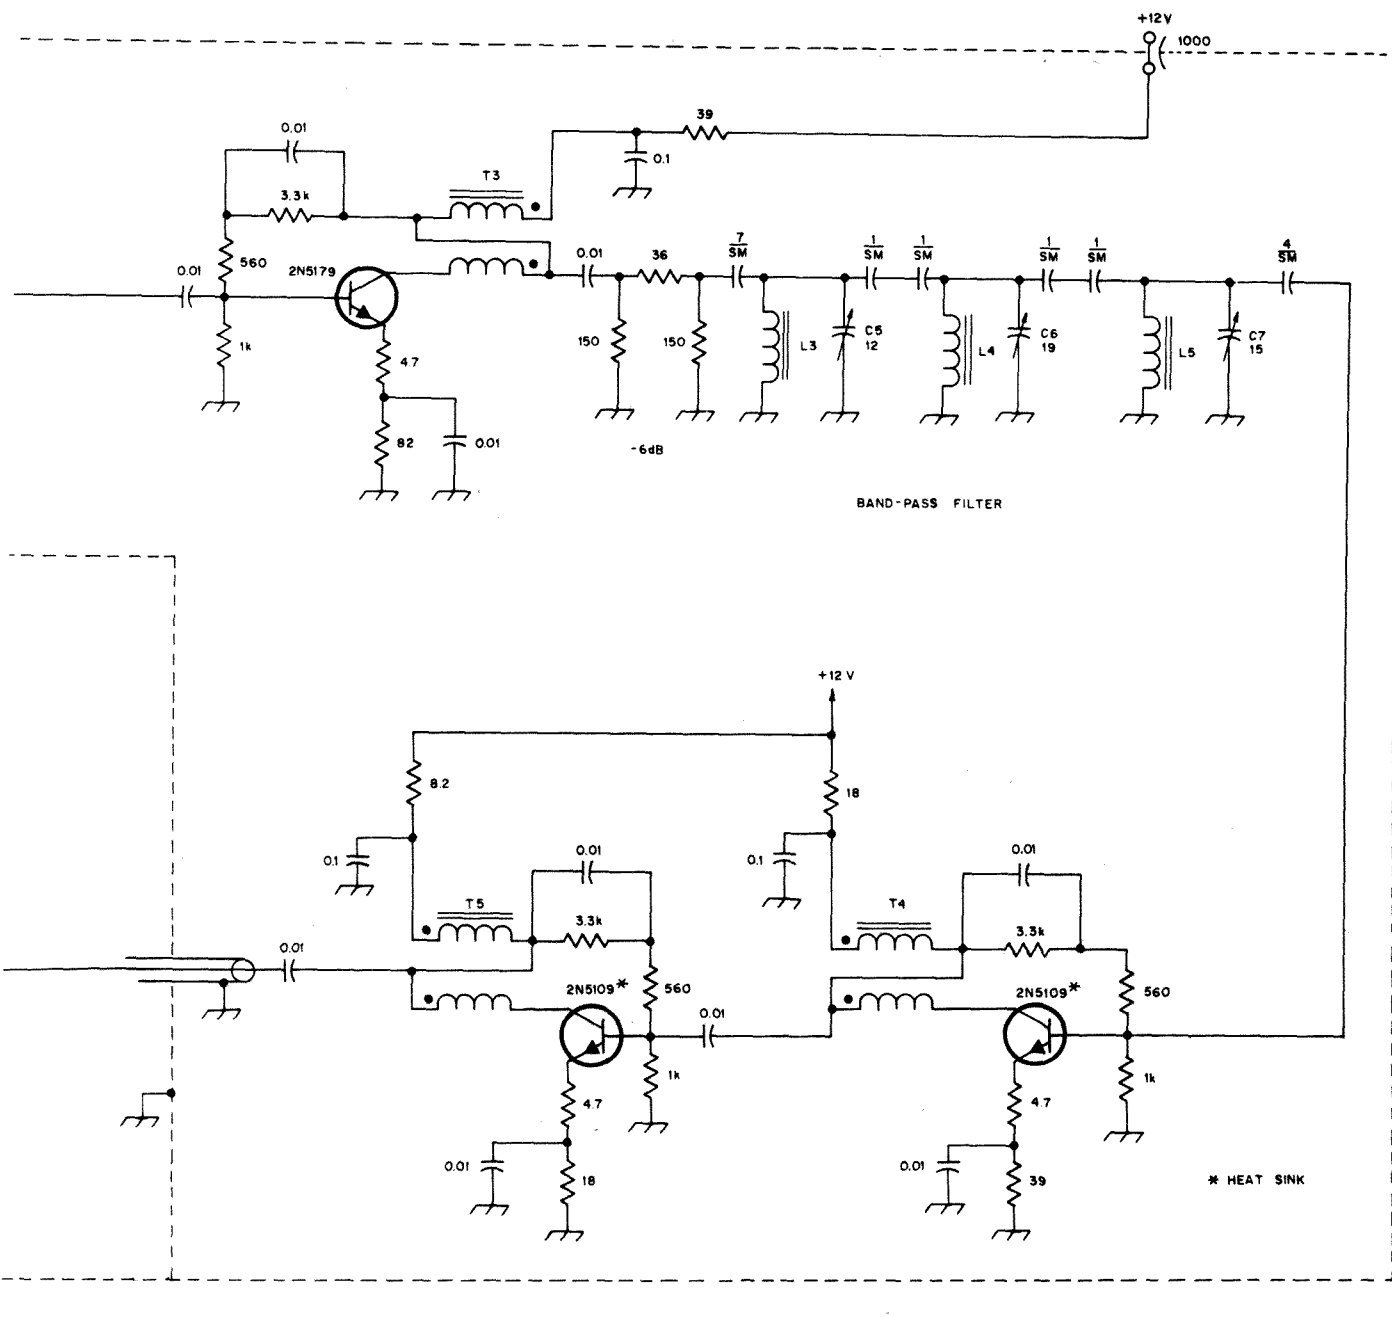

The converter is constructed in two sections: the low-level section consisting of the LO, mixer, band-pass filter and class-A amplifiers and the power-amplifier/low-pass filter section. No printed circuit board is needed for the low-level section; rather, the components are mounted directly on a piece of etched copper-clad board. The component leads going to ground support the components above the board. Among the many advantages to this style of construction is the ease with which the circuits can be modified. Also, if a printed-circuit board is used, the components used to lay out the board, such as variable capacitors,

are likely to be the only types that can be used. This makes it difficult for the builder to use junk box components.

Note that the LO and its filter are completely enclosed by a shield made of double-sided circuit-board material. This was found to be necessary to ensure that 22-MHz LO energy does not find its way into the amplifier stages. It was expected that a 1-inch-high shield around the LO would provide sufficient isolation — this is not the case; a complete enclosure is required. It is recommended that a shield enclosure be constructed around the remaining portion of the low-level section. This will prevent feedback from the power-amplifier board to the class-A stages. It was not necessary to do this in the prototype shown in the photographs, but is good practice when the two boards are mounted in the same enclosure (such as an aluminum chassis).

The power-amplifier board is constructed on a printed board (Fig. 38). It is

Compress winding to cover half of core.  
 R1 — 220-ohm, 1-W resistor in series with a 500-ohm, 1/2-W trimmer.  
 RFC1 — 10-μH solenoid type RF choke (Miller 74F105AP or equiv.).  
 RFC2 — 1.2-μH solenoid type RF choke (Miller

74F126AP or equiv.).  
 T1 — 27 turns primary, 5 turns secondary, no. 28 enamel on T37-6 core.  
 T2 — 5 bifilar turns, no. 26 enamel on FT37-61 core.

T3 — 7 bifilar turns, no. 28 enamel on FT23-43 core.

plied to the oscillator and class-A amplifiers. The oscillator is adjusted by setting C2 at mid-range. Next, C3 is tuned for maximum output as measured with a VTVM and RF probe connected to pin 8 of the mixer. C2 can then be adjusted to bring the frequency to exactly 22 MHz. If a frequency counter with a high-impedance input is used, it should be connected to pin 8 of the mixer. If the counter has a 50-ohm input it can be connected to J1.

The adjustment of C2 and C3 will interact so the procedure should be repeated. J1 should always be connected to a load close to 50 ohms. If a receive converter is not being used, a 50-ohm resistor, mounted in a BNC connector, should be connected to J1.

The band-pass filter is aligned by applying a 28.7-MHz CW signal to the input of the converter and adjusting C5, C6 and C7 for maximum output at the output of the

last amplifier. Check the frequency response of the filter by varying the frequency of the input signal from 28 to 29 MHz. The output power should not vary more than 1 dB within the passband of the filter. The 50-ohm resistor at the output of the last class-A amplifier should now be removed and the power amplifier connected through a short length of coaxial cable.

To align the input and output networks  
**VHF Radio Equipment 31-15**

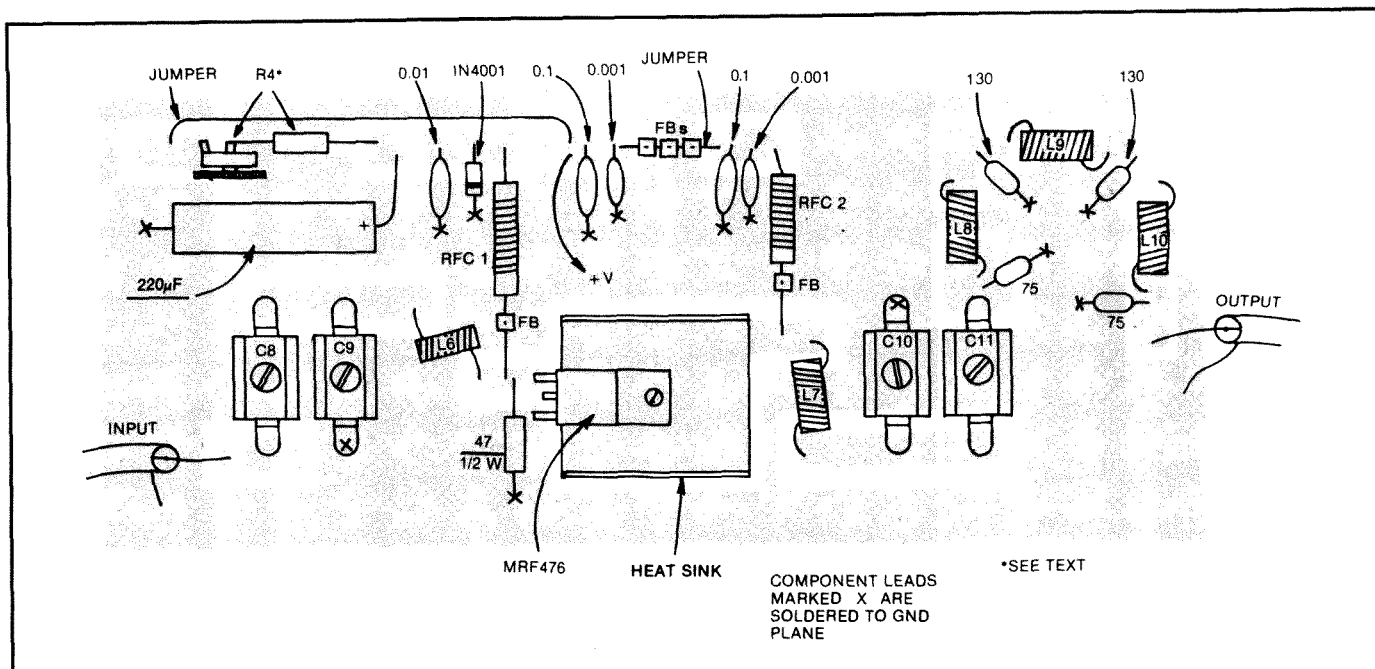

Fig. 38 — Parts-placement guide for the 6-meter transmitting converter. All components mount on the foil side of the board. A full-size etching pattern can be found at the back of this book.

Fig. 39 — Spectral analysis of 6-meter transmitting converter. Display at A shows the fundamental and second harmonic. The harmonic is 73 dB below the 3-watt carrier. The fundamental has been notched 30 dB to prevent overload of the spectrum analyzer. Each horizontal division is 20 MHz. A close-in display is shown in B: Each horizontal division is 2 MHz and the center frequency is 50 MHz. The  $2 \times 28$ -MHz spurious product (which falls in channel 2) is attenuated more than 75 dB relative to the carrier power. The two-tone IMD spectrum is shown in C; the third-order products are 34 dB below PEP. Each horizontal division is 2 kHz. In all three displays each vertical division is 10 dB.

of the final, connect the amplifier output to a wattmeter and 50-ohm load. Attach the amplifier to a 12-volt, 1-A power supply (maximum current drain is approximately 750 mA for the complete converter) and place a milliammeter in the collector supply line at the point marked  $\times$  in Fig. 37. With no drive applied, turn on the dc power and

adjust R1 for a collector current of 35 to 40 mA. Apply just enough 29-MHz drive to the input of the converter to get an indication on the wattmeter and peak C8 through C11 for maximum output. Now increase the drive slowly, keeping the networks peaked, until the output power is 4 watts. Do not maintain the output at 4 watts any longer than is necessary. It is

important that the output network be adjusted while the output is at the 3.5- to 4-watt level. If it is adjusted at a lower level the IMD performance will be degraded. When the output is adjusted as described above, the third-order IMD products should be at least 32 dB below the 3-watt-PEP level (Fig. 39C).

# Linear Transverters for 144 and 220 MHz

The CW and SSB portions of the 144- and 220-MHz bands have swelled with activity during the past few years. Although there is plenty of commercially made CW and SSB gear for 144 MHz, there is little available for 220. Paul Drexler, WB3JYO, designed and built the linear transverters described here and shown in Figs. 40 through 62. These projects enable the use of a standard 28-MHz transceiver as a tunable IF for 144- or 220-MHz operation. Construction is less complicated than building a complete transceiver, and all of the good features of the HF rig (such as a clean SSB source, stable VFO and good crystal filters) are incorporated. Chapters 11 and 12 contain additional information on transverter theory. Although these transverters may be tuned for any segment of operation, they were designed mainly to cover the lower portion of each band (144 to 145 MHz and 220 to 221 MHz). A 12-V power supply and an antenna are the only other equipment necessary to complete the VHF station.

The complete transverter design includes a minimum of hard-to-find components and should be easily reproducible. Although the text and illustrations center around the 220-MHz transverter, component values are given for the 144-MHz unit as well. Except for the local oscillator (LO), all circuits are common to both designs.

The receive converter has a 0.6-dB noise figure and an overall conversion gain of 28 dB. These figures were verified on an HP8970A noise-figure meter with an HP346A noise source. Transmit-converter

power output is a conservative 1 W under linear operation. The companion amplifier produces 8 to 10 W of linear output power. Much care was taken to make the transmit chain as clean as possible, and the receive converter incorporates techniques to maximize sensitivity and dynamic range.

## CIRCUIT DESCRIPTION

Fig. 41 shows the transverter block

diagram. The main difference between the 144- and 220-MHz versions is the LO. Although transceive operation is depicted, the experimenter may choose to limit construction to either transmit only or receive only. LO energy is injected into a high-level (+17 dBm) doubly balanced mixer during receive. Received signals are amplified by a GaAsFET preamplifier and then filtered before entering the mixer. The 28-MHz

Fig. 40 — The 144- or 220-MHz transverter is built using a modular circuit approach. Each circuit is boxed and mounted on a chassis with interconnections of short lengths of 50-ohm coaxial cable.

RFC1-RFC4 — 2.2- $\mu\text{H}$  molded miniature RF

signal at the output port of the mixer is sent to a post amplifier and band-pass filter, and then to the 28-MHz IF receiver.

On transmit, LO energy and a low-level RF signal from the 28-MHz IF transceiver are fed to a standard-level (+7 dBm) doubly balanced mixer. The mixer output is filtered to eliminate the image and other unwanted responses, and then the desired signal is amplified by five stages to reach the 1-W level. The output of the 1-W transmit converter is further filtered to meet FCC rules and regulations. An optional 8- to 10-W amplifier is described for those desiring greater power output.

This transverter is built in a modular fashion. All of the major circuit blocks are built into separate enclosures and interconnected by 50-ohm coaxial cable. Modular construction lends itself to on-the-air experimentation and development, as well as simple troubleshooting. Any stage may be removed from the circuit for modification, or a new stage may be substituted. Although commercially available diecast boxes (BUD CU-123 and CU-124 or Hammond 1590A and 1590B) are used here, double-sided PC-board enclosures or Miniboxes may be used. Mounting all cir-

cuits in individual boxes is highly recommended for versatility and shielding. All component connections are made using direct, point-to-point construction techniques.

### Local Oscillator

A schematic diagram of the local oscillator for the 220-MHz transverter is shown in Fig. 42. A frequency of 96 MHz has been chosen so that only one stage of multiplication is necessary to obtain the needed 192-MHz LO frequency. The crystal, Y1, is a series-resonant, fifth-overtone type in an HC-18/U package. The oscillator used is a common-base circuit derived from an article by Joe Reisert, W1JR.<sup>1</sup> Most crystal oscillators tend to oscillate at a frequency slightly higher than the crystal's fundamental mode of operation. In this circuit, L2 cancels the  $C_o$  crystal capacitance, thus bringing the oscillator down to the desired frequency.

The author chose to use a 95.95-MHz crystal (for a 191.9-MHz LO); an IF fre-

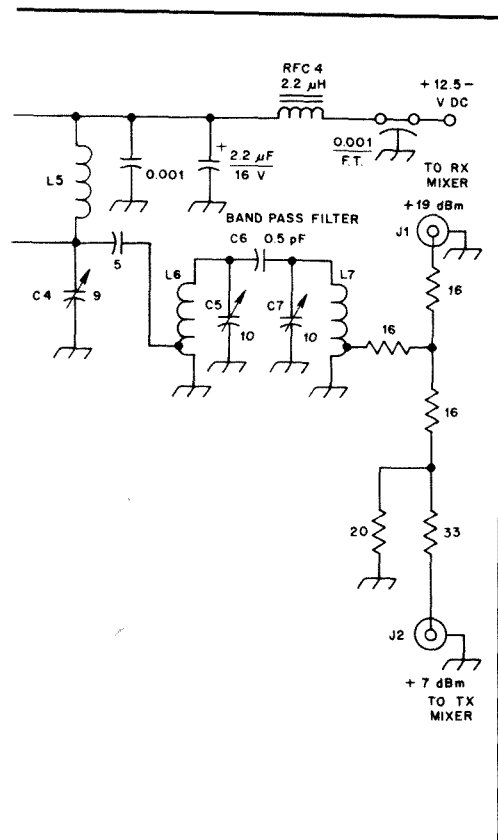

quency of 28.1 MHz corresponds to an operating frequency of 220.0 MHz. Strong signals from stations operating on 10 meters may be picked up by the transverter interconnecting cables, interfering with signals being received from 220 MHz. Also, when more than one transverter with a 28-MHz IF is operated in the same room (at a multioperator VHF contest station, for example), it is not uncommon to hear signals from the other IF transceivers.

Oscillator output is fed into an active doubler constructed with a CA3049 transistor array. This circuit is based on a suggestion by Bill Strunk, K3ZMA. The doubler features as much as 7-dB gain and excellent harmonic suppression because of its balanced input circuit. A CA3054 or MC3346 transistor array may be used in place of the CA3049.

Output energy from the doubler is further amplified by Q3 and Q4 to bring the LO to the required mixer input level. Filtering is accomplished at the LO output by a lightly coupled double-tuned filter. All spurious and harmonic energy is better than 55 dB below the desired signal. A clean LO is necessary to avoid interference problems caused by undesired mixing products

<sup>1</sup>Reisert, Joe, "VHF/UHF Receivers," *Ham Radio*, March 1984, pp. 42-46.

choke.

Y1 — Fifth-overtone, 96-MHz series-resonant crystal, HC-18/U holder.

during receive and transmit.

After the filter, a resistive power divider is used to drive the transmit and receive mixers. Resistive pads attenuate the LO signal to the proper level while providing a 50-Ω impedance for the mixer input.

Although a similar lineup could be employed for 144 MHz, a three-stage 116-MHz oscillator is shown schematically in Fig. 43. The 144-MHz transverter uses a 116-MHz series-resonant crystal (Y1) to avoid frequency multipliers. Oscillator output is amplified by Q2 and Q3 until it reaches the level necessary to drive both the transmit and receive mixers. LO output is filtered by a double-tuned band-pass filter. After the filter, a resistive power divider is used to drive the transmit and receive mixers; again, pads attenuate the signal to the proper level.

With the filters properly adjusted, all spurious outputs from the LO are about 58 dB below the fundamental. Fig. 44 shows the spectral output from the LO receive port.

### Receive Converter

The 144- and 220-MHz receive converters are identical, except for the tuned

circuits in the front end. In each case, the converter consists of a GaAsFET preamplifier, a mixer/duplexer circuit and an optional 28-MHz post amplifier. The mixer/duplexer and post amplifier circuits are the same, regardless of band. Each of the three receive converter blocks is built into a separate module. This was done to facilitate experimentation and development of each stage. Of course, it is possible to build all three circuits in one box. This subject will be addressed in the construction portion of this article.

### Mixer

The heart of the receive converter is a Mini-Circuits SRA-1H high-level, doubly balanced mixer (DBM). See Fig. 45. This mixer requires an LO injection level of +17 dBm, compared with the +7 dBm injection level required for standard mixers. The high-level mixer offers superior strong-signal handling characteristics while maintaining the port-to-port isolation, image suppression and simplicity inherent in a DBM. The SRA-1H is modestly priced and available in small quantities directly from the manufacturer.

Reactive terminations can ruin the excellent IMD characteristics of a DBM.<sup>2,3</sup> The IF port, in particular, is most sensitive to a nonresistive 50-ohm termination. Anything short of a 20-dB resistive pad at the IF port will result in increased IMD products and a lower third-order-intercept point. Feeding the output of a DBM directly into a narrowband amplifier will decrease the mixer's third-order intercept point as compared to a purely resistive termination. The diplexer circuit shown in Fig. 45 represents one solution to the problem of proper mixer termination. The diplexer's low-pass response presents a 20-dB return loss at 28 MHz and terminates higher frequencies into 50 ohms.

### RF Preamplifier

A low-noise, high-dynamic-range GaAsFET preamplifier is used in front of the mixer to overcome mixer conversion loss. The GaAsFET device offers exceptional performance, compared with most bipolars and MOSFETs, and designs abound.<sup>4,5</sup> The circuit in Fig. 46 has proven reliable during many hours of on-the-air operation. This simple design offers a noise figure of 0.4 dB, as measured on an HP8970A noise-figure meter with the HP346A noise source. This noise figure is much lower than the feed line loss preceding the preamplifier; performance is exceptional for all applications short of in-

tensive EME receiving. A 30-mA bias current achieves optimum signal-handling capability. The third-order-intercept point is +25 dBm. Gain is 24 dB.

The double-tuned filter between the preamp and mixer provides a reasonable degree of filtering. A trap (L2) is used to attenuate the 164-MHz (188 MHz for the 2-meter version) image. Fig. 47A shows the swept frequency response of the 220-MHz version. A comb line or helical filter might be used if greater selectivity is required.

### 28-MHz Post Amplifier

For most amateur applications, a 28-MHz post amplifier is not necessary. It serves to amplify the 28-MHz IF signal to increase S-meter readings. The author lives among several of the "big gun" VHF stations in southeastern Pennsylvania, so high dynamic range is essential to avoid overload problems. The receive converter operates nicely without any post amplification, thereby preserving the IF receiver's dynamic range.

The 28-MHz post amplifier shown in Fig. 48 has been included here for those operators fortunate enough to live away from strong in-band signals. The 2N5109 is readily available and provides good performance at low cost. In this circuit, the device is biased to provide 13-dB gain with a third-order-intercept point of +26 dBm. The design features a tuned input circuit and a broadband output transformer. A double-tuned band-pass filter at the output assures a clean signal for the IF receiver. Fig. 47B shows the swept frequency response of the post amplifier.

If you live in an area with loud local signals, yet want to use a post amplifier, a pad may be used between the post amplifier and the IF receiver to reduce the converter gain to a level that the IF receiver can handle. The value of attenuation will depend on the IF receiver's ability to handle large signals. When you first connect the receive converter to the IF receiver, you will probably notice that the S-meter on the receiver moves up to S3 or higher (a lot depends on the nature of your specific receiver), even with no signals present. To determine the right pad value for your application, place a variable step attenuator in the line between post amp and IF receiver and increase the attenuation until the IF receiver S-meter is just above zero. If you want to leave the step attenuator in the line, fine. If not, you can build a pad with the correct value from the attenuator tables given in Chapter 25 of this *Handbook*.

### Transmit Converter

A schematic diagram for the 1-W transmit converter is shown in Fig. 49. The 192-MHz LO (116-MHz LO for the 144-MHz version) and 28-MHz signals are mixed in a Mini-Circuits SRA-1 standard-level DBM. A pad is necessary to limit the 28-MHz input to a maximum level of -10 dBm, ensuring good linearity and

spectral purity. No parts values are shown for the IF pad; the exact resistor values will depend on the amount of 28-MHz drive available from the transverter output of your IF transceiver. For example, if your IF rig delivers 20 mW (+13 dBm) at the transverter output, you would need to build a 23-dB pad. See Chapter 25 for tables listing resistor values for different levels of attenuation.

Mixer output is fed through a resistive pad for proper termination, and then filtered by a double-tuned band-pass filter to reduce the image and other undesired mixing products. Two 2N2857 amplifier stages follow the filter, followed by two 2N4427 stages. The final amplifier stage is a 2N5946. All stages are biased for linear operation. The 2N5946 may be substituted with a lower-power 2N5945 or 2N5944 device; if you substitute, you may have to alter the input and output matching, as well as the bias circuit. A 7-element Chebyshev low-pass filter (Fig. 50) follows the 2N5946. Swept filter response is shown in Fig. 51B. The output is exceptionally clean; a spec-

tral plot is shown in Fig. 51A.

Although some designers may question the use of five stages to achieve 1-watt output, there are several good reasons for doing so. This transmit converter is rated

for conservative operation at a healthy, filtered 1-W output. It is not "almost" a watt, like some four-stage designs. All stages are run below their maximum possible output level, ensuring clean, linear

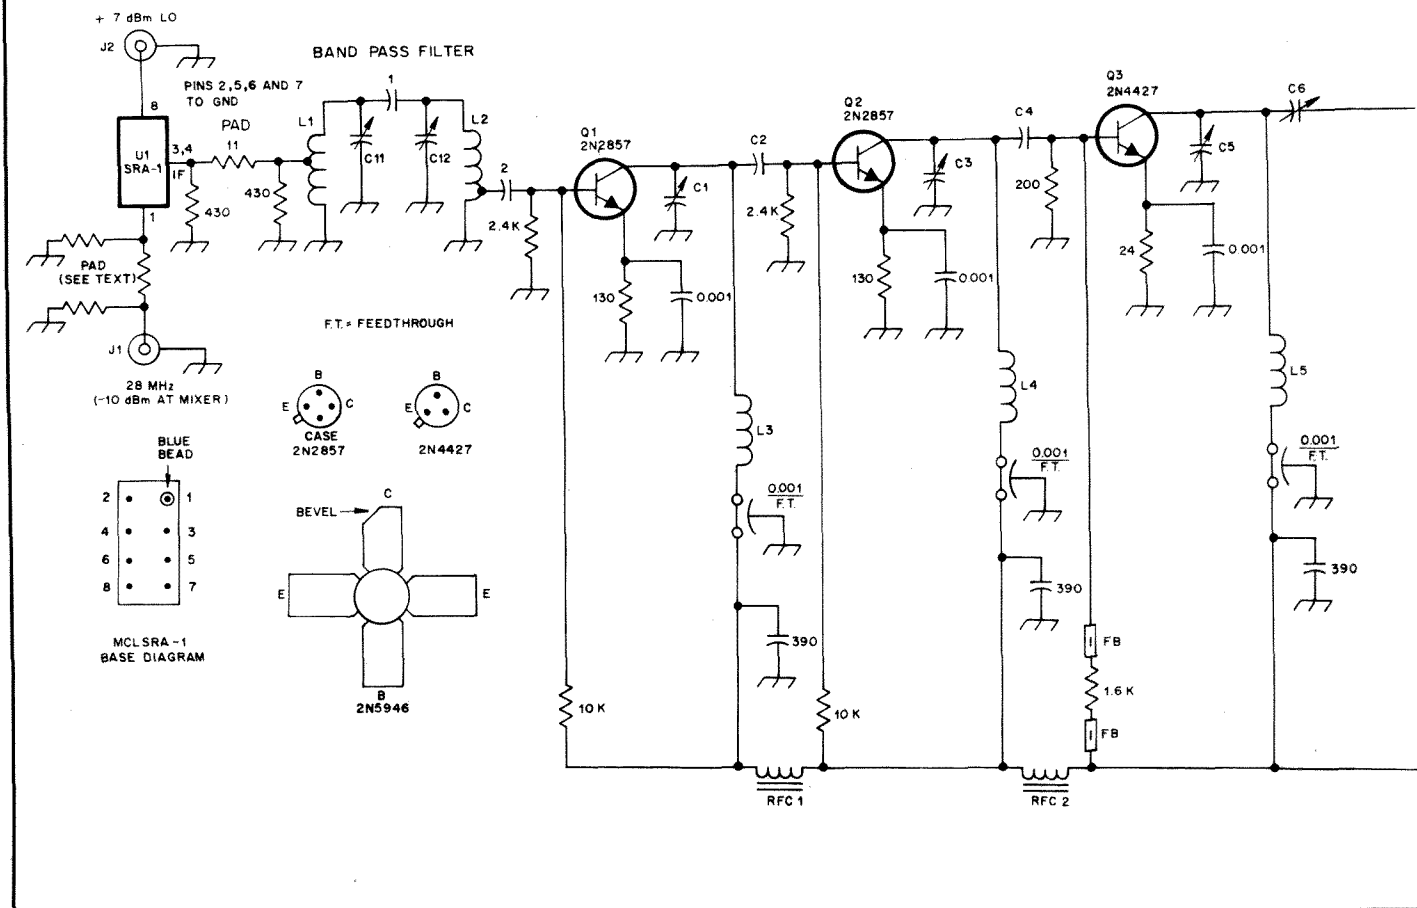

Fig. 49 — Schematic diagram of the 144- and 220-MHz transmit converter. All resistors are  $\frac{1}{4}$ -W carbon-composition types unless otherwise noted. Capacitors are silver-mica or miniature monolithic ceramic types unless otherwise noted. Capacitors marked with polarity are electrolytic.

C1, C3, C5, C6, C7 — Miniature ceramic trimmer, 220 MHz: 8 pF (max.); 144 MHz: 25 pF (max.).

C2 — Silver-mica capacitor, 220 MHz: 2 pF; 144 MHz: 3 pF.

C4 — Silver-mica capacitor, 220 MHz: 3 pF; 144 MHz: 5 pF.

C8 — Miniature ceramic trimmer, 220 MHz:

15 pF (max.); 144 MHz: 25 pF (max.).

C9, C10 — 25-pF (max.) miniature ceramic trimmer (same for both bands).

C11, C12 — Ceramic piston trimmer or miniature ceramic trimmer, 220 MHz: 10 pF (max.); 144 MHz: 25 pF (max.).

J1-J3 — Chassis-mount female BNC connector.

L1, L2 — 220 MHz: 4t no. 20 tinned, 0.250-inch ID, spaced one wire dia. Tap at 1t from ground. 144 MHz: Same as 220 MHz except coil is 6t.

L3, L4, L5 — 220 MHz: 3t no. 20 tinned, 0.250-inch ID, spaced one wire dia. 144 MHz: Same as 220 MHz except coil is 5t.

L6 — 220 MHz: 1t no. 20 tinned, 0.250-inch ID.

Fig. 50 — Schematic diagram of 7-element Chebyshev low-pass filter. Capacitors are silver-mica types.

C1, C3 — 220 MHz: 15 pF; 144 MHz: 27 pF.

C2 — 220 MHz: 18 pF; 144 MHz: 30 pF.

L1, L4 — 220 MHz: 3t no. 22 enam.,  $\frac{3}{16}$ -inch ID, close wound; 144 MHz also 3t.

L2, L3 — 220 MHz: 4t no. 22 enam.,  $\frac{3}{16}$ -inch ID, close wound; 144 MHz: 5t.

operation. The gain from the extra stage also allows the use of the filters after the mixer and at the output. The author lives in an area where the VHF bands are congested, so clean, linear operation is a must for sound relations with other amateurs sharing the band.

### Power Amplifier

An optional 8- to 10-W linear power

amplifier is shown schematically in Fig. 52. This amplifier uses another 2N5946 transistor. The design is relatively simple. Input matching is accomplished by C1, C2 and L1. L2, C3 and C4 match the output. The only differences between the 220-MHz and 144-MHz versions are the values of L1 and L2.

The bias circuit, suggested by Dave Mascaro, WA3JUF, uses an LM317 ad-

justable regulator to provide a stiff bias supply. The LM317 circuit is capable of providing 30- to 40-mA of stable bias current.

### Switching

Fig. 53 is a schematic diagram of the transverter switching circuitry. K1 is used to switch power to the transverter modules in transmit and receive. When the trans-

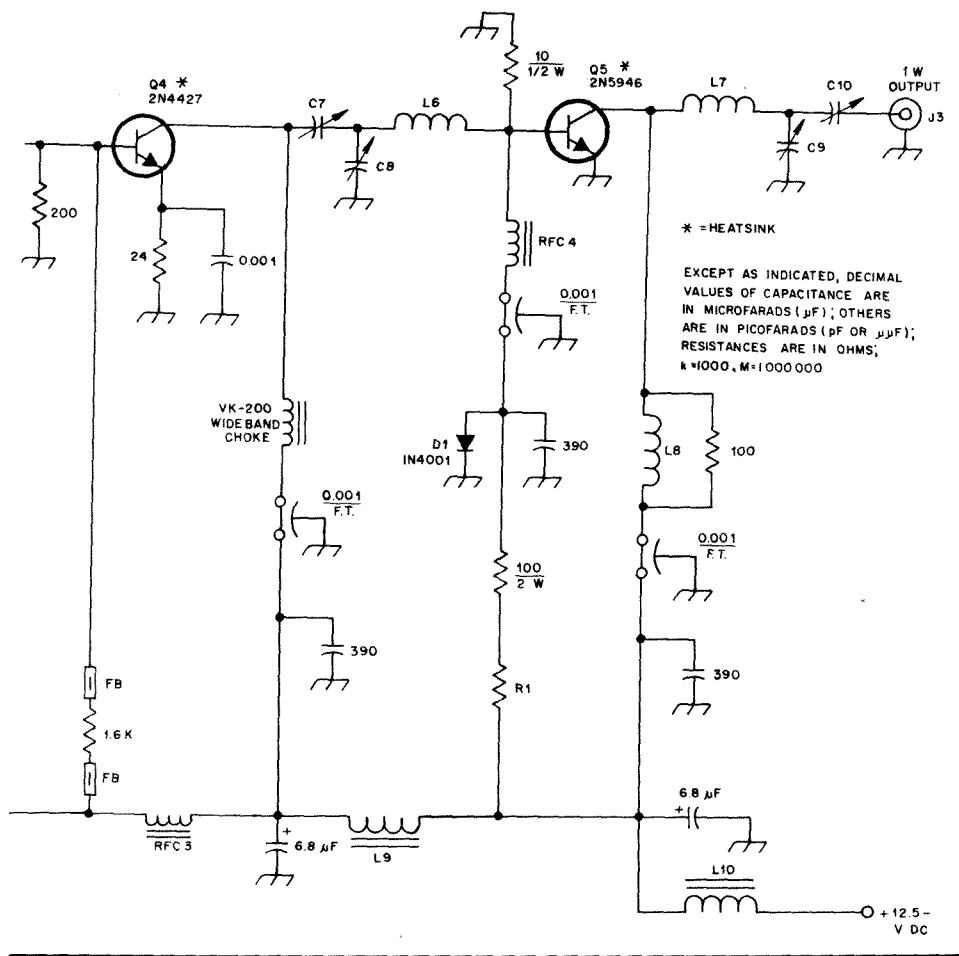

Fig. 51 — The plot at A shows the spectral output of the 1-W, 220-MHz transmit converter after filtering. All harmonics and spurious emissions are at least 60 dB below the fundamental output. This transmit converter meets current FCC spectral-purity specifications. The plot at B is the swept frequency response of the low-pass filter shown in Fig. 50.

144 MHz: 2t no. 20 tinned, 0.250-inch ID, spaced one wire dia.  
 L7 — 220 MHz: 1t no. 20 tinned, 0.250-inch ID.  
 144 MHz: 3t no. 20 tinned, 0.250-inch ID, spaced one wire dia.  
 L8 — 220 MHz: 6t no. 20 enam., 0.250-inch ID, close wound. 144 MHz: Same as 220 MHz except coil is 8t.  
 L9, L10 — 15 t no. 22 enam. on T44-10 toroid

core (same for both bands).  
 R1 — Start with 68-ohm, 2-W resistor; vary for proper bias. See text.  
 RFC1-RFC4 — 220 MHz: 1.8-μH miniature molded RF choke; 144 MHz: 2.2-μH miniature molded RFC.  
 U1 — Mini-Circuits SRA-1 standard level, doubly balanced mixer. Available directly from the manufacturer. See text.

verter is powered on, 12.5-V dc is applied directly to the LO and through K1 to the VHF preamplifier and 28-MHz post amplifier. When J2 is closed, K1 removes power from the preamplifier and post amplifier and applies 12.5-V dc to the transmit converter and power amplifier. The LO, used for transmit and receive, is always on.

When J2 is closed, K2 is also energized. K2, an RF relay, switches the antenna between the VHF preamplifier input and the power amplifier output. Relays of this type are generally available at flea markets at modest prices. Since most HF transceivers have separate transverter input and output connections, no relay switching for the IF rig is included. The transmit converter IF input is connected directly to the transverter output on the HF transceiver, while the post amplifier output is connected directly to the transverter input on the HF transceiver.

Relays with 26-V dc coils were used here

since most surplus coaxial relays require this voltage. While relays with any coil voltage could be used, it is a good idea to run relays and electronics from separate power supplies to avoid possible problems caused by voltage transients that occur when the relay coils are switched. The diode and capacitor connected across the relay coil power line help to alleviate transients.

### CONSTRUCTION TECHNIQUES

Although this project is not intended for a first-time effort, anyone having a reasonable amount of VHF construction experience should encounter no difficulty. As with all VHF circuits, a certain amount of construction care is required.

Proper grounding techniques, RF bypassing and shielding will ensure stable operation. Feedthrough grounding is used to provide a low-inductance ground return to both sides of the PC board. Basically, this means drilling a hole through the PC

board at key points where components must have a good RF ground and installing a rivet or piece of no. 20 tinned wire soldered to both sides of the board. See Fig. 54. Check the schematic diagrams for each circuit and install ground feedthroughs accordingly.

High-quality, low-inductance capacitors ensure a good RF bypass. Ceramic chip capacitors work best. These can be expensive, however, so they are used only where absolutely necessary. Epoxy encapsulated, miniature, monolithic ceramic capacitors work quite well as bypass capacitors.

Tight shielding between the input and output of each stage of the transmit converter eliminates the likelihood of feedback. Shielding was only found necessary on the transmit converter.

The variable capacitors used in each stage are miniature ceramic or piston trimmers. The value of these capacitors is not critical as long as you use capacitors with maximum values close to those specified in the schematic diagram. For example, there are many capacitors available with a range from 2 to 8 pF or 2 to 12 pF. Any of these will work fine in circuits that call for 9- or 10-pF-maximum variables. Ceramic piston trimmers are most convenient for building the double-tuned band-pass filters. Johan-

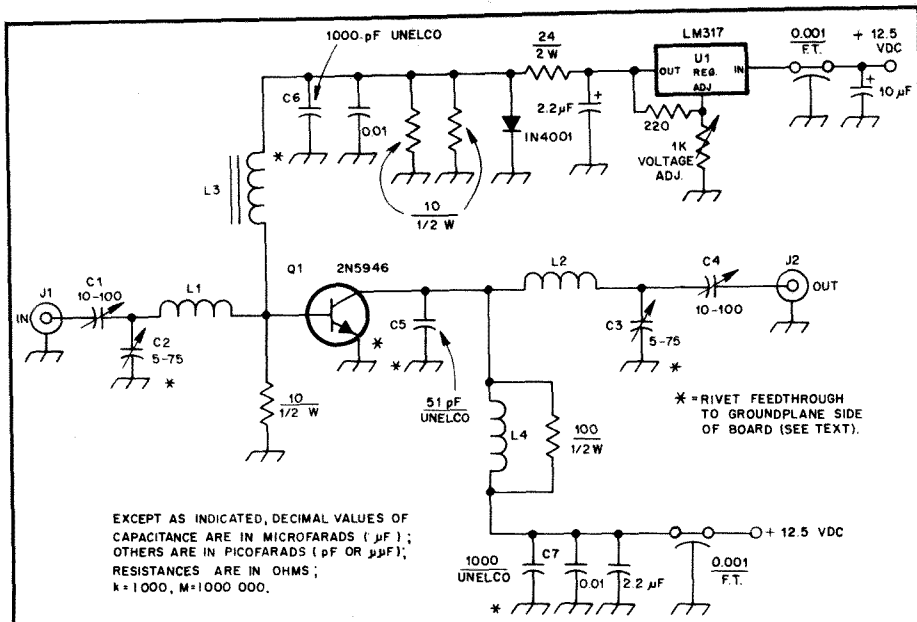

Fig. 52 — Schematic diagram of the 8- to 10-W power amplifier. Capacitors are monolithic ceramic types unless otherwise noted. Capacitors marked with polarity are electrolytic.

- C1, C4 — 10-100 pF mica trimmer (Arco 406 or equiv.).
- C2, C3 — 5-75 pF mica trimmer (Arco 405 or equiv.).
- C5 — 51 pF metal-clad book-mica capacitor. See text.
- C6, C7 — 1000 pF metal-clad book-mica capacitor. See text.
- J1, J2 — Chassis-mount female BNC connector.
- L1 — 220 MHz:  $\frac{1}{2}$  t no. 20 tinned, 0.250-inch ID ("hairpin loop"); 144 MHz: 1 t no. 20 tinned, 0.250-inch ID.
- L2 — 220 MHz: 1 t no. 20 tinned, 0.250-inch ID; 144 MHz: 2 t no. 20 tinned, 0.250-inch ID, spaced one wire dia.
- L3 — VK-200 wideband RF choke.
- L4 — 8 t no. 20 enam., 0.250-inch ID, close wound.
- Q1 — 2N5946 or Thompson-CSF SD1160 RF power transistor.
- U1 — Three-terminal adjustable voltage regulator, 1 A (LM317 or equiv.).

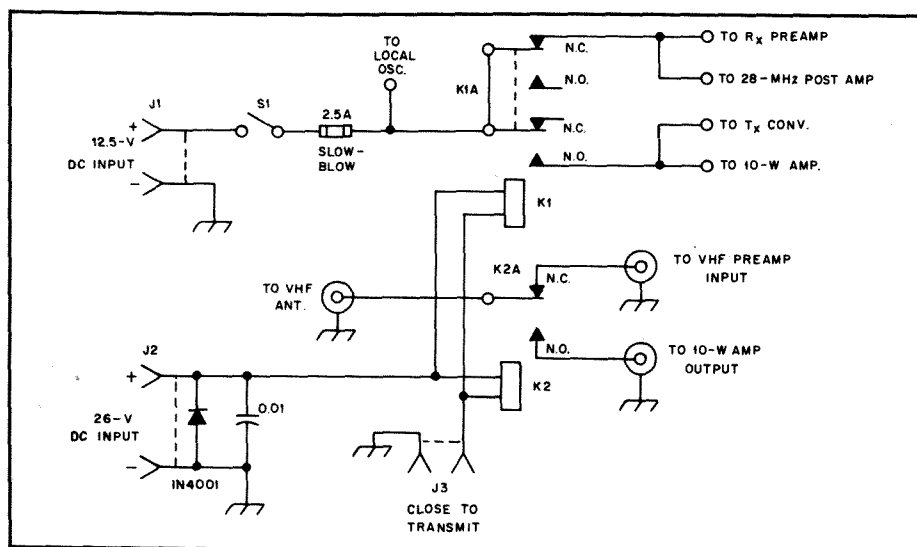

Fig. 53 — Schematic diagram of the transverter switching arrangement.

- J1, J2 — Chassis-mount female Cinch-Jones power plug.
- J3 — Chassis-mount phono jack.
- K1 — DPDT power relay, 3-A contacts, 26-V dc coil.
- K2 — SPDT coaxial antenna changeover relay, BNC connectors, 26-V dc coil.
- S1 — SPDT switch, 5-A contacts.

son, Trimtronics or Voltronics all manufacture 8- to 10-pF maximum piston trimmers suitable for these filters.

"Dead bug" layout is best suited for VHF/UHF construction. As shown in the accompanying photographs, components are supported by their leads above the

ground plane. In most cases, component leads are soldered directly to the leads of other components, keeping the length of each interconnection to a minimum. A low-inductance RF ground is achieved since the component leads are soldered directly to the ground plane. This construction

Fig. 54 — Detail of the feedthrough grounding used to achieve a good RF ground. See text for details.

method eliminates the need for designing an etched PC board, a task not easily accomplished at VHF and above.

Each circuit, or "module," is built on a piece of double-sided circuit board stock and mounted in a separate metal enclosure. In the transverter shown in the photographs, each module is built into a small Hammond 1590 series diecast box. In each case, the box cover has been discarded. The circuit board holding the components has been shaped to fit the box tightly in place of the cover. Each module has BNC connectors for RF input and output. Voltage is supplied through a feedthrough capacitor. The result is an RF-tight enclosure for each part of the circuit. Since the 1-W transmit converter board is large, and a suitable diecast box is expensive, the transmit converter is mounted under the chassis that supports the rest of the modules.

### Finding Parts

These days, it is becoming increasingly difficult to find parts. This transverter makes use of parts available from a number of sources. The parts suppliers table in Chapter 35 lists many possible sources, and still others advertise in *QST* and other amateur magazines. Some parts sources are listed below. You can find addresses and other information in Chapter 35 for companies that are listed by name only here. This list is by no means complete; these are sources that the author knows of that will sell to individuals in small quantities.

- Advanced Receiver Research, Box 1242, Burlington, CT 06013 (MGF1402 GaAsFETs)
- Amidon Associates (toroid cores, ferrite beads, VK-200 chokes)
- Applied Invention (piston trimmers, chip caps)
- MHz Electronics, 3802 N. 27th Ave., Phoenix, AZ 85017 (transistors, book-mica capacitors)
- Microwave Components of Michigan (trimmers, piston trimmers, GaAsFETs, chip caps, feedthrough caps, diecast boxes)
- Mini-Circuits, P.O. Box 166, Brooklyn, NY 11235 (mixers, T1 in 192-MHz LO)
- Mouser Electronics (resistors, capacitors, ceramic trimmers, molded RF chokes, diecast boxes)
- Radiokit (toroid cores, ferrite beads, Arco variables, diecast boxes)

## Local Oscillator

Build the local oscillator first; you'll need LO energy to test most of the other stages. Before soldering anything, gather all of the necessary components and lay them out on the board in order to plan adequate room before constructing. Follow the schematic diagram and refer to Fig. 55 for an idea of how to lay out the board. Although the 192-MHz LO for the 220-MHz transverter is shown, layout is similar for the 116-MHz version.

Once the general layout scheme has been achieved, the components may be soldered together, beginning with Q1. Keep component leads short, but leave enough room so that you can change components if necessary. Make sure that the leads of Y1 are as short as possible and that the crystal will not touch the box that the LO will be installed in. A dab of silicone sealant will hold the crystal in place.

Q1, Q2 and Q3 are mounted "belly up" with their leads sticking into the air. Note that Q1 and Q3 have a lead that is connected to the case. Solder this lead to ground. The collector of Q4 is tied to the case, so it is mounted with the leads facing the ground plane. Make sure that the case of Q4 does not touch the ground plane or other components.

Dc power for the LO enters the case through a feedthrough capacitor. Miniature molded RF chokes and bypass capacitors decouple the power line at each stage. In Fig. 55, these RFCs and capacitors are arranged in a horizontal line that traverses the top of the board. Q1 is powered through an 8-V, three-terminal regulator IC. Mount the associated bypass capacitors as close to the IC body as possible.

Q2 has several unused sections. Cut off all unused leads before soldering it into the circuit. T1 is a trifilar-wound transformer on a T25-12 toroid core. See Fig. 56 for details. Although the transformer used here was wound by hand, a Mini-Circuits model T4-1 may also be used.

The output filter uses two ceramic piston trimmer capacitors mounted through the circuit board. These piston trimmers make it convenient to mount L6 and L7; common ceramic trimmers like those used in the rest of the circuit will also work here. A shield made from a piece of double-sided circuit-board material separates L6 and L7, eliminating overcoupling and ensuring a "clean" filter response. Although a 0.5-pF ceramic chip capacitor was used to couple the two filter sections, a ¼-inch-long gimmick capacitor made from two pieces of no. 28 enameled wire twisted tightly together will work here.

One of the advantages of dead bug construction — one that you should take advantage of — is that each stage can be tested individually. After you build the basic oscillator (Q1 and associated components), you can test for 96 (or 116) MHz

Fig. 55 — The 192-MHz local oscillator is laid out in the order it is drawn on the schematic diagram. Q1 is at the far left; Q4 is near the center of the board. The band-pass filter is at the right, next to J1 and J2. The resistors used for the power divider and pad are soldered into the circuit with virtually no lead length.

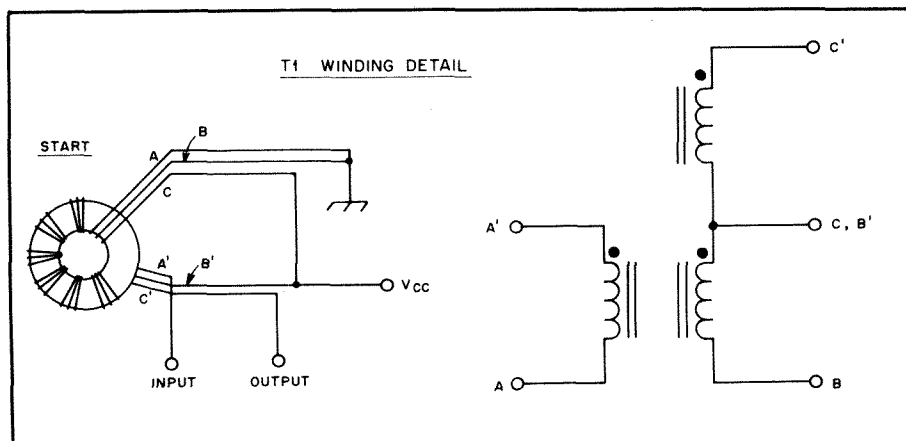

Fig. 56 — Winding details for T1 in the 192-MHz LO. Label one end of three 5-inch pieces of enameled wire as shown. Holding all three wires flat, in parallel, begin threading the toroid starting with the unlabeled end of the three wires. Carefully wind the toroid by feeding the entire group of wires in parallel. Once seven turns have been wound, use an ohmmeter to trace the unlabeled ends. Label the end of wire A by A', and so on. After the windings have been properly labeled, connect T1 as shown.

Fig. 57 — Closeup of the VHF RF preamplifier. The input components at the left of the board are mounted with as little lead length as possible, to minimize losses.

output by capacitively coupling into a receiver or spectrum analyzer from the 50-ohm pad at the output of the stage. When you are sure Q1 is working, build the next stage and test it. Proceed alternately building and testing each stage until you reach the final output stage.

When all of the LO stages are complete, check the operating frequency with a counter or spectrum analyzer. Tune each stage for maximum output. Tuning is somewhat interactive, so recheck each stage after you have done the initial tuneup. Each variable capacitor should have a definite peak. If you have a method of checking low power levels, check the output at the receive and transmit ports. Power output should be as indicated on the drawings.

All other stages are constructed in a like manner. Lay the board out in advance; start at the input and work toward the output. Test each stage after you build it, and fix any problems before continuing to the next stage.

### Preamplifier
